THE comments on Dr. Bond's lecture to which Prof. Drummond refers, may be justified perhaps by zoological illustrations even if the botanists are unaware of any causes of mutation and have no evidence of reversion. For example, Muller has shown that when the eggs of normal specimens of Drosophila are subjected to X-ray radiation, they give rise to 'mutations' of the same kind as some of those which turn up in Morgan's cultures. Berndt, in discussing the 'fancy races' of goldfish, admits that the cause of the production of 'mutants' is aquarium conditions. In a word, the general cause of mutations may be described as 'germ-damage' due to bad environmental conditions acting at a critical period of growth. As to reversion, Morgan himself encountered this in some of his extreme mutants and described it as 'mutation backwards.' It can be seen any day in the London squares, where a considerable proportion of our escaped dovecote pigeons are rapidly returning to the ancestral form of *Columba livia*.

THE WRITER OF THE NOTES.

On Experimental Growth *in situ*.

On the hypothesis of senescence elaborated by Robertson ("Chemical Basis of Growth and Senescence," 1923), adult tissue can only revert to a reproductive phase when the so-called *kern-plasma* relation and nutrient level of its elements has been reduced, and the inhibitory products of previous growth (autocatalysts) have been—and continue to be—removed. But Gye and Barnard have shown that ultramicroscopic organisms occur in (and can be cultivated from) the fluids derived from—at least—some cancerous tissues. Such ultramicroscopic organisms also exhibit specificity. Let Robertson's hypothesis be accepted, then it is a reasonable assumption, which can probably be tested, that these ultramicroscopic organisms may primarily be feeding on the products of autocatalysis in the tissues in which they are found. If, therefore, these organisms could be cultivated in fluids derived from healthy tissues homologous with those from which they were derived, or even in the tissues themselves, partial proof of the assumption would be obtained.

Now Gye and Barnard have actually shown that pathological growth may be produced in some cases by a 'specific factor' plus a 'virus.' But apparently it is not possible to stimulate growth in a tissue by merely injecting into it a culture or extraction containing the pathological organisms. Robertson's hypothesis, however, demands two conditions for resultant growth in adult tissues, namely, (*a*) reduction of the *kern-plasma* relation, which may be effected by various stimuli (chemical, physical, mechanical abrasion or irritation, cutting, or agents causing disruption or decay of cells, etc.), as well as (*b*) removal of the autocatalysts. Thus the mere injection of organisms to remove (presumably) the autocatalysts in a tissue may not be enough to stimulate growth, and reproduce the hyperplasia without the concurrent reduction of the *kern-plasma* relationship.

In order, therefore, to induce unrestricted growth in a tissue *in situ* it is necessary *ex hypothesi* (1) to stimulate the tissue in some way to regenerative activity—thereby ensuring the reduction of the *kern-plasma* ratio; and (2) to add pathological organisms which will remove the autocatalytic products of the stimulated growth, and permit continued growth; such organisms having been derived from a tissue homologous with that in which the new growth is required. It is possible that experiments fulfilling the conditions outlined above may not have been tried, and no excuse is needed for advancing any reasonable suggestion on this important subject.

Postulates of Hydrodynamics.

Of a mass of fluid satisfying the condition of continuity and having a continuous velocity field, the mathematical theory of fluid motion postulates that fluid elements—line, surface, volume—not crossing a surface of discontinuity, of which there may be a finite number, maintain their identity and order of magnitude.

As a dynamical consequence, in a perfect fluid, the forces being restricted to surface pressures and potential body forces, the initial distribution of vorticity is inherent in the volume elements of fluid, and remains so in the subsequent motion.

In particular, if the initial motion is irrotational everywhere (except in the sheets of vorticity), the subsequent motion is irrotational (except in the sheets of vorticity).

Without questioning the correctness of these propositions in the realm of mathematical logic, the present writer has found them a formidable barrier to the understanding of actual fluid motions familiar to the physicist and the engineer, and offers the following physical propositions.

Fluid elements—line, surface, volume—can be effectively subdivided into two or more distinct portions separated by intervening fluid.

A mass of perfect fluid consisting of several distinct parts, each with its own velocity potential, and separated by thin sheets of transition (in mathematical limit, vortex sheets) may be effectively redistributed so that the identity of the irrotational elements of volume falls below the threshold of observability, and new mean elements with an effective finite distribution of vorticity become the objects of physical observation and measurement through the whole or part of the joint mass.

The Spectrum of Ionised Argon (A II).

For some time the spectrum of ionised argon (A II) has been a subject of investigation in the Amsterdam Laboratory 'Physica.' My analysis of the spectrum of neutral fluorine F I (*Verslagen.*, Amsterdam, June 1926, Dec. 1926. *Zeits. f. Phys.*, **39**, 869; 1926) and the analysis of the spectrum of ionised neon Ne II (*Versl.*, Amsterdam, May 1927. Nature, **119**, 925; 1927. *Zeits. f. Phys.*, **44**, 157; 1927. **46**, 856; 1928) formed preliminary steps for the analysis of the A II spectrum. A great part of the A II lines have now been classified by me. I have found a doublet and a quartet term system. The term structure exhibits a perfect analogy to that of F I and Ne II. The following triplet $4p^4S$-$4s^4P$: (9) 3729,300; (8) 3850,565; (7) 3928,599 involving the deep quartet $4s^4P$ term with the term differences: 844,40 and 515,70, gives the key for the analysis of the spectrum. As examples, the other deep quartet terms are given:

$4p^4P$: with the term differences : 307,75 and 357,30
$4p^4D$ „ „ 439,36; 494,57; and 260,32.
$(3)d^4D$ „ „ 153,98; 149,62; and 107,03.

The complete term table for A II, the lists of classified lines, the new measurements, and the analogy with the spectrum of ionised neon will be published in the *Zeits. f. Phys.*

The Buoyancy of Whales.

Mr. Gray's suggestion (Nature, Mar. 17, p. 421) that whales dying at the surface sometimes float because the air in their lungs is held in by the valves of the blowhole is very interesting, and perhaps helps also in understanding how whales can remain so long under water. There are, however, so many unusual features about whales that one cannot help wondering whether other explanations are not possible. It is, for example, conceivable that whales breathe differently from other mammals, and that the muscular effort they expend in breathing is used not for drawing air into their lungs but for driving it out. On this view the filling of the lungs would be due to the elastic recoil of the thoracic wall and expansion of the cavity following the muscular contraction, and when a whale dies and the muscles relax the lungs would fill with air if the blowhole is above the surface or with water if it is below.

Helium in Deep Diving and Caisson Working.[1]

By Prof. J. H. Hildebrand, University of California,
and Dr. R. R. Sayers and W. P. Yant, United States Bureau of Mines.

In diving and in caisson operations where men are subjected to air pressures above ordinary atmospheric pressure, the amount of air dissolved in the blood stream and body tissues increases. The excess oxygen can be disposed of by the ordinary combustion process, but the excess nitrogen tends to separate in the form of bubbles when the pressure is released As the amount dissolved is approximately proportional to the pressure, there may be enough separating in the blood stream and tissues of a diver or caisson worker coming up rapidly from a considerable depth to produce 'caisson illness.' This is accompanied by severe bodily pains, and, in more severe cases, unconsciousness or even death.

It is therefore necessary to prolong the time of ascent in deep diving or of decompression in caisson working sufficiently to allow the excess nitrogen to escape from the tissues through the lungs. This period of decompression increases rapidly with the depth or pressure to which the worker has been exposed and with the duration of exposure, and becomes almost prohibitive at depths greater than 200 feet, except in emergencies and for very short exposures. According to present-day diving regulations and practice, it requires but 3 to 8 minutes, depending on the individual diver, to descend to a depth of 200 feet, but after a stay of 45 minutes at the bottom, 2 or more hours would be required to bring the diver to the surface in safety. Mechanical troubles, accidents to the diver, unusually cold water, or stormy weather may make it difficult or impossible to allow such a period, and even at best the proportion of the total time available for work at the bottom rapidly becomes too short to be practical as great depths are approached.

Theoretical studies of the general problem of solubility, begun by the senior writer some years ago, made it evident that the least soluble gas, almost regardless of the solvent, should be helium. As he was familiar with the theory of caisson illness, the idea naturally arose of substituting helium for the nitrogen of air for respiration by divers and caisson workers Eventually a small amount of helium was obtained from the United States Bureau of Mines through the courtesy of R. B. Moore, former Chief Chemist, with whom the problem had been previously discussed.

Progress was slow, in the absence of suitable equipment, and it became evident that to bring the matter to any practical fruition would require large-scale experiments and access to considerable quantities of helium, of which the United States Government was the only producer. Meanwhile, the sinking of a submarine at a depth that rendered access by divers difficult, suggested that any consideration of personal profit should give way to the prompt working out of the practical problems involved. Accordingly, the senior author wrote in January 1924 to S. C. Lind, then Chief Chemist of the Bureau of Mines, suggesting that the Bureau undertake the necessary experimental work. This suggestion was accepted, and the senior writer was associated with the Bureau as consulting chemist. The work was put into the hands of Dr. R. R. Sayers, Chief Surgeon for the Bureau of Mines, and W. P. Yant, Supervising Chemist, Health Laboratory Section.

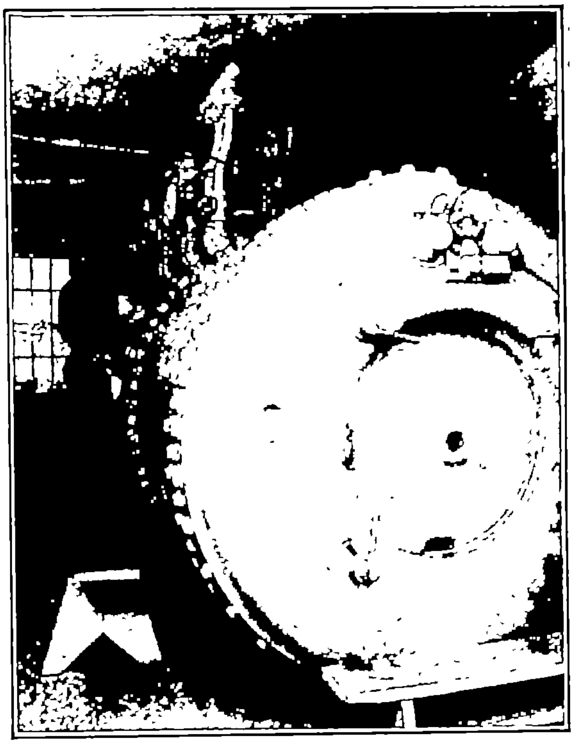

Fig 1—Compression chamber used for conducting experiments on men This was built at the Norfolk Navy Yard and was of 1⅜ in. steel and capable of withstanding a working pressure of 600 lb per sq. in, and a much greater test pressure. Note telephone and electric light connexions above door, and gauges and valves for regulating and indicating pressure One of the horizontal lines leading from the manifold extends through the reducing valve to the bank of air bottles and the other to a supply of pure oxygen or of helium-oxygen mixture.

As is so often the case, it has since been brought to light that the idea occurred independently to different individuals. On Aug. 15, 1919, an application for a patent was filed, and on Nov. 6, 1923, issued, to C. J. Cooke, of Washington, D.C., for the use of a respirable mixture of oxygen and helium for workers under pressure; and at about the same time Elihu Thomson, it appears, had a similar idea. In a paper, "Helium Production and Uses," by Prof. J. C. McLennan, in Nature of Aug. 19, 1920, is the following statement:

"It has been suggested by Elihu Thomson and others that if divers were supplied with a mixture of oxygen and helium, the rate of expulsion of carbon dioxide from the lungs might be increased, and the period of submergence as a consequence be considerably lengthened.”

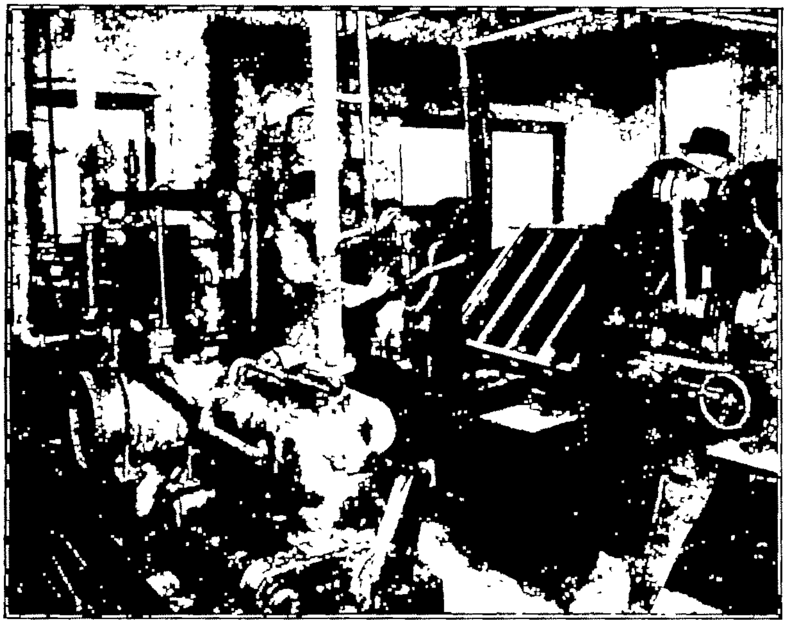

Fig 2.—Air compressors and apparatus for compressing air into a storage bank consisting of thirty 2-cub. ft free air capacity cylinders. The air is compressed to approximately 1800 lb per sq in., which gives sufficient volume in the bank to fill the large test chamber to a pressure of 100 lb. per sq. in. within two or three minutes. All these cylinders are connected in parallel to a manifold from which the air is released through a reducing valve. One compressor is electrically driven and the other by means of a gasoline engine This ensures two independent sources of power and an adequate air supply in the event of difficulties being experienced in these experiments, and extended recompression of the men being necessary to allay the occurrence of caisson disease

As a matter of fact, however, the work at the Bureau of Mines was undertaken and pursued to a considerable fruition before any of those concerned with it became cognizant of the claims of either Mr Cooke or Dr. Thomson. It may be added also, that if the statement by Prof. McLennan correctly expresses the idea of Dr. Thomson, this was based upon an incorrect assumption, for caisson illness does not depend upon the diffusion of carbon dioxide from the lungs. (For discussion of priority claims see E. Thomson, *Science*, Jan. 14, 1927; J. H. Hildebrand, *Science*, Mar. 15, 1927; and W. P Yant, *Ind. and Eng. Chem.*, news edition, Mar. 10, 1927.)

The fact remains that the use of helium for deep diving could become practical only after extensive and costly experimentation for the development of a suitable technique. Investigations planned toward this end were initiated by the Bureau of Mines and continued later with the co-operation of the Navy Department. The results of the initial investigations made by the Bureau were published, in part, in its *Reports of Investigations Serial 2670*, February 1925, entitled “Possibilities in the Use of Helium–Oxygen Mixtures as a Mitigation of Caisson Disease,” by R. R. Sayers, W. P. Yant, and J. H. Hildebrand. This publication recounts the results of a series of tests with small animals It was found at the outset that rats could be subjected to a helium-oxygen mixture for 1 hour at a pressure of 20 atmospheres, corresponding to about 600 feet of water, or more than three times the maximum pressure at which extensive diving operations have been conducted, and further, that they could be brought out of this pressure safely in 34 minutes.

It was found important to reduce the proportion of oxygen from 21 per cent. by volume, the proportion in air, to a much smaller proportion, varying from 1·5 to 15 per cent. according to the pressure employed. In most of the studies a pressure of 10 atmospheres was used, with varying periods of exposure, up to 5 hours. It was found that animals could be brought out from the helium–oxygen mixture

New Problems in Quantum Theory.

FIFTEEN years have elapsed since Niels Bohr first published a series of papers which were the beginning of a new epoch in the development of the quantum theory. Adopting the atomic model proposed by Rutherford, in which electrons circle round a massive nucleus under the action of a Coulomb force of electric attraction, Bohr gained immediate success in interpreting the spectrum of hydrogen and of ionised helium. For his purpose he was compelled to assume the existence of 'stationary states,' and the emission of monochromatic radiation in the transition between two such states of an atomic system.

In one sense the new method raised as many difficulties as it removed, and to some of the more conservative physicists the account of Bohr's atom read like a fairy tale. Further progress in the interpretation of line spectra was made through the generalisations of Wilson and Sommerfeld, but in spite of the inclusion of a widening circle of facts and the fulfilment of predictions, it came to be realised that a more radical procedure was necessary before a consistent and complete theory could be evolved. In the forward movement few have been more active than Bohr himself. The employment of a spinning electron by Goudsmit and Uhlenbeck removed many discrepancies, and it seems as if some form of magnetic electron is likely to be accepted as a fundamental constituent of an atomic system. The magneton of S. B. McLaren with its quantum of angular momentum may be regarded as the prototype of all such magnetic electrons.

Within the last few years the matrix mechanics of Heisenberg, Born, and Jordan, the quantum algebra of Dirac, and the undulatory mechanics of Schrödinger, have led to remarkable theoretical developments. The new wave mechanics gave rise to the hope that an account of atomic phenomena might be obtained which would not differ essentially from that afforded by the classical theories of electricity and magnetism. Unfortunately, Bohr's statement in the following communication of the principles underlying the description of atomic phenomena gives little, if any, encouragement in this direction.

In classical mechanics it is assumed that the position of a particle (such as an electron) can be determined at a specified instant of time by means of its co-ordinates. As the time varies it is supposed to be possible to trace the path of the particle through space, or to determine its 'world line' in the four-dimensional world. Further, it is assumed that the concept of causality may be applied in considering the effect of the action of external forces. Thus in classical physics we have a causal space-time co-ordination, based on the assumption that the methods or tools of measurement do not affect the phenomena which are observed.

In the new quantum theory the outlook is changed, for any attempt to observe the position or motion of an electron involves illumination by light, and this implies interaction between the electron and the light employed in making the measurement. The position and the path of an electron become vague. Thus there is introduced in the new quantum mechanics an indefiniteness which contrasts with the clear-cut concepts of classical mechanics. Bohr asserts that in any phenomenon which we may attempt to observe there is an essential discontinuity, or rather individuality, which may be symbolised by Planck's constant h. The causal space-time co-ordination of atomic phenomena must on this view be abandoned, and we are left with a somewhat vague statistical description.

The strange conflict which has been waged between the wave theory of light and the light quantum hypothesis has resulted in a remarkable dilemma. But now we have a parallel dilemma, for a material particle manifests some of the attributes of wave motion. Can these apparently contradictory views be reconciled? According to Bohr, the pictures ought to be regarded not as contradictory but as complementary. Radiation in free space is not open to observation, and is a mere abstraction. An isolated material particle likewise can never be observed and is also an abstraction. It is only through their interaction with other systems that the properties of these abstractions can be defined and observed.

It must be confessed that the new quantum mechanics is far from satisfying the requirements of the layman who seeks to clothe his conceptions in figurative language. Indeed, its originators probably hold that such symbolic representation is inherently impossible. It is earnestly to be hoped that this is not their last word on the subject, and that they may yet be successful in expressing the quantum postulate in picturesque form.

The Quantum Postulate and the Recent Development of Atomic Theory.[1]

By Prof. N. Bohr, For. Mem. R.S.

In connexion with the discussion of the physical interpretation of the quantum theoretical methods developed during recent years, I should like to make the following general remarks regarding the principles underlying the description of atomic phenomena, which I hope may help to harmonise the different views, apparently so divergent, concerning this subject.

1. Quantum Postulate and Causality.

The quantum theory is characterised by the acknowledgment of a fundamental limitation in the classical physical ideas when applied to atomic phenomena. The situation thus created is of a peculiar nature, since our interpretation of the experimental material rests essentially upon the classical concepts. Notwithstanding the difficulties which hence are involved in the formulation of the quantum theory, it seems, as we shall see, that its essence may be expressed in the so-called quantum postulate, which attributes to any atomic process an essential discontinuity, or rather individuality, completely foreign to the classical theories and symbolised by Planck's quantum of action.

This postulate implies a renunciation as regards the causal space-time co-ordination of atomic processes. Indeed, our usual description of physical phenomena is based entirely on the idea that the phenomena concerned may be observed without disturbing them appreciably. This appears, for example, clearly in the theory of relativity, which has been so fruitful for the elucidation of the classical theories. As emphasised by Einstein, every observation or measurement ultimately rests on the coincidence of two independent events at the same space-time point. Just these coincidences will not be affected by any differences which the space-time co-ordination of different observers otherwise may exhibit. Now the quantum postulate implies that any observation of atomic phenomena will involve an interaction with the agency of observation not to be neglected. Accordingly, an independent reality in the ordinary physical sense can neither be ascribed to the phenomena nor to the agencies of observation. After all, the concept of observation is in so far arbitrary as it depends upon which objects are included in the system to be observed. Ultimately every observation can of course be reduced to our sense perceptions. The circumstance, however, that in interpreting observations use has always to be made of theoretical notions, entails that for every particular case it is a question of convenience at what point the concept of observation involving the quantum postulate with its inherent 'irrationality' is brought in.

This situation has far-reaching consequences. On one hand, the definition of the state of a physical system, as ordinarily understood, claims the elimination of all external disturbances. But in that case, according to the quantum postulate, any observation will be impossible, and, above all, the concepts of space and time lose their immediate sense. On the other hand, if in order to make observation possible we permit certain interactions with suitable agencies of measurement, not belonging to the system, an unambiguous definition of the state of the system is naturally no longer possible, and there can be no question of causality in the ordinary sense of the word. The very nature of the quantum theory thus forces us to regard the space-time co-ordination and the claim of causality, the union of which characterises the classical theories, as complementary but exclusive features of the description, symbolising the idealisation of observation and definition respectively. Just as the relativity theory has taught us that the convenience of distinguishing sharply between space and time rests solely on the smallness of the velocities ordinarily met with compared to the velocity of light, we learn from the quantum theory that the appropriateness of our usual causal space-time description depends entirely upon the small value of the quantum of action as compared to the actions involved in ordinary sense perceptions. Indeed, in the description of atomic phenomena, the quantum postulate presents us with the task of developing a 'complementarity' theory the consistency of which can be judged only by weighing the possibilities of definition and observation.

This view is already clearly brought out by the much-discussed question of the nature of light and the ultimate constituents of matter. As regards light, its propagation in space and time is adequately expressed by the electromagnetic theory. Especially the interference phenomena *in vacuo* and the optical properties of material media are completely governed by the wave theory superposition principle. Nevertheless, the conservation of energy and momentum during the interaction between radiation and matter, as evident in the photoelectric and Compton effect, finds its adequate expression just in the light quantum idea put forward by Einstein. As is well known, the doubts regarding the validity of the superposition principle on one hand and of the conservation laws on the other, which were suggested by this apparent contradiction, have been definitely disproved through direct experiments. This situation would seem clearly to indicate the impossibility of a causal space-time description of the light phenomena. On one hand, in attempting to trace the laws of the time-spatial propagation of light according to the quantum postulate, we are confined to statistical considerations. On the other hand, the fulfilment of the claim of causality for the individual light processes, characterised by the quantum of action, entails a renunciation as regards the space-time description. Of course, there can be no question of a quite independent application of the ideas of space and time and of causality. The two views of the nature of light are rather to be considered as different attempts at an interpretation of experimental evidence in which the limitation of the classical concepts is expressed in complementary ways.

---

[1] The content of this paper is essentially the same as that of a lecture on the present state of the quantum theory delivered on Sept. 16, 1927, at the Volta celebration in Como. For a summary of the theory just previous to the development of the new methods the reader is referred to a lecture of the author, "Atomic Theory and Mechanics," published in this periodical (Nature, 116, 809; 1925). The rapid development which has taken place since has given rise to a considerable number of publications. The present paper is confined to a few references to recent articles which have a special bearing on the subject now under discussion.

The problem of the nature of the constituents of matter presents us with an analogous situation. The individuality of the elementary electrical corpuscles is forced upon us by general evidence. Nevertheless, recent experience, above all the discovery of the selective reflection of electrons from metal crystals, requires the use of the wave theory superposition principle in accordance with the original ideas of L. de Broglie. Just as in the case of light, we have consequently in the question of the nature of matter, so far as we adhere to classical concepts, to face an inevitable dilemma, which has to be regarded as the very expression of experimental evidence. In fact, here again we are not dealing with contradictory but with complementary pictures of the phenomena, which only together offer a natural generalisation of the classical mode of description. In the discussion of these questions, it must be kept in mind that, according to the view taken above, radiation in free space as well as isolated material particles are abstractions, their properties on the quantum theory being definable and observable only through their interaction with other systems. Nevertheless, these abstractions are, as we shall see, indispensable for a description of experience in connexion with our ordinary space-time view.

The difficulties with which a causal space-time description is confronted in the quantum theory, and which have been the subject of repeated discussions, are now placed into the foreground by the recent development of the symbolic methods. An important contribution to the problem of a consistent application of these methods has been made lately by Heisenberg (*Zeitschr. f. Phys.*, **43**, 172; 1927). In particular, he has stressed the peculiar reciprocal uncertainty which affects all measurements of atomic quantities. Before we enter upon his results it will be advantageous to show how the complementary nature of the description appearing in this uncertainty is unavoidable already in an analysis of the most elementary concepts employed in interpreting experience.

2. QUANTUM OF ACTION AND KINEMATICS.

The fundamental contrast between the quantum of action and the classical concepts is immediately apparent from the simple formulæ which form the common foundation of the theory of light quanta and of the wave theory of material particles. If Planck's constant be denoted by h, as is well known,

$$E\tau = I\lambda = h, \quad . \quad . \quad . \quad (1)$$

where E and I are energy and momentum respectively, τ and λ the corresponding period of vibration and wave-length. In these formulæ the two notions of light and also of matter enter in sharp contrast. While energy and momentum are associated with the concept of particles, and hence may be characterised according to the classical point of view by definite space-time co-ordinates, the period of vibration and wave-length refer to a plane harmonic wave train of unlimited extent in space and time. Only with the aid of the superposition principle does it become possible to attain a connexion with the ordinary mode of description. Indeed, a limitation of the extent of the wave-fields in space and time can always be regarded as resulting from the interference of a group of elementary harmonic waves. As shown by de Broglie (Thèse, Paris, 1924), the translational velocity of the individuals associated with the waves can be represented by just the so-called group-velocity. Let us denote a plane elementary wave by

$$A \cos 2\pi(\nu t - x\sigma_x - y\sigma_y - z\sigma_z + \delta),$$

where A and δ are constants determining respectively the amplitude and the phase. The quantity $\nu = 1/\tau$ is the frequency, σ_x, σ_y, σ_z the wave numbers in the direction of the co-ordinate axes, which may be regarded as vector components of the wave number $\sigma = 1/\lambda$ in the direction of propagation. While the wave or phase velocity is given by ν/σ, the group-velocity is defined by $d\nu/d\sigma$. Now according to the relativity theory we have for a particle with the velocity v:

$$I = \frac{v}{c^2}E \text{ and } v\,dI = dE,$$

where c denotes the velocity of light. Hence by equation (1) the phase velocity is c^2/v and the group-velocity v. The circumstance that the former is in general greater than the velocity of light emphasises the symbolic character of these considerations. At the same time, the possibility of identifying the velocity of the particle with the group-velocity indicates the field of application of space-time pictures in the quantum theory. Here the complementary character of the description appears, since the use of wave-groups is necessarily accompanied by a lack of sharpness in the definition of period and wave-length, and hence also in the definition of the corresponding energy and momentum as given by relation (1).

Rigorously speaking, a limited wave-field can only be obtained by the superposition of a manifold of elementary waves corresponding to all values of ν and σ_x, σ_y, σ_z. But the order of magnitude of the mean difference between these values for two elementary waves in the group is given in the most favourable case by the condition

$$\Delta t\Delta\nu = \Delta x\Delta\sigma_x = \Delta y\Delta\sigma_y = \Delta z\Delta\sigma_z = 1,$$

where Δt, Δx, Δy, Δz denote the extension of the wave-field in time and in the directions of space corresponding to the co-ordinate axes. These relations—well known from the theory of optical instruments, especially from Rayleigh's investigation of the resolving power of spectral apparatus—express the condition that the wave-trains extinguish each other by interference at the space-time boundary of the wave-field. They may be regarded also as signifying that the group as a whole has no phase in the same sense as the elementary waves. From equation (1) we find thus:

$$\Delta t\Delta E = \Delta x\Delta I_x = \Delta y\Delta I_y = \Delta z\Delta I_z = h \quad . \quad (2)$$

as determining the highest possible accuracy in the definition of the energy and momentum of the individuals associated with the wave-field. In general, the conditions for attributing an energy and a momentum value to a wave-field by means of formula (1) are much less favourable. Even if the composition of the wave-group corresponds in the beginning to the relations (2), it will in the course of time be subject to such changes that it becomes less and less suitable for representing an individual. It is this very circumstance which gives rise to the paradoxical character of the problem of the nature of light and of material particles. The limitation in the classical concepts expressed through relation (2) is, besides, closely connected with the limited validity of classical mechanics, which in the wave theory of matter corresponds to the geometrical optics, in which the propagation of waves is depicted through 'rays.' Only in this limit can energy and momentum be unambiguously defined on the basis of space-time pictures. For a general definition of these concepts we are confined to the conservation laws, the rational formulation of which has been a fundamental problem for the symbolical methods to be mentioned below.

In the language of the relativity theory, the content of the relations (2) may be summarised in the statement that according to the quantum theory a general reciprocal relation exists between the maximum sharpness of definition of the space-time and energy-momentum vectors associated with the individuals. This circumstance may be regarded as a simple symbolical expression for the complementary nature of the space-time description and the claims of causality. At the same time, however, the general character of this relation makes it possible to a certain extent to reconcile the conservation laws with the space-time co-ordination of observations, the idea of a coincidence of well-defined events in a space-time point being replaced by that of unsharply defined individuals within finite space-time regions.

This circumstance permits us to avoid the well-known paradoxes which are encountered in attempting to describe the scattering of radiation by free electrical particles as well as the collision of two such particles. According to the classical concepts, the description of the scattering requires a finite extent of the radiation in space and time, while in the change of the motion of the electron demanded by the quantum postulate one seemingly is dealing with an instantaneous effect taking place at a definite point in space. Just as in the case of radiation, however, it is impossible to define momentum and energy for an electron without considering a finite space-time region. Furthermore, an application of the conservation laws to the process implies that the accuracy of definition of the energy momentum vector is the same for the radiation and the electron. In consequence, according to relation (2), the associated space-time regions can be given the same size for both individuals in interaction.

A similar remark applies to the collision between two material particles, although the significance of the quantum postulate for this phenomenon was disregarded before the necessity of the wave concept was realised. Here this postulate does indeed represent the idea of the individuality of the particles which, transcending the space-time description, meets the claim of causality. While the physical content of the light quantum idea is wholly connected with the conservation theorems for energy and momentum, in the case of the electrical particles the electric charge has to be taken into account in this connexion. It is scarcely necessary to mention that for a more detailed description of the interaction between individuals we cannot restrict ourselves to the facts expressed by formulæ (1) and (2), but must resort to a procedure which allows us to take into account the coupling of the individuals, characterising the interaction in question, where just the importance of the electric charge appears. As we shall see, such a procedure necessitates a further departure from visualisation in the usual sense.

3. MEASUREMENTS IN THE QUANTUM THEORY.

In his investigations already mentioned on the consistency of the quantum theoretical methods, Heisenberg has given the relation (2) as an expression for the maximum precision with which the space-time co-ordinates and momentum-energy components of a particle can be measured simultaneously. His view was based on the following consideration: On one hand, the co-ordinates of a particle can be measured with any desired degree of accuracy by using, for example, an optical instrument, provided radiation of sufficiently short wave-length is used for illumination. According to the quantum theory, however, the scattering of radiation from the object is always connected with a finite change in momentum, which is the larger the smaller the wave-length of the radiation used. The momentum of a particle, on the other hand, can be determined with any desired degree of accuracy by measuring, for example, the Doppler effect of the scattered radiation, provided the wave-length of the radiation is so large that the effect of recoil can be neglected, but then the determination of the space co-ordinates of the particle becomes correspondingly less accurate.

The essence of this consideration is the inevitability of the quantum postulate in the estimation of the possibilities of measurement. A closer investigation of the possibilities of definition would still seem necessary in order to bring out the general complementary character of the description. Indeed, a discontinuous change of energy and momentum during observation could not prevent us from ascribing accurate values to the space-time co-ordinates, as well as to the momentum-energy components before and after the process. The reciprocal uncertainty which always affects the values of these quantities is, as will be clear from the preceding analysis, essentially an outcome of the limited accuracy with which changes in energy and momentum can be defined, when the wave-fields used for the determination of the space-time co-ordinates of the particle are sufficiently small.

In using an optical instrument for determinations of position, it is necessary to remember that the formation of the image always requires a convergent beam of light. Denoting by λ the wave-length of the radiation used, and by ϵ the so-called numerical aperture, that is, the sine of half the angle of convergence, the resolving power of a microscope is given by the well-known expression $\lambda/2\epsilon$. Even if the object is illuminated by parallel light, so that the momentum h/λ of the incident light quantum is known both as regards magnitude and direction, the finite value of the aperture will prevent an exact knowledge of the recoil accompanying the scattering. Also, even if the momentum of the particle were accurately known before the scattering process, our knowledge of the component of momentum parallel to the focal plane after the observation would be affected by an uncertainty amounting to $2\epsilon h/\lambda$. The product of the least inaccuracies with which the positional co-ordinate and the component of momentum in a definite direction can be ascertained is therefore just given by formula (2). One might perhaps expect that in estimating the accuracy of determining the position, not only the convergence but also the length of the wave-train has to be taken into account, because the particle could change its place during the finite time of illumination. Due to the fact, however, that the exact knowledge of the wave-length is immaterial for the above estimate, it will be realised that for any value of the aperture the wave-train can always be taken so short that a change of position of the particle during the time of observation may be neglected in comparison to the lack of sharpness inherent in the determination of position due to the finite resolving power of the microscope.

In measuring momentum with the aid of the Doppler effect—with due regard to the Compton effect—one will employ a parallel wave-train. For the accuracy, however, with which the change in wave-length of the scattered radiation can be measured the extent of the wave-train in the direction of propagation is essential. If we assume that the directions of the incident and scattered radiation are parallel and opposite respectively to the direction of the position co-ordinate and momentum component to be measured, then $c\lambda/2l$ can be taken as a measure of the accuracy in the determination of the velocity, where l denotes the length of the wave-train. For simplicity, we here have regarded the velocity of light as large compared to the velocity of the particle. If m represents the mass of the particle, then the uncertainty attached to the value of the momentum after observation is $cm\lambda/2l$. In this case the magnitude of the recoil, $2h/\lambda$, is sufficiently well defined in order not to give rise to an appreciable uncertainty in the value of the momentum of the particle after observation. Indeed, the general theory of the Compton effect allows us to compute the momentum components in the direction of the radiation before and after the recoil from the wave-lengths of the incident and scattered radiation. Even if the positional co-ordinates of the particle were accurately known in the beginning, our knowledge of the position after observation nevertheless will be affected by an uncertainty. Indeed, on account of the impossibility of attributing a definite instant to the recoil, we know the mean velocity in the direction of observation during the scattering process only with an accuracy $2h/m\lambda$. The uncertainty in the position after observation hence is $2hl/mc\lambda$. Here, too, the product of the inaccuracies in the measurement of position and momentum is thus given by the general formula (2).

Just as in the case of the determination of position, the time of the process of observation for the determination of momentum may be made as short as is desired if only the wave-length of the radiation used is sufficiently small. The fact that the recoil then gets larger does not, as we have seen, affect the accuracy of measurement. It should further be mentioned, that in referring to the velocity of a particle as we have here done repeatedly, the purpose has only been to obtain a connexion with the ordinary space-time description convenient in this case. As it appears already from the considerations of de Broglie mentioned above, the concept of velocity must always in the quantum theory be handled with caution. It will also be seen that an unambiguous definition of this concept is excluded by the quantum postulate. This is particularly to be remembered when comparing the results of successive observations. Indeed, the position of an individual at two given moments can be measured with any desired degree of accuracy; but if, from such measurements, we would calculate the velocity of the individual in the ordinary way, it must be clearly realised that we are dealing with an abstraction, from which no unambiguous information concerning the previous or future behaviour of the individual can be obtained.

According to the above considerations regarding the possibilities of definition of the properties of individuals, it will obviously make no difference in the discussion of the accuracy of measurements of position and momentum of a particle if collisions with other material particles are considered instead of scattering of radiation. In both cases we see that the uncertainty in question equally affects the description of the agency of measurement and of the object. In fact, this uncertainty cannot be avoided in a description of the behaviour of individuals with respect to a co-ordinate system fixed in the ordinary way by means of solid bodies and unperturbable clocks. The experimental devices—opening and closing of apertures, etc.—are seen to permit only conclusions regarding the space-time extension of the associated wave-fields.

In tracing observations back to our sensations, once more regard has to be taken to the quantum postulate in connexion with the perception of the agency of observation, be it through its direct action upon the eye or by means of suitable auxiliaries such as photographic plates, Wilson clouds, etc. It is easily seen, however, that the resulting additional statistical element will not influence the uncertainty in the description of the object. It might even be conjectured that the arbitrariness in what is regarded as object and what as agency of observation would open up a possibility of avoiding this uncertainty altogether. In connexion with the measurement of the position of a particle, one might, for example, ask whether the momentum transmitted by the scattering could not be determined by means of the conservation theorem from a measurement of the change of momentum of the microscope—including light source and photographic plate—during the process of observation. A closer investigation shows, however, that such a measurement is impossible, if at the same time one wants to know the position of the microscope with sufficient accuracy. In fact, it follows from the experiences which have found expression in the wave theory of matter, that the position of the centre of gravity of a body and its total momentum can only be defined within the limits of reciprocal accuracy given by relation (2).

Strictly speaking, the idea of observation belongs to the causal space-time way of description. Due to the general character of relation (2), however, this idea can be consistently utilised also in the quantum theory, if only the uncertainty expressed through this relation is taken into account. As remarked by Heisenberg, one may even obtain an instructive illustration to the quantum theoretical description of atomic (microscopic) phenomena by comparing this uncertainty with the uncertainty, due to imperfect measurements, inherently contained in any observation as considered in the ordinary description of natural phenomena. He remarks on that occasion that even in the case of macroscopic phenomena we may say, in a certain sense, that they are created by repeated observations. It must not be forgotten, however, that in the classical theories any succeeding observation permits a prediction of future events with ever-increasing accuracy, because it improves our knowledge of the initial state of the system. According to the quantum theory, just the impossibility of neglecting the interaction with the agency of measurement means that every observation introduces a new uncontrollable element. Indeed, it follows from the above considerations that the measurement of the positional co-ordinates of a particle is accompanied not only by a finite change in the dynamical variables, but also the fixation of its position means a complete rupture in the causal description of its dynamical behaviour, while the determination of its momentum always implies a gap in the knowledge of its spatial propagation. Just this situation brings out most strikingly the complementary character of the description of atomic phenomena which appears as an inevitable consequence of the contrast between the quantum postulate and the distinction between object and agency of measurement, inherent in our very idea of observation.

4. Correspondence Principle and Matrix Theory.

Hitherto we have only regarded certain general features of the quantum problem. The situation implies, however, that the main stress has to be laid on the formulation of the laws governing the interaction between the objects which we symbolise by the abstractions of isolated particles and radiation. Points of attack for this formulation are presented in the first place by the problem of atomic constitution. As is well known, it has been possible here, by means of an elementary use of classical concepts and in harmony with the quantum postulate, to throw light on essential aspects of experience. For example, the experiments regarding the excitation of spectra by electronic impacts and by radiation are adequately accounted for on the assumption of discrete stationary states and individual transition processes. This is primarily due to the circumstance that in these questions no closer description of the space-time behaviour of the processes is required.

Here the contrast with the ordinary way of description appears strikingly in the circumstance that spectral lines, which on the classical view would be ascribed to the same state of the atom, will, according to the quantum postulate, correspond to separate transition processes, between which the excited atom has a choice. Notwithstanding this contrast, however, a formal connexion with the classical ideas could be obtained in the limit, where the relative difference in the properties of neighbouring stationary states vanishes asymptotically and where in statistical applications the discontinuities may be disregarded. Through this connexion it was possible to a large extent to interpret the regularities of spectra on the basis of our ideas about the structure of the atom.

The aim of regarding the quantum theory as a rational generalisation of the classical theories led to the formulation of the so-called correspondence principle. The utilisation of this principle for the interpretation of spectroscopic results was based on a symbolical application of classical electrodynamics, in which the individual transition processes were each associated with a harmonic in the motion of the atomic particles to be expected according to ordinary mechanics. Except in the limit mentioned, where the relative difference between adjacent stationary states may be neglected, such a fragmentary application of the classical theories could only in certain cases lead to a strictly quantitative description of the phenomena. Especially the connexion developed by

Ladenburg and Kramers between the classical treatment of dispersion and the statistical laws governing the radiative transition processes formulated by Einstein should be mentioned here. Although it was just Kramers' treatment of dispersion that gave important hints for the rational development of correspondence considerations, it is only through the quantum theoretical methods created in the last few years that the general aims laid down in the principle mentioned have obtained an adequate formulation.

As is known, the new development was commenced in a fundamental paper by Heisenberg, where he succeeded in emancipating himself completely from the classical concept of motion by replacing from the very start the ordinary kinematical and mechanical quantities by symbols, which refer directly to the individual processes demanded by the quantum postulate. This was accomplished by substituting for the Fourier development of a classical mechanical quantity a matrix scheme, the elements of which symbolise purely harmonic vibrations and are associated with the possible transitions between stationary states. By requiring that the frequencies ascribed to the elements must always obey the combination principle for spectral lines, Heisenberg could introduce simple rules of calculation for the symbols, which permit a direct quantum theoretical transcription of the fundamental equations of classical mechanics. This ingenious attack on the dynamical problem of atomic theory proved itself from the beginning to be an exceedingly powerful and fertile method for interpreting quantitatively the experimental results. Through the work of Born and Jordan as well as of Dirac, the theory was given a formulation which can compete with classical mechanics as regards generality and consistency. Especially the element characteristic of the quantum theory, Planck's constant, appears explicitly only in the algorithms to which the symbols, the so-called matrices, are subjected. In fact, matrices, which represent canonically conjugated variables in the sense of the Hamiltonian equations, do not obey the commutative law of multiplication, but two such quantities, q and p, have to fulfil the exchange rule

$$pq - qp = \sqrt{-1}\frac{h}{2\pi}. \quad . \quad . \quad . \quad (3)$$

Indeed, this exchange relation expresses strikingly the symbolical character of the matrix formulation of the quantum theory. The matrix theory has often been called a calculus with directly observable quantities. It must be remembered, however, that the procedure described is limited just to those problems, in which in applying the quantum postulate the space-time description may largely be disregarded, and the question of observation in the proper sense therefore placed in the background.

In pursuing further the correspondence of the quantum laws with classical mechanics, the stress placed on the statistical character of the quantum theoretical description, which is brought in by the quantum postulate, has been of fundamental importance. Here the generalisation of the symbolical method made by Dirac and Jordan represented a great progress by making possible the operation with matrices, which are not arranged according to the stationary states, but where the possible values of any set of variables may appear as indices of the matrix elements. In analogy to the interpretation considered in the original form of the theory of the 'diagonal elements' connected only with a single stationary state, as time averages of the quantity to be represented, the general transformation theory of matrices permits the representation of such averages of a mechanical quantity, in the calculation of which any set of variables characterising the 'state' of the system have given values, while the canonically conjugated variables are allowed to take all possible values. On the basis of the procedure developed by these authors and in close connexion with ideas of Born and Pauli, Heisenberg has in the paper already cited above attempted a closer analysis of the physical content of the quantum theory, especially in view of the apparently paradoxical character of the exchange relation (3). In this connexion he has formulated the relation

$$\Delta q \Delta p \sim h \quad . \quad . \quad . \quad . \quad (4)$$

as the general expression for the maximum accuracy with which two canonically conjugated variables can simultaneously be observed. In this way Heisenberg has been able to elucidate many paradoxes appearing in the application of the quantum postulate, and to a large extent to demonstrate the consistency of the symbolic method. In connexion with the complementary nature of the quantum theoretical description, we must, as already mentioned, constantly keep the possibilities of definition as well as of observation before the mind. For the discussion of just this question the method of wave mechanics developed by Schrödinger has, as we shall see, proved of great help. It permits a general application of the principle of superposition also in the problem of interaction, thus offering an immediate connexion with the above considerations concerning radiation and free particles. Below we shall return to the relation of wave mechanics to the general formulation of the quantum laws by means of the transformation theory of matrices.

5. WAVE MECHANICS AND QUANTUM POSTULATE.

Already in his first considerations concerning the wave theory of material particles, de Broglie pointed out that the stationary states of an atom may be visualised as an interference effect of the phase wave associated with a bound electron. It is true that this point of view at first did not, as regards quantitative results, lead beyond the earlier methods of quantum theory, to the development of which Sommerfeld has contributed so essentially. Schrödinger, however, succeeded in developing a wave-theoretical method which has opened up new aspects, and has proved to be of decisive importance for the great progress in atomic physics during the last years. Indeed, the proper vibrations of the Schrödinger wave equation have been found to furnish a representation of the stationary states of an atom meeting all requirements. The energy of each state is connected with the corresponding period of vibration according to the general quantum relation (1). Furthermore, the number of nodes in the various characteristic vibrations gives a simple interpretation to the concept of quantum number which was already known from the older methods, but at first did not seem to appear in the matrix formulation. In addition, Schrödinger could associate with the solutions of the wave equation a continuous distribution of charge and current, which, if applied to a characteristic vibration, represents the electrostatic and magnetic properties of an atom in the corresponding stationary state. Similarly, the superposition of two characteristic solutions corresponds to a continuous vibrating distribution of electrical charge, which on classical electrodynamics would give rise to an emission of radiation, illustrating instructively the consequences of the quantum postulate and the correspondence requirement regarding the transition process between two stationary states formulated in matrix mechanics. Another application of the method of Schrödinger, important for the further development, has been made by Born in his investigation of the problem of collisions between atoms and free electric particles. In this connexion he succeeded in obtaining a statistical interpretation of the wave functions, allowing a calculation of the probability of the individual transition processes required by the quantum postulate. This includes a wave-mechanical formulation of the adiabatic principle of Ehrenfest, the fertility of which appears strikingly in the promising investigations of Hund on the problem of formation of molecules.

In view of these results, Schrödinger has expressed the hope that the development of the wave theory will eventually remove the irrational element expressed by the quantum postulate and open the way for a complete description of atomic phenomena along the line of the classical theories. In support of this view, Schrödinger, in a recent paper (*Ann. d. Phys.*, 83, p. 956; 1927), emphasises the fact that the discontinuous exchange of energy between atoms required by the quantum postulate, from the point of view of the wave theory, is replaced by a simple resonance phenomenon. In particular, the idea of individual stationary states would be an illusion and its applicability only an illustration of the resonance mentioned. It must be kept in mind, however, that just in the resonance problem mentioned we are concerned with a closed system which, according to the view presented here, is not accessible to observation. In fact, wave mechanics just as the matrix theory on this view represents a symbolic transcription of the problem of motion of classical mechanics adapted to the requirements of quantum theory and only to be interpreted by an explicit use of the quantum postulate. Indeed, the two formulations of the interaction problem might be said to be complementary in the same sense as the wave and particle idea in the description of the free individuals. The apparent contrast in the utilisation of the energy concept in the two theories is just connected with this difference in the starting-point.

The fundamental difficulties opposing a space-time description of a system of particles in interaction appear at once from the inevitability of the superposition principle in the description of the behaviour of individual particles. Already for a free particle the knowledge of energy and momentum excludes, as we have seen, the exact knowledge of its space-time co-ordinates. This implies that an immediate utilisation of the concept of energy in connexion with the classical idea of the potential energy of the system is excluded. In the Schrödinger wave equation these difficulties are avoided by replacing the classical expression of the Hamiltonian by a differential operator by means of the relation

$$p = \sqrt{-1}\frac{h}{2\pi}\frac{\delta}{\delta q}, \quad . \quad . \quad . \quad (5)$$

where p denotes a generalised component of momentum and q the canonically conjugated variable. Hereby the negative value of the energy is regarded as conjugated to the time. So far, in the wave equation, time and space as well as energy and momentum are utilised in a purely formal way.

The symbolical character of Schrödinger's method appears not only from the circumstance that its simplicity, similarly to that of the matrix theory, depends essentially upon the use of imaginary arithmetic quantities. But above all there can be no question of an immediate connexion with our ordinary conceptions because the 'geometrical' problem represented by the wave equation is associated with the so-called co-ordinate space, the number of dimensions of which is equal to the number of degrees of freedom of the system, and hence in general greater than the number of dimensions of ordinary space. Further, Schrödinger's formulation of the interaction problem, just as the formulation offered by matrix theory, involves a neglect of the finite velocity of propagation of the forces claimed by relativity theory.

On the whole, it would scarcely seem justifiable, in the case of the interaction problem, to demand a visualisation by means of ordinary space-time pictures. In fact, all our knowledge concerning the internal properties of atoms is derived from experiments on their radiation or collision reactions, such that the interpretation of experimental facts ultimately depends on the abstractions of radiation in free space, and free material particles. Hence, our whole space-time view of physical phenomena, as well as the definition of energy and momentum, depends ultimately upon these abstractions. In judging the applications of these auxiliary ideas we should only demand inner consistency, in which connexion special regard has to be paid to the possibilities of definition and observation.

In the characteristic vibrations of Schrödinger's wave equation we have, as mentioned, an adequate representation of the stationary states of an atom allowing an unambiguous definition of the energy of the system by means of the general quantum relation (1). This entails, however, that in the interpretation of observations, a fundamental renunciation regarding the space-time description is unavoidable. In fact, the consistent application of the concept of stationary states excludes, as we shall see, any specification regarding the behaviour of the separate particles in the atom. In problems where a description of this behaviour is essential, we are bound to use the general solution of the wave equation which is obtained by superposition of characteristic solutions. We meet here with a complementarity of the possibilities of definition quite analogous to that which we have considered earlier in connexion with the properties of light and free material particles. Thus, while the definition of energy and momentum of individuals is attached to the idea of a harmonic elementary wave, every space-time feature of the description of phenomena is, as we have seen, based on a consideration of the interferences taking place inside a group of such elementary waves. Also in the present case the agreement between the possibilities of observation and those of definition can be directly shown.

According to the quantum postulate any observation regarding the behaviour of the electron in the atom will be accompanied by a change in the state of the atom. As stressed by Heisenberg, this change will, in the case of atoms in stationary states of low quantum number, consist in general in the ejection of the electron from the atom. A description of the 'orbit' of the electron in the atom with the aid of subsequent observations is hence impossible in such a case. This is connected with the circumstance that from characteristic vibrations with only a few nodes no wave packages can be built up which would even approximately represent the 'motion' of a particle. The complementary nature of the description, however, appears particularly in that the use of observations concerning the behaviour of particles in the atom rests on the possibility of neglecting, during the process of observation, the interaction between the particles, thus regarding them as free. This requires, however, that the duration of the process is short compared with the natural periods of the atom, which again means that the uncertainty in the knowledge of the energy transferred in the process is large compared to the energy differences between neighbouring stationary states.

In judging the possibilities of observation it must, on the whole, be kept in mind that the wave mechanical solutions can be visualised only in so far as they can be described with the aid of the concept of free particles. Here the difference between classical mechanics and the quantum theoretical treatment of the problem of interaction appears most strikingly. In the former such a restriction is unnecessary, because the 'particles' are here endowed with an immediate 'reality,' independently of their being free or bound. This situation is particularly important in connexion with the consistent utilisation of Schrödinger's electric density as a measure of the probability for electrons being present within given space regions of the atom. Remembering the restriction mentioned, this interpretation is seen to be a simple consequence of the assumption that the probability of the presence of a free electron is expressed by the electric density associated with the wave-field in a similar way to that by which the probability of the presence of a light quantum is given by the energy density of the radiation.

As already mentioned, the means for a general consistent utilisation of the classical concepts in the quantum theory have been created through the transformation theory of Dirac and Jordan, by the aid of which Heisenberg has formulated his general uncertainty relation (4). In this theory also the Schrödinger wave equation has obtained an instructive application. In fact, the characteristic solutions of this equation appear as auxiliary functions which define a transformation from matrices with indices representing the energy values of the system to other matrices, the indices of which are the possible values of the space coordinates. It is also of interest in this connexion to mention that Jordan and Klein (*Zeitsch. f. Phys.*, **45**, 751; 1927) have recently arrived at the formulation of the problem of interaction expressed by the Schrödinger wave equation, taking as starting-point the wave representation of individual particles and applying a symbolic method closely related to the deep-going treatment of the radiation problem developed by Dirac from the point of view of the matrix theory, to which we shall return below.

6. REALITY OF STATIONARY STATES.

In the conception of stationary states we are, as mentioned, concerned with a characteristic application of the quantum postulate. By its very nature this conception means a complete renunciation as regards a time description. From the point of view taken here, just this renunciation forms the necessary condition for an unambiguous definition of the energy of the atom. Moreover, the conception of a stationary state involves, strictly speaking, the exclusion of all interactions with individuals not belonging to the system. The fact that such a closed system is associated with a particular energy value may be considered as an immediate expression for the claim of causality contained in the theorem of conservation of energy. This circumstance justifies the assumption of the supra-mechanical stability of the stationary states, according to which the atom, before as well as after an external influence, always will be found in a well-defined state, and which forms the basis for the use of the quantum postulate in problems concerning atomic structure.

In a judgment of the well-known paradoxes which this assumption entails for the description of collision and radiation reactions, it is essential to consider the limitations of the possibilities of definition of the reacting free individuals, which is expressed by relation (2). In fact, if the definition of the energy of the reacting individuals is to be accurate to such a degree as to entitle us to speak of conservation of energy during the reaction, it is necessary, according to this relation, to co-ordinate to the reaction a time interval long compared to the vibration period associated with the transition process, and connected with the energy difference between the stationary states according to relation (1). This is particularly to be remembered when considering the passage of swiftly moving particles through an atom. According to the ordinary kinematics, the effective duration of such a passage would be very small as compared with the natural periods of the atom, and it seemed impossible to reconcile the principle of conservation of energy with the assumption of the stability of stationary states (cf. *Zeits. f. Phys.*, **34**, 142; 1925). In the wave representation, however, the time of reaction is immediately connected with the accuracy of the knowledge of the energy of the colliding particle, and hence there can never be the possibility of a contradiction with the law of conservation. In connexion with the discussion of paradoxes of the kind mentioned, Campbell (*Phil. Mag.*, i. 1106; 1926) suggested the view that the conception of time itself may be essentially statistical in nature. From the view advanced here, according to which the foundation of space-time description is offered by the abstraction of free individuals, a fundamental distinction between time and space, however, would seem to be excluded by the relativity requirement. The singular position of the time in problems concerned with stationary states is, as we have seen, due to the special nature of such problems.

The application of the conception of stationary states demands that in any observation, say by means of collision or radiation reactions, permitting a distinction between different stationary states, we are entitled to disregard the previous history of the atom. The fact that the symbolical quantum theory methods ascribe a particular phase to each stationary state the value of which depends upon the previous history of the atom, would for the first moment seem to contradict the very idea of stationary states. As soon as we are really concerned with a time problem, however, the consideration of a strictly closed system is excluded. The use of simply harmonic proper vibrations in the interpretation of observations means, therefore, only a suitable idealisation which in a more rigorous discussion must always be replaced by a group of harmonic vibrations, distributed over a finite frequency interval. Now, as already mentioned, it is a general consequence of the superposition principle that it has no sense to co-ordinate a phase value to the group as a whole, in the same manner as may be done for each elementary wave constituting the group.

This inobservability of the phase, well known from the theory of optical instruments, is brought out in a particularly simple manner in a discussion of the Stern-Gerlach experiment, so important for the investigation of the properties of single atoms. As pointed out by Heisenberg, atoms with different orientation in the field may only be separated if the deviation of the beam is larger than the diffraction at the slit of the de Broglie waves representing the translational motion of the atoms. This condition means, as a simple calculation shows, that the product of the time of passage of the atom through the field, and the uncertainty due to the finite width of the beam of its energy in the field, is at least equal to the quantum of action. This result was considered by Heisenberg as a support of relation (2) as regards the reciprocal uncertainties of energy and time values. It would seem, however, that here we are not simply dealing with a measurement of the energy of the atom at a given time. But since the period of the proper vibrations of the atom in the field is connected with the total energy by relation (1), we realise that the condition for separability mentioned just means the loss of the phase. This circumstance removes also the apparent contradictions, arising in certain problems concerning the coherence of resonance radiation, which have been discussed frequently, and were also considered by Heisenberg.

To consider an atom as a closed system, as we have done above, means to neglect the spontaneous emission of radiation which even in the absence of external influences puts an upper limit to the lifetime of the stationary states. The fact that this neglect is justified in many applications is connected with the circumstance that the coupling between the atom and the radiation field, which is to be expected on classical electrodynamics, is in general very small compared to the coupling between the particles in the atom. It is, in fact, possible in a description of the state of an atom to a considerable extent to neglect the reaction of radiation, thus disregarding the unsharpness in the energy values connected with the lifetime of the stationary states according to relation (2) (cf. *Proc. Camb. Phil. Soc.*, 1924 (Supplement), or *Zeits. f. Phys.*, **13**, 117; 1923). This is the reason why it is possible to draw conclusions concerning the properties of radiation by using classical electrodynamics.

The treatment of the radiation problem by the new quantum theoretical methods meant to begin with just a quantitative formulation of this correspondence consideration. This was the very starting-point of the original considerations of Heisenberg. It may also be mentioned that an instructive analysis of Schrödinger's treatment of the radiation phenomena from the point of view of the correspondence principle has been recently given by Klein (*Zeits. f. Phys.*, **41**, 707; 1927). In the more rigorous form of the theory developed by Dirac (*Proc. Roy. Soc.*, A, vol. 114, p. 243; 1927) the radiation field itself is included in the closed system under consideration. Thus it became possible in a rational way to take account of the individual character of radiation demanded by the quantum theory and to build up a dispersion theory, in which the final width of the spectral lines is taken into consideration.

The renunciation regarding space-time pictures characterising this treatment would seem to offer a striking indication of the complementary character of the quantum theory. This is particularly to be borne in mind in judging the radical departure from the causal description of Nature met with in radiation phenomena, to which we have referred above in connexion with the excitation of spectra.

In view of the asymptotic connexion of atomic properties with classical electrodynamics, demanded by the correspondence principle, the reciprocal exclusion of the conception of stationary states and the description of the behaviour of individual particles in the atom might be regarded as a difficulty. In fact, the connexion in question means that in the limit of large quantum numbers where the relative difference between adjacent stationary states vanishes asymptotically, mechanical pictures of electronic motion may be rationally utilised. It must be emphasised, however, that this connexion cannot be regarded as a gradual transition towards classical theory in the sense that the quantum postulate would lose its significance for high quantum numbers. On the contrary, the conclusions obtained from the correspondence principle with the aid of classical pictures depend just upon the assumptions that the conception of stationary states and of individual transition processes are maintained even in this limit.

This question offers a particularly instructive example for the application of the new methods. As shown by Schrödinger (*Naturwiss.*, **14**, 664; 1926), it is possible, in the limit mentioned, by superposition of proper vibrations to construct wave groups small in comparison to the 'size' of the atom, the propagation of which indefinitely approaches the classical picture of moving material particles, if the quantum numbers are chosen sufficiently large. In the special case of a simple harmonic vibrator, he was able to show that such wave groups will keep together even for any length of time, and will oscillate to and fro in a manner corresponding to the classical picture of the motion. This circumstance Schrödinger has regarded as a support of his hope of constructing a pure wave theory without referring to the quantum postulate. As emphasised by Heisenberg, the simplicity of the case of the oscillator, however, is exceptional and intimately connected with the harmonic nature of the corresponding classical motion. Nor is there in this example any possibility for an asymptotical approach towards the problem of free particles. In general, the wave group will gradually spread over the whole region of the atom, and the 'motion' of a bound electron can only be followed during a number of periods, which is of the order of magnitude of the quantum numbers associated with the proper vibrations. This question has been more closely investigated in a recent paper by Darwin (*Proc. Roy. Soc.*, A, vol. 117, 258; 1927), which contains a number of instructive examples of the behaviour of wave groups. From the viewpoint of the matrix theory a treatment of analogous problems has been carried out by Kennard (*Zeits. f. Phys.*, **47**, 326; 1927).

Here again we meet with the contrast between the wave theory superposition principle and the assumption of the individuality of particles with which we have been concerned already in the case of free particles. At the same time the asymptotical connexion with the classical theory, to which a distinction between free and bound particles is unknown, offers the possibility of a particularly simple illustration of the above considerations regarding the consistent utilisation of the concept of stationary states. As we have seen, the identification of a stationary state by means of collision or radiation reactions implies a gap in the time description, which is at least of the order of magnitude of the periods associated with transitions between stationary states. Now, in the limit of high quantum numbers these periods may be interpreted as periods of revolution. Thus we see at once that no causal connexion can be obtained between observations leading to the fixation of a stationary state and earlier observations on the behaviour of the separate particles in the atom.

Summarising, it might be said that the concepts of stationary states and individual transition processes within their proper field of application possess just as much or as little 'reality' as the very idea of individual particles. In both cases we are concerned with a demand of causality complementary to the space-time description, the adequate application of which is limited only by the restricted possibilities of definition and of observation.

7. THE PROBLEM OF THE ELEMENTARY PARTICLES.

When due regard is taken of the complementary feature required by the quantum postulate, it seems, in fact, possible with the aid of the symbolic methods to build up a consistent theory of atomic phenomena, which may be considered as a rational generalisation of the causal space-time description of classical physics. This view does not mean, however, that classical electron theory may be regarded simply as the limiting case of a vanishing quantum of action. Indeed, the connexion of the latter theory with experience is based on assumptions which can scarcely be separated from the group of problems of the quantum theory. A hint in this direction was already given by the well-known difficulties met with in the attempts to account for the individuality of ultimate electrical particles on general mechanical and electrodynamical principles. In this respect also the general relativity theory of gravitation has not fulfilled expectations. A satisfactory solution of the problems touched upon would seem to be possible only by means of a rational quantum-theoretical transcription of the general field theory, in which the ultimate quantum of electricity has found its natural position as an expression of the feature of individuality characterising the quantum theory. Recently Klein (*Zeits. f. Phys.*, **46**, 188; 1927) has directed attention to the possibility of connecting this problem with the five-dimensional unified representation of electromagnetism and gravitation proposed by Kaluza. In fact, the conservation of electricity appears in this theory as an analogue to the conservation theorems for energy and momentum. Just as these concepts are complementary to the space-time description, the appropriateness of the ordinary four-dimensional description as well as its symbolical utilisation in the quantum theory would, as Klein emphasises, seem to depend essentially on the circumstance that in this description electricity always appears in well-defined units, the conjugated fifth dimension being as a consequence not open to observation.

Quite apart from these unsolved deep-going problems, the classical electron theory up to the present time has been the guide for a further development of the correspondence description in connexion with the idea first advanced by Compton that the ultimate electrical particles, besides their mass and charge, are endowed with a magnetic moment due to an angular momentum determined by the quantum of action. This assumption, introduced with striking success by Goudsmit and Uhlenbeck into the discussion of the origin of the anomalous Zeeman effect, has proved most fruitful in connexion with the new methods, as shown especially by Heisenberg and Jordan. One might say, indeed, that the hypothesis of the magnetic electron, together with the resonance problem elucidated by Heisenberg (*Zeits. f. Phys.*, **41**, 239; 1927), which occurs in the quantum-theoretical description of the behaviour of atoms with several electrons, have brought the correspondence interpretation of the spectral laws and the periodic system to a certain degree of completion. The principles underlying this attack have even made it possible to draw conclusions regarding the properties of atomic nuclei. Thus Dennison (*Proc. Roy. Soc.*, A, vol. 115, 483; 1927), in connexion with ideas of Heisenberg and Hund, has succeeded recently in a very interesting way in showing how the explanation of the specific heat of hydrogen, hitherto beset with difficulties, can be harmonised with the assumption that the proton is endowed with a moment of momentum of the same magnitude as that of the electron. Due to its larger mass, however, a magnetic moment much smaller than that of the electron must be associated with the proton.

The insufficiency of the methods hitherto developed as concerns the problem of the elementary particles appears in the questions just mentioned from the fact that they do not allow of an unambiguous explanation of the difference in the behaviour of the electric elementary particles and the 'individuals' symbolised through the conception of light quanta expressed in the so-called exclusion principle formulated by Pauli. In fact, we meet in this principle, so important for the problem of atomic structure as well as for the recent development of statistical theories, with one among several possibilities, each of which fulfils the correspondence requirement. Moreover, the difficulty of satisfying the relativity requirement in quantum theory appears in a particularly striking light in connexion with the problem of the magnetic electron. Indeed, it seemed not possible to bring the promising attempts made by Darwin and Pauli in generalising the new methods to cover this problem naturally, in connexion with the relativity kinematical consideration of Thomas so fundamental for the interpretation of experimental results. Quite recently, however, Dirac (*Proc. of the Roy. Soc.*, A, **117**, 610; 1928) has been able successfully to attack the problem of the magnetic electron through a new ingenious extension of the symbolical method and so to satisfy the relativity requirement without abandoning the agreement with spectral evidence. In this attack not only the imaginary complex quantities appearing in the earlier procedures are involved, but his fundamental equations themselves contain quantities of a still higher degree of complexity, that are represented by matrices.

Already the formulation of the relativity argument implies essentially the union of the space-time co-ordination and the demand of causality characterising the classical theories. In the adaptation of the relativity requirement to the quantum postulate we must therefore be prepared to meet with a renunciation as to visualisation in the ordinary sense going still further than in the formulation of the quantum laws considered here. Indeed, we find ourselves here on the very path taken by Einstein of adapting our modes of perception borrowed from the sensations to the gradually deepening knowledge of the laws of Nature. The hindrances met with on this path originate above all in the fact that, so to say, every word in the language refers to our ordinary perception. In the quantum theory we meet this difficulty at once in the question of the inevitability of the feature of irrationality characterising the quantum postulate. I hope, however, that the idea of complementarity is suited to characterise the situation, which bears a deep-going analogy to the general difficulty in the formation of human ideas, inherent in the distinction between subject and object.

Printed in Great Britain by R. & R. Clark, Limited, *Edinburgh.*

safely in so short a time as 4 to 7 minutes, whereas animals brought from a nitrogen–oxygen mixture in 26 minutes or more became paralysed, and many died at once or within a few days. These general conclusions were confirmed in a large number of experiments.

It was interesting to find that the advantage of the helium was considerably greater than was expected on the basis of its smaller solubility. Helium diffuses more rapidly than nitrogen on account of its smaller molecules, which move nearly three times as fast. Hence, not only is less helium dissolved in the blood stream, but also it can escape into the lungs with much greater rapidity during decompression.

Large-scale experiments with men are now in progress under the direction of the Navy Department. The apparatus in use is partly shown in the accompanying illustrations. Considerable time has been spent upon the revision of the decompression tables in order to have an authoritative basis for further work with helium.

On Oct. 4, 1927, United States Patent 1,644,363 was issued to W. P. Yant, R. R. Sayers, and J. H. Hildebrand. Under the terms of this patent, persons under compression are supplied with a mixture for respiration consisting mainly of oxygen and nitrogen and containing a lower percentage of oxygen than air, and while under decompression with a gas comprising mainly oxygen and helium.

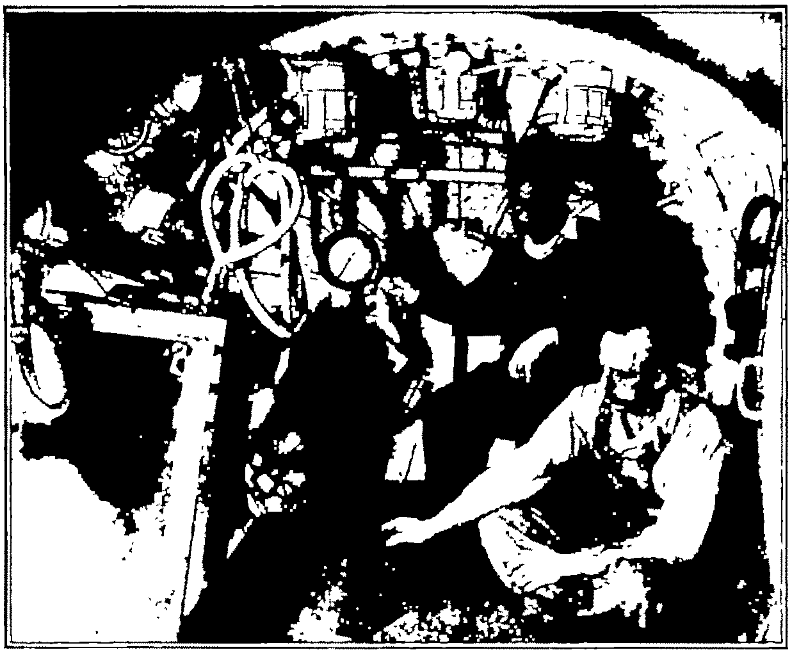

FIG. 4.—Interior of main compartment with test apparatus. Note electric lights, pressure gauge, control valve, hatches for closing windows in event of fracture of windows, and small tending lock at rear. This tending lock is operated similarly to the man lock, and is provided for passing in and out apparatus, food, etc. In connexion with the regulating valves, it should be stated that there are controls inside the chamber as well as outside, but the attendant on the outside can prohibit the use of the inside controls by closing off certain valves. This is done in order to prevent a man whose judgment may be impaired from releasing the pressure at a time or at a rate which is not safe. The oxygen breathing apparatus hanging to the wood support is used for administering helium. This is supplied from an external cylinder through a high pressure line and the man breathes helium from the bag, but at the same time has an air pressure surrounding his body. This obviates the necessity of filling the tank with that gas and conserves the supply of helium.

The Frequency of Rain over the British Isles.

By Dr. JOHN GLASSPOOLE.

THE perennial interest in the chances of good weather in our short English summer is quickened by the advance of spring. While the weather map is the vade-mecum of the forecaster of to-morrow's rain, it cannot help us to arrange our holidays in advance. We can, however, derive a great deal of information from a study of the accumulated statistics of the past.

Rainfall is measured at 9 A.M. at some 4000 stations in the British Isles, the smallest amount recorded being 0·01 inch. A day with 0·01 inch or more is defined as a rain-day. Although the rain-day includes many days with too little rain to be of practical importance, it is only such statistics which are available for any length of time. In considering the frequency of rain over the British Isles, it is necessary, therefore, to consider first of all the distribution of the number of rain-days, and to supplement this information by statistics from the limited number of stations for which more detailed observations are available.

Although a station with a relatively large annual rainfall is usually one with a large number of rain-days, the two quantities do not vary in the same proportion.[1] In the first place, the variations of the number of rain-days over the British Isles are much less than the corresponding variations of rainfall. In other words, both the variations of average monthly and annual values from place to place, and also the variations of average monthly values at one place, are much more uniform in the case of rain-days. The second difference is that, even at stations with the same rainfall, the average number of rain-days increases from the south-east to the north-west of the British Isles. Both these differences can be illustrated from the map reproduced as Fig. 1, which shows the distribution of the average number of rain-days during the six summer months, April to September (a period of 183 days).

---

[1] The question is dealt with in two recent papers: "The Distribution over the British Isles in Time and Space of the Average Number of Days with Rain," "British Rainfall, 1926," pp. 260-279, and "The Distribution over the British Isles of the Average Number of Days with Rain during each Month of the Year," *Q J R Meteor. Soc.*, 54; 1928.

The range of the number of rain-days on the map is from 65 in the neighbourhood of the Thames Estuary to just above 120 in parts of the western Highlands of Scotland. The corresponding range in the summer rainfall is from 9 inches at Shoeburyness to 45 inches in the western Highlands, so that while in the latter locality during the summer rain-days are only twice as frequent as in the former, the rainfall is five times as much. Even a comparison of the values on the map for areas at about sea-level indicates that there is a persistent increase in the frequency of rain-days from the south-east to north-west. In the south-east, therefore, there is a much greater chance of long spells of dry weather. In fact, all records of rainless calendar months have occurred in the south-eastern half of the British Isles. Such occurrences are rare; but small areas in February 1891, July 1911, April 1912, June 1921, and June 1925 were free from rain.

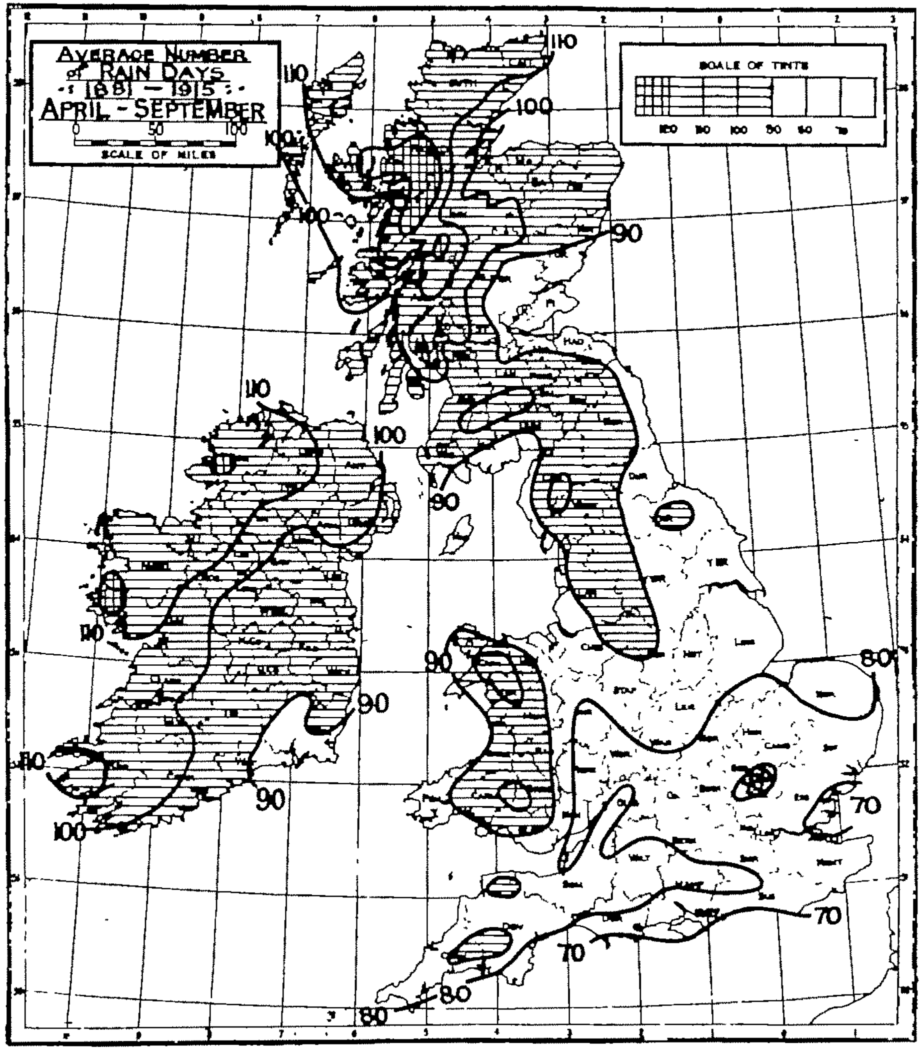

Fig. 1.—Average number of rain-days during the summer.

The main characteristics of the variations in the number of rain-days from month to month are apparent from the general values for the whole country. These are set out below, together with the corresponding values of the rainfall.

The table shows that there are in general 20 more days with rain in the winter than in the summer six months, this being the case nearly everywhere in the British Isles. The three months April, May, and June are the driest months of the year and the months of fewest rain-days, while December gives the maximum value in each column. The subsidiary maximum in August, associated with relatively intense convection rains, is well marked. Of the summer months, May and June are therefore on the average more favourable for holiday makers, both on account of the greater frequency of rainless days and the smaller amount of rain. The mean rainfall per rain-day over the British Isles generally is 0·20 inch, and some conception of this amount is afforded by considering it as the quantity which would fall during 3½ hours of continuous rain, the rate of rain being the average for London. In this connexion it may be of interest to recall that on the average rain falls in London for 1·2 out of 24 hours.

Some indication of the risks of a wet day is afforded by a consideration of the frequency of occurrence of days with specified amounts of rain. At Camden Square (London), with 25 inches a year, 0·01 inch or more falls on 163 days, of which 75 occur in the summer. There are, on the average, 40 days a year with 0·20 inch or more, 9 days with 0·50 inch or more, and only one day with 1 inch or more. The heaviest daily falls are about evenly divided between the intense thunderstorm rains of the summer months and the more persistent and more widespread rains of the winter. Of the two most remarkable falls on record at Camden Square, in one so much as 3·28 inches fell in two intense downpours, giving in all a duration of only one hour, while in the other about the same quantity (actually 3·43 inches) was spread over 3 days with continuous rain for 58 hours. The mean values for the individual months show that the distribution during the year is fairly uniform. The greatest contrast in the frequency of falls of 0·20 inch or more is afforded by the spring and autumn. In each of the former months there are usually two or three such falls, while in the latter there are four or perhaps five.

THE GENERAL NUMBER OF RAIN-DAYS AND RAINFALL OVER THE BRITISH ISLES, 1881 TO 1915.

	Rain-days.	Rainfall.
		in.
January	19	3·78
February	17	3·26
March	18	3·22
April	15	2·52
May	15	2·61
June	14	2·64
July	16	3·25
August	17	3·88
September	15	3·09
October	19	4·25
November	19	4·19
December	20	4·72
Year	204	41·41

As the number of rain-days increases towards the north-west, it is obvious that of two stations with the same average annual rainfall the one to the north-west will in general record the greater frequency of days with small amounts. Further, as the variations in the number of rain-days from place to place are smaller than the variations in the actual rainfall, the frequency of days with large amounts will be greater at the wetter of two stations. Some indication of the extent of the increase due to both these factors is afforded by setting out statistics for Glasgow alongside those already given for London.

AVERAGE VALUES, LONDON AND GLASGOW.

	London.	Glasgow.
Annual rainfall (inches)	25	37
Rain-days in year	163	212
" " summer	75	99
Days with 0·20 in. or more during year	40	66
Days with 0·50 in. or more during year	9	12
Days with 1·00 in. or more during year	1	2

The differences which occur at stations in the same locality but with widely different rainfall are illustrated by a comparison of the daily falls made at Ben Nevis Observatory and those made at Fort William at the foot of the mountain, and only about 4 miles away in a horizontal direction. The mean values are set out below :

MEAN ANNUAL NUMBER OF DAYS, 1885–1903.

Station Altitude (feet) Average Annual Rainfall (inches).	Ben Nevis. 4405. 159.	Fort William. 31. 78.
	days.	days
0·01 in. or more	263	244
0·50 in. or more	106	52
1 in. or more	53	15

Although the total rainfall at Ben Nevis is twice that at Fort William, the number of rain-days is practically the same. Rain falls, however, much more heavily on Ben Nevis, so that the number of days with larger amounts is much greater. At Fort William the 52 days with 0·50 inch or more contribute 62 per cent. of the rainfall, and at Ben Nevis the 106 days contribute as much as 82 per cent. of the total rainfall.

Another important consideration is whether more rain falls during the day than at night.

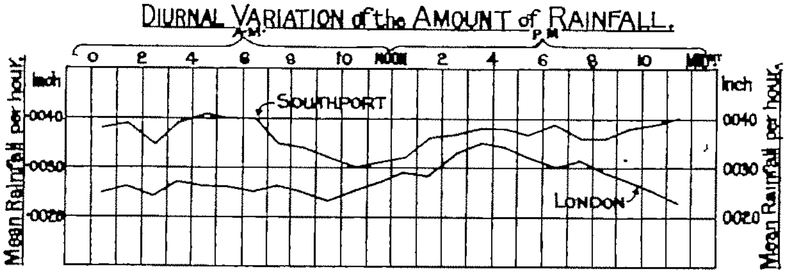

FIG. 2.—Comparison of mean hour values of rainfall.

Precise information from the traces of recording instruments covering a long period has been published at various times for some thirteen stations. Actually the total amount of rain during the day and night at these stations (that is, dividing the day at 6 A.M. and 6 P.M.) is practically identical. The proportion during the day varies at the individual stations from 52 per cent. to 48 per cent. of the total rain. More rain falls at night at stations in the west, for example, Valentia (in the west of Ireland), Falmouth, Southport, Glasgow, and Bidston (in Cheshire), while the inland stations and those to the east give more during the day. At Camden Square (London) there is a slight excess of rain in the day, and this holds good throughout the summer, but there is a reversal of these conditions in the winter, when the rain is greater at night.

Holiday resorts along the west coasts have therefore a slight natural advantage during the summer over those along the well-advertised 'dry east coast.' The actual mean hourly amounts are shown in the diagram for two typical stations, London and Southport, with 52 and 48 per cent. of the total rain in the day respectively. At the former there is a definite maximum in the afternoon, with a minimum between 9 and 10 in the morning, typical of inland stations, and a subsidiary maximum of midnight. At Southport, the early morning maximum usually found at coast stations is well marked, while there is a subsidiary maximum in the late afternoon. As recording rain-gauges are comparatively rare, and as the generalisations set out in the diagram alone involve more than half a million tabulations, it is not surprising that the complete story of the diurnal variation of rainfall has not yet been written.

Obituary.

Prof. Antonio Abetti.

On Feb. 20 there passed away at Arcetri, Florence, aged eighty-two years, after a short illness, Prof. Antonio Abetti, the *doyen* of Italian astronomers. Born at Gorizia, in Frioul, in 1846, he took his degree in mathematics at the University of Padua in 1867, and at once entered the astronomical observatory of that city, rendered famous, like that of Pisa and Florence, by Galileo Galilei. As assistant to Prof. Santini, then director, he was one of the Italian astronomical party of 1874 for observing the transit of Venus in India. After Santini's death, he collaborated at Padua with Prof. Lorenzoni and went to Florence in 1893 as director of the Arcetri Observatory, the reorganisation of which, begun by Donati, he completed, raising it, as the Institute of Astrophysics, to one of the most important in Italy. He remounted Amici's famous equatorial and did important work in the study of the minor planets or asteroids, on which he published numerous papers.

On reaching the age limit in 1921, Abetti retired and was succeeded by his son, Prof. Giorgio Abetti, who, trained at Arcetri and under Prof. G. E. Hale at the Mount Wilson Observatory, California, installed at Arcetri the 'Galilei Sun Tower' as an Italian replica of the Mount Wilson Tower. The Arcetri Astrophysical Tower and Institute were described by the present writer in *Engineering* of April 30, 1926. Prof. Antonio Abetti kept up his interest in the institute until a few days before his death. In 1901 he delivered at the opening of the Royal University of Florence an important inaugural address on "Galileo in Arcetri." His son and successor, Prof. Giorgio Abetti, was a member of the astrophysical section of the De Filippi Expedition, 1913–14, to Trans-Himalaya, the Karakoram, and Chinese Turkestan.

C. Du Riche Preller.

We regret to announce the following deaths:

Prof. Launcelot Harrison, Challis professor of zoology in the University of Sydney since 1922 and president of the Linnean Society of New South Wales, on Feb. 20.

M. Félix Henneguy, professor of comparative embryology at the Collège de France, Paris, since 1900, and president for five years of the Société de Biologie, aged seventy-seven years.

Dr. J. M. Hulth, principal librarian of the Royal University Library, Upsala, known for his "Bibliographia Linnæana," of which the first volume was published in 1907, on Mar. 29, aged sixty-two years.

Mr. G. P. Miln, for more than forty years honorary secretary of the Chester Society of Natural Science, Literature, and Art, and a trustee of the National Institute of Agricultural Botany, on Feb. 14, aged sixty-six years.

News and Views.

The announcement in the House of Lords on Mar. 29 of the names of the committee on motor spirit containing lead tetraethyl will doubtless serve to quiet somewhat the public controversy over the possible dangers of this spirit. The committee includes distinguished representatives from the fields of medicine, physiology, and chemistry, whose names and reputations are such as to carry the greatest possible weight with the public. The report of the committee will be awaited with interest and confidence. The following are the terms of reference: "To inquire into the possible dangers to health resulting from the use of motor spirit containing lead tetraethyl or similar lead-containing compounds, and to report what precautions, if any, are desirable for the protection of the public or of individuals in connection with the use or handling of such motor spirit."

It is a matter of regret that in the discussion of ethyl petrol, both in the Press and in the House of Lords, incorrect and misleading statements have been issued through lack of correct information. Thus such statements that the *use* of the spirit (instead of sale) is prohibited in New York City and in the Holland Tunnel under the Hudson River are entirely incorrect; while the reference to deaths by poisoning with lead tetraethyl in the United States in 1924 are misleading, since these fatalities occurred in the experimental manufacture of lead tetraethyl and had nothing to do with the use of the substance in motor spirit. On the contrary, there was read in the House of Lords a letter from the Surgeon General of the United States to the British Ministry of Health, stating that "notwithstanding the late publicity given to the investigations and the general use of the substance all over the United States and Canada, no instance of lead poisoning has been reported in the lay or medical press or to any of our Federal or State Authorities." Final decision, of course, rests with the Government committee, but while awaiting its report, it would appear that the above letter should at least lessen the fears of the extreme alarmists.

A committee including the names of the leading physiologists of Great Britain, and also two from the United States, has been formed to issue an appeal for funds to commemorate the work of those great partners in physiology, Bayliss and Starling. This partnership lasted for about thirty years and was fruitful beyond measure for physiology and its applications to medicine; in addition, it has made the name of University College, London, known throughout the world. Their written works are monuments to their industry and learning, but it is felt that a further memorial, in the form of a studentship in physiology, is necessary, and in this form would have been approved by Bayliss and Starling themselves. It is proposed, therefore, to create a Bayliss and Starling studentship at University College, open to any graduate in science or medicine, for a year or more of such training in physiology and biochemistry as would fit him for research. A small part of the funds collected may be devoted to a simple memorial tablet in the entrance hall of the Institute of Physiology at University College. Subscriptions should be sent to Prof. Lovatt Evans, Institute of Physiology, University College, Gower Street, London, W.C.1.

Dr. A. W. Hill, Director of the Royal Botanic Gardens, Kew, attended the annual meeting of the New Zealand Institute on Jan. 26 last, when he was elected an honorary member. In replying to the president's welcome, Dr. Hill thanked the Board for the honour conferred upon him, and remarked that he noticed among the roll of names of honorary members that of Mr. E. Meyrick, his old teacher at Marlborough College, who had been instrumental in directing his studies into the channel of nature study, and had been a source of much inspiration to him. He remarked that New Zealand possesses a remarkable flora, and promised that he would do his best while in the Dominion to further the idea of the establishment of a National Botanic Garden. In this direction he thought it might be advisable to have one section in Auckland and another in Dunedin, with a director to link the two together as a national institution, and thus to avoid any possible jealousies as had occurred in other countries. In the course of his tour of New Zealand, Dr. Hill climbed Aleck's Knob, in the glacier region, which has not previously been explored by a botanist. This necessitated a climb of 4200 feet, but the array of alpine plants on the meadow at the top repaid the exertion expended in the climb. The plants there were in striking contrast to anything available to European botanists. All the flowers were pure white. Beside the Ourisias, *Ranunculus Lyalli* and *Hebe* (*Veronica*) *macrantha*, there were Lilaepsis and *Caltha novæ-zealandica*, on which Dr. Hill is working in England. The size of these plants on their native heath surprised Dr. Hill, especially the large Celmisias, and he was also much interested in the native hybrid plants.

Warm tribute was paid by Dr. Hill to Dr. L. Cockayne, of the State Forest Service of New Zealand, for his work on natural plant hybrids. Dr. Cockayne was awarded the Mueller Medal for research work in New Zealand over a period of twenty-five years, at the meeting of the Australasian Association for the Advancement of Science, held at Hobart (Tasmania) in January last. The Royal Society of London recently allotted Dr. Cockayne £100 for research work on hybridisation, and on the flora and vegetation of New Zealand. Other scientific workers who have lately visited New Zealand include Dr. J. P. Lotsy, the Dutch botanist, who toured the country in 1925. It will be remembered that Dr. Lotsy, at the Leeds meeting of the British Association last year, discussed New Zealand plants and their hybrids. Dr. O. Olsen, of Oslo, has also visited New Zealand recently, and found during his visit of three months a fertile field for botanical, geological, and ornithological study, where 20 per cent. of the geological specimens are unknown to science. Yet another, Dr. G. Einar Du Rietz, of the University of Upsala, toured New Zealand, and was, by courtesy of the Government, afforded an opportunity of making a voyage round the islands (some uninhabited) south of New Zealand by the steamer that makes the rounds supplying lighthouses and replenishing depots for castaways by shipwreck. He expressed the belief that the high-mountain flora of New Zealand is the best subject in the world for study, and that the country is well suited for the establishment of original botanical species.

The concluding section of "The Oxford English Dictionary" is announced for publication on April 19. It is an event of capital importance for English scholarship and indirectly a matter of moment to all the world. English is the richest language man has ever framed, and the most widely used. The effect of the War has been to extend its vogue, and, as the two great English-speaking communities—the British Empire and the United States—are also the most powerful nations, it is inevitable that the use of English will spread still further in future. Another consideration makes the publication of this work of special importance at the present moment. English is the official language of India and also its accepted medium of higher education. In China, too, English is much the most familiar of European tongues. We may therefore look for a continued extension of some form of English throughout both those countries, which between them contain nearly half the human race; and, if English is to be used, it is essential that it retain some recognisable connexion with correct English as built up and spoken in the land of its birth. This cannot be done by means of English teachers, who are a diminishing quantity in India and still fewer in China. A standard and comprehensive work is therefore of the first importance, from which other and smaller books may be drawn for those who cannot enjoy the monumental original.

Fifty guineas is a 'long' price, and beyond any but fair-sized town libraries and large schools, yet it is not out of proportion to what has been expended on the production of the work. The Oxford Press alone has spent £300,000, and this takes no account of the unpaid labour on which the book was based. All the collectors of the original references were volunteers, scattered over Great Britain and elsewhere. Work of this sort has been going on for nearly seventy years since the dictionary was first thought of by the

Philological Society. In 1884 the Oxford University Press assumed the responsibility, after Sir John Murray had met the Delegates of the Press in 1878 and become charged with the editorship. It is as much a monument of his zeal, industry, and organising powers as it is of the English language itself. Already supplements are beginning to appear, containing words, many of them dealing with science and technology, which have won the rights of citizenship since the work began. Of these supplements, at least the first will be furnished gratis to purchasers of the whole book.

THE recently issued *Annual Report* of the British Research Association for the Woollen and Worsted Industries provides concrete evidence of the increasing attention which the fundamental scientific principles underlying the wool textile industry are receiving both in Great Britain and overseas. In an article on "Research in the Textile Industry," which appeared in NATURE of Nov. 19 last, attention was directed to the fundamental problem of the textile industry, namely, a complete knowledge of the properties of the wool fibre, and a definite measure of the 'quality' of the fibre. The importance of this matter, not only to Great Britain, but also to wool growers in the dominions overseas, has been recognised and, as a result, the Under-Secretary for the Colonies has approved the recommendation of the Empire Marketing Board that a grant should be made for the prosecution of research on the problems connected with the standardisation of raw wool. This research will be undertaken jointly by the Research Association and by the Animal Breeding Research Department of the University of Edinburgh Other important activities of the Research Association include the determination of standard tests for fastness of dyestuffs, particularly with a view to the prescription of standard tests for fastness to light, washing, and perspiration. An investigation into the determination of a suitable branding substance for sheep is in progress, but the final results are not yet available. The Association is availing itself on a very considerable scale of the existing research facilities in the universities and similar institutions. A mass attack of this kind on the many problems of the textile industry should ensure real progress in the application of science to that industry.

IN our issue of June 11, 1927, p. 864, reference was made to a small booklet published by Mr. E. A. Chapman, 69 Hayter Road, London, S.W.2, on certain so-called "Mystery Pearl Shells" which were in his possession. Various opinions had been expressed as to the origin of these shells, and Prof. Dakin, who examined them at our request, concluded that they had been cleverly cut from large pearl shells. In any event, however, their history (they came from Ireland) was left unexplained. At the request of Mr. Chapman another booklet has been written, and has been published by him in explanation of the previous one. It bears the title, "A Short History of a Notable Irish Family," and is by P. C. Gallagher (formerly of University College, Dublin). The pamphlet, which is very beautifully illustrated, suggests that the shells, which appear to have been heirlooms, were handed down in the O'Donnell family from a certain Hugh Roe O'Donnell, a brilliant figure, chieftain of Tirconnail and King of Donegal in the time of Elizabeth. We are not in a position to comment upon the historical details involving the O'Donnell family, but it is quite conceivable that the shells came originally from a Spanish source, as the booklet suggests, and that they were presented long years ago (possibly by some wrecked member of a Spanish ship) to this Irish family. It seems curious that others are not known to exist, unless these were the only result of some capable carver's whim. If they are shells of some real species, one would expect still more to find specimens in some of the world's museums. The whole matter is surprising.

AUTOMATIC operation of electrical equipment has in several cases made it possible to dispense, at least for a certain period, with human agency entirely. For example, lights on buoys are sometimes operated by a selenium cell, the flow of current through which is regulated by the light falling on it. When darkness comes the alteration in the resistance of the cell, and consequently of the current, switches on the light, and when daylight breaks, switches it off. Similarly, the action of some fire alarms depends on smoke affecting the amount of light falling on the cell. According to a recent *Daily Science News Bulletin*, issued by Science Service of Washington, a somewhat analogous automatic control was used recently to unveil a portrait of George Washington. All that was necessary to perform the operation was to telephone a certain signal. The apparatus used, called a televox, depends upon a device that only responds when a sound of a definite maintained frequency is made. The televox is tuned to a certain note produced either by a tuning-fork or a whistle. When this note is sounded, the movable armature of an electromagnet makes a contact which completes a local circuit. The current in this local circuit may start a motor, turn on or off a light, or do any similar operation. By having several instruments, each with its relay, a complicated mechanical operation can be gone through by sending a series of different notes which may, if desired, be so chosen that they form a tune. Experiments have been made for many years on controlling motor-cars and aeroplanes by radio waves. The televox system, however, is to control by sound.

THE London School of Hygiene and Tropical Medicine has placed an order with Messrs. R. and J. Beck, Ltd., for more than two hundred microscopes for use in the new laboratories now in course of construction in Gower Street. The order has been given on the recommendation of a small committee which has had the matter under consideration for some time, in consultation with the Department of Applied Optics, National Institute for Medical Research. The type of microscope selected embodies certain features that have been evolved to meet the needs of the heads of departments at the School. The base is of rigid construction, with points of support sufficiently wide spread to ensure stability in any position. The foot is of the type now being produced by Messrs. Beck, combining the advantages of the horse-shoe or Continental model with the so-called English foot. The stage is of the completely built-in mechanical type with travel of 1¼ in + 1 in., the entire top plate of the stage forming the moving part. On the stage a slide-holder of new design is provided, as suggested by Prof. Topley, in which the slide is firmly held without springs. The fine adjustment is of the double lever pattern, operated by milled heads on either side. The body is 2 in. in diameter and is provided with an adjustable graduated draw-tube. The sub-stage is actuated by rack and pinion, and all sub-stage appliances are carried on Akehurst slides. Thus the interchange of illuminating systems is both easy and accurate. The optical equipment is ample for all bacteriological requirements, and the objectives are to be coloured externally so as to enable them to be recognised at sight. Messrs. Beck have agreed that certain rigid tests shall be applied to the whole equipment before delivery is accepted.

We have received a copy of the "Descriptive Account and Catalogue of the Home Office Industrial Museum and Exhibits," recently published by H.M. Stationery Office. In the introduction it is explained that the Museum, which is situated in Horseferry Road, Westminster, is intended to serve as a permanent exhibition of methods, arrangements, and appliances for promoting the safety, health, and welfare of industrial workers. The exhibition is the first of its kind in Great Britain, though others exist in Berlin, Munich, Milan, Amsterdam, and other cities abroad. The exhibits may be classified under three main headings. The safety section contains actual machines, plants, and appliances as they would be installed in a factory. Many actual protective devices are shown, but a wider range is exhibited by the aid of models and photographs. In the health section the exhibits include photographs illustrating the prevention of various industrial diseases (lead poisoning, silicosis, dermatitis, etc.), charts indicating the incidence of such diseases, 'cautionary notices' as issued by the Home Office, etc. Two sections are devoted specially to ventilation and lighting—the latter including an excellent series of cabinets illustrating fundamental principles. The welfare section contains rooms fitted up to serve as ambulance rooms, rest rooms, and canteens, and first-aid equipment, protective clothing, etc., are shown. The catalogue contains a detailed account of all exhibits, with illustrations. Various sections, such as machine tools, drilling and milling machines, and machinery used in the textile and printing industries, in bakehouses, etc., are dealt with in turn. Finally, reference may be made to the nature of the building, which in itself serves as a useful exhibit, special attention having been devoted to the ventilation, lighting, and other essentials to health and safety.

The Easter conference of the Society for Experimental Biology took place at Oxford on Mar. 23 and 24. By kind invitation of Prof. E. S. Goodrich and Prof. A. G. Tansley, meetings were held in the Zoological and Botanical Laboratories. At the first session, among many interesting papers, Mr. G. R. de Beer gave an account of his experiments on the development of the nervous system in Anura, and a paper by Dr. T. A. Stephenson on the nature of 'physiological' species was followed by a lively discussion. Discussions of considerable interest also took place during the second session, particularly after a paper by Mr. P. A. Buxton on the physical factors which determined the behaviour of the mosquito. In a paper by Captain G. C. C. Damant on the secretion of gases in the bladders of seaweeds, the remarkable fact appeared that nitrogen as well as oxygen was secreted into the bladders under a considerable pressure. The last session was occupied chiefly with discussions of the nature of oxidation in living cells and carbohydrate metabolism in various groups of the animal kingdom. The chairman, Dr. D. Keilin, gave an account of the polyphenol oxidase and cytochrome system in cells.

A useful pamphlet on "Rats and how to kill them" has been compiled by Mr. A. Moore Hogarth (London: John Bale, Sons and Danielsson, Ltd., 6*d.* net). It reprints the Rats and Mice (Destruction) Act of 1919, and gives full instructions for trapping, poisoning, fumigating, or otherwise destroying rats. These instructions are practical and ought to increase the effectiveness of the anti-rat campaign. But it can scarcely be said that all the author's suggestions are practical: he advocates that rat-catchers should be taught, amongst much else, elementary pathology; that zoological laboratories in the universities should devote part of their time to the economics of the rat; and that elementary school children should be instructed in rat life-history and the "toxicity of the various raticides in common use." He speaks of the barn owl as if it were the only ratter of its kind, of the pine-marten as if he did not know that it was almost extinct, and of the ferret as if it were a wild creature. With more reason he advocates an international codification of rat laws, a synchronised rat campaign in Britain twice a year, and local bye-laws to encourage rat-proofing. He states that the cost of feeding British rats per annum would pay for 1,864,235,290 bottles of Bass—a less offer in kind should attract a record army of Pied Pipers.

Sir John Russell, Director of the Rothamsted Experimental Station, has been elected an honorary member of the New Zealand Institute.

Prof. G. Elliot Smith will deliver the Huxley Memorial Lecture at the Royal College of Science, South Kensington, on Friday, May 4. His subject will be "Conversion in Science."

It is announced in *Science* that the Charles P. Daly Gold Medal of the American Geographical Society of New York has been presented to Prof. Alois Musil, of the Charles' University, Prague, for his explorations in northern Arabia and Mesopotamia and his historical researches relating to this part of the world.

Dr. E. F. Armstrong, managing director of the British Dyestuffs Corporation, Ltd.; Dr. J. B. McEwen, Principal of the Royal Academy of Music; and Prof. R. W. Seton-Watson, Masaryk professor of Central European history in the University of London, have been elected members of the Athenæum, under the provisions of Rule II. of the Club, which empowers the annual election by the Committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public service."

In April of last year the eighth annual meeting of the American Geophysical Union was held, like its predecessors, at Washington. The transactions of the Union at this meeting have been issued as a *Bulletin of the National Research Council* (No. 61, pp. 295). The Union met usually in six sections, but one resolution passed in general assembly may be noted: since it appears that, in future, reports of much of the seismological work done in Japan will be published in Japanese only, the National Research Council was requested to provide (1) for the translation into English of such reports as are selected for the purpose by the American Geophysical Union, and (2) that mimeographed copies of the translations be distributed under suitable financial arrangements. The reports and papers dealt with in the sectional meetings include many of great interest. Three general symposia were held, one on climatic control, another on the sun's ultra-violet light and the ozone content of the earth's atmosphere, and a third on correlations of various radio phenomena with solar and terrestrial magnetic and electric activities.

Applications are invited for the following appointments, on or before the dates mentioned:—A secretary of University College Hospital Medical School—The Dean, University College Hospital Medical School, University Street, W.C.1 (April 18). A technical officer at the Royal Aircraft Establishment, South Farnborough, to assist in design and experimental development work in connexion with aerial beacons and aerodrome illumination generally—A.271, The Chief Superintendent, Royal Aircraft Establishment, South Farnborough, Hants (April 21). A professor of mechanical engineering in the Engineering College of the Benares Hindu University—Box P4360, 33 Norfolk Street, Strand, W.C.2 (April 30). An assistant lecturer in physics at the University College of the South-West of England, Exeter—The Registrar. A mathematical master, able to teach elementary physics and chemistry, at the Prince of Wales' Royal Indian Military College, Dehra Dun, U.P., India—The Secretary, Military Department, India Office, S.W.1. A junior assistant chemist under the Directorate of Explosives Research of the Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

Search for a Planet outside Neptune.—Ever since the discovery of Neptune by the perturbations that it produced on Uranus, attempts have been made to extend the method to still more remote regions. Prof. W. H. Pickering is one of those who have attacked this problem; in his research he examined the observations of Saturn, Uranus, and Neptune, and noted discordances between prediction and observation. His latest paper on the subject is in *Popular Astronomy* for March. He notes that if Adams and Le Verrier had used Saturn as well as Uranus in their calculations, they would have had material for making a better estimate of the distance and period of the perturbing planet; the reason being that conjunctions of the unknown planet with Saturn occurred every 36 years, so that the observations covered several conjunctions.

Prof. Pickering gives the shape that the curve of residuals should follow about the time of conjunction of each planet with an external perturbing one. He finds some evidence of conjunction of the unknown with Neptune about 1906, with Uranus about 1841, with Saturn about 1850, 1885, 1917. He finally assigns to the unknown the same period as Neptune, 164·8 years, but a more eccentric orbit. He makes aphelion passage about the year 1891, in longitude 72°. The present position of the planet is given as R.A. 8 h. 51 m., N. Decl. 16¼°; mass about half that of the earth, magnitude 12. When in opposition it would retrograde at the rate of 4″ or 5″ per hour, sufficient to show a short trail on photographic plates. Whether the planet is there or not, the investigation seems sufficiently ingenious to be worthy of notice.

Spectroscopic Parallaxes of 125 *B*-type Stars.—Mr. D. L. Edwards has been engaged for some years in deducing spectroscopic parallaxes of *B*-type stars at the Norman Lockyer Observatory. *Mon. Not. R.A.S.* for January contain his fifth paper on the subject. The research is much more difficult than in the case of stars of late type. Two methods are employed: (1) photometric measures of the intensities of certain hydrogen and helium lines by means of a wedge; (2) classification based on spectral type and line character. Standard stars of well-determined parallax were observed in order to check the curves used for converting measures into absolute magnitudes. The magnitudes of the stars in this paper range from 0·6 (Achernar) to 6·9. The absolute magnitudes range from −3·4 (α Camelopardalis) to +0·1 (γ Cassiopeia). The largest parallaxes are Regulus 0·060″ and Achernar 0·040″.

Minimum of ε Aurigæ.—This star, of spectral type *F5p*, the light of which varies between 3·3 and 4·1, is now approaching minimum, which is predicted to last about 700 days. It is an appropriate time for publishing an elaborate study of its spectrum, which Miss Cecilia H. Payne does in *Harvard Bulletin 855*, basing it on five plates, ranging in date from 1890 until 1927; last year's plate was standardised by comparison with the hydrogen lines in the spectrum of Vega, and it served to calibrate the other four. A list is given of the wave-length, origin, and intensity of about 170 lines. Certain iron lines are found to be suitable for the determination of absolute magnitude. The following absolute magnitudes of stars of this type are given: Procyon 3·1, α Persei −1·3, *b* Velorum −2·5, ι Scorpii −2·8, ε Aurigæ −4·0. This last star is therefore a supergiant at a distance of more than six hundred light-years. Miss Payne notes that search should be made during minimum for possible spectral changes.

Research Items.

DUALISM IN AFRICAN RELIGIONS.—In *Ancient Egypt*, pt. 4, 1927, Mr. G. W. B. Huntingford contributes some further notes on the dualism which can be observed in the various forms of African religions. In the Nilo-Hamitic group the good and evil gods are manifestations of the elements. The Galla, in addition to their god *Wak*, believe that there are two kinds of sunshine, *adu* the white, which destroys, and *biftu* (from *bifti*, colour), the good, which gives life. *Adu* is from the same stem as *adi*, a fabulous being white in colour, apparently a kind of Ἔμπουσα. The black and red gods of the Masai are the heavens in fine weather and in storm, or rather in dry and wet weather. The Nandi do not distinguish the good and bad thunder by colour. The Hottentot beliefs are contrasted. According to Kolben, they have two good deities and one bad, the "God of all Gods," the moon, and the "Father of all Mischief." The Galla, Masai, and Nandi pairs of gods are additional to their supreme god and do not come within their ceremonial system. The beliefs in good and evil forces in opposition may be divided into three groups: (1) Where the forces are the elements and subordinate to the chief deity, as among Galla, Masai, and Nandi; (2) where the forces are spirits, as among the Baganda, Azande, and Lugwari; and (3) where the worship is that of a trinity, the third member of which is evil, as among the Hottentots. It would appear, therefore, that dualism in East Africa is not limited to tribes of Hamitic speech as has been thought. The fact that the same colours appear as attributes of good and evil in other parts of Africa is perhaps a coincidence; though the opposition of red and black which appears on the Gold Coast is singular. Among the Galla the unlucky colour is white.

THE CART TRACKS OF MALTA.—Following closely on Miss Murray's communication to *Man* (see NATURE, Feb. 25, p. 297), Prof. Zammit has published in *Antiquity* for March a study of the cart-tracks of Malta, illustrated by a number of excellent air photographs. His conclusions as to the origin, purpose, and date of these ruts or deep grooves on the limestone, which are of such frequent occurrence in the island, are the result of a long and exhaustive examination. There can be little doubt that they were made by a wheeled vehicle—strong, heavy carts with wooden wheels without metal tyres. The sharp curves preclude the idea of a sledge with runners. They are triangular in section, and can easily be distinguished from the grooves, rectangular in section, made by the modern metal-tyred wheel. Further, it must be concluded that human power was used for traction, as the ancient ways show no sign of being cut up in the way in which modern tracks have been cut up by the hooves of animals. It is also probable that the tracks were started by human labour and deepened later by use. There are definite signs that they were first carefully laid. In only one case does a pair of tracks appear to enter the sea, namely, at the Bay of St. George at Birzebuggia, where they probably appear on the other side of the bay now covered with silt and field soil. There is nothing to suggest the existence of these tracks when the island was connected with the continent, quite independently of the fact that the islands could not have been inhabited by an industrial population at the end of the Ice Age. Nor are they so late as the Roman occupation. Further, they are earlier than the rock-cut tombs of the Phœnician occupation, one of which cuts right across one of the cart tracks. As they do not go near the megalithic monuments they were not used for carting stone for these buildings. They were used by the energetic neolithic population for carting earth for their terrace cultivation made necessary by the bare character of the high lands and for carrying water to the ships of a busy maritime traffic in harbours near which were no springs.

PREPARATIONS OF VITAMINS A AND D.—We have received from Messrs. The British Drug Houses Ltd., London, N.1, samples of their "Radiostoleum" capsules. The oil in these gelatin capsules contains vitamins A and D: the latter is manufactured by irradiation of ergosterol, and together with a vitamin A concentrate is supplied in solution in a tasteless vegetable oil. No cod-liver oil is used in the preparation of this product. The vitamin A and D content is standardised by animal feeding tests and is twenty times that of the finest cod-liver oil: and in the case of vitamin A, the physiological assays are checked by a chemical test. 'Radiostoleum' may be used in all conditions in which cod-liver oil has hitherto been administered. It is supplied in capsules, in boxes of 50, and also in solution, in bottles containing half a fluid ounce.

THE NATURAL HISTORY OF THE HAKE.—In *Min. Agric. Fish., Fishery Invest.*, Ser. 2, vol. 10, No. 2, 1927, Mr. C. F. Hickling gives an account of the food and feeding of the hake, and of the periodic changes in the hake fishery. This paper is of especial interest, as it is based on observations made and experience gained during fourteen months of sea-time on commercial trawlers, and is illustrated to a considerable extent by statistical data supplied by the Ministry's Statistical Section. From a study of the weekly figures of landing of hake at Cardiff during the years 1922–25, it appears that from the fifth to the ninth full moons of the year there is a regular fluctuation in the landings, such that more fish is landed at full moon than at new moon. Mr. Hickling suggests that this is the result of a monthly period of activity in the reproductive organs of the fish. There is also a daily change in the abundance of hake on the sea-bottom. Long experience has taught skippers that there is so little hake on the sea-bottom during the hours of darkness that it is rarely worth while to trawl at night, especially when the hours of darkness are long, as in winter. This apparent nightly migration vertically from the sea bottom is believed by the author to be due to a 'sleep rhythm' in the fish, which is inactive by day but active by night. In support of this theory, it is pointed out that (*a*) it can be shown that the hake feeds at night, but apparently not during the day, and (*b*) the surface methods of catching hake, which are most successful at night, depend upon the hake seizing a hook or becoming entangled in stationary trammel-nets, whereas the method of catching hake on the bottom, which is most successful by day, depends upon the hake being swept along passively into a trawl which may be moving very slowly relatively to the hake's own presumed speed of locomotion.

LEECHES ON FISHES.—Mr. David H. Thompson ("An Epidemic of Leeches on Fishes in Rock River," State of Illinois Department of Registration and Education. Division of the Natural History Survey. Bulletin, vol. 17, art. 3, 1927) describes an epidemic of leeches in the fish *Ictiobus cyprinella*, the so-called 'red-mouth buffalo.' In the winter of 1925–26 almost every fish of this species in Rock River, near Rockford, Illinois, was infested by the leech *Pisciola* *punctata* Verrill, from one to fifty on each fish. This leech was rare, and for two years of continuous work on the river during the handling of fish, had not been seen. It appeared quite suddenly in February when the river was covered with ice, and continued throughout March until the temperature was a few degrees above freezing-point over a stretch of twenty miles. By the end of April none was to be seen. The leeches were so numerous that the bottom of the boat in which had been a few hundred pounds of fishes was almost completely covered with them. The next winter at the same time, although several fishes were infested, the numbers were not nearly so great as to cause an epidemic. After the leeches had left their hosts they were found among water plants, where they apparently leave their egg cocoons. The young leeches attach themselves to the fishes, at first feeding on mucus, later on blood, and grow to maturity very quickly in the cold winter months. The leech is said not to harm its host, but in this case they were certainly harmful, as is shown by the large marks left on the fishes in the places of attachment, and also by the fact that the fishes with many leeches were so thin that they were quite unfit for food. This is the first time that this leech has appeared in sufficient quantities to affect the market, and no reason can be brought forward for its presence in such enormous numbers.

STARCH AND CAMBIAL ACTIVITY IN THE WOODY TWIG.—Swarbrick has recently directed attention to the complexity of the problems associated with the appearance and disappearance of starch in the woody twig (*Journal of Pomology and Horticultural Science*, 6, 296-312; 1928). Curtis has previously drawn conclusions as to the necessity of phloem for translocation from the retention of the starch in a region of the stem isolated between two rings made down to the cambium (*American Journal of Botany*, 7, 101-124; 1920). Swarbrick now shows that the retention of this starch depends upon the absence of buds in the region lying between the rings and is associated with the absence of cambial activity under these conditions. If buds are present, then cambial activity is initiated in this region and the starch quickly disappears. Experience with disbudded twigs, upon which an occasional adventitious bud regenerates, shows that, whilst a limited amount of cambial activity and xylem formation is found below this bud and nowhere else on the twig, starch hydrolysis begins below this bud and then continues throughout all the tissues of the twig below this bud. In this case starch disappearance seems rather dependent upon cambial activity than the latter upon the food reserves, and both seem to be connected with the initiation of bud development.

WOOD-PULP IN AUSTRALIA.—When ground wood or mechanical pulp was first introduced, the paper industry received considerable impetus in countries where soft wood was easily obtained, and the later development of the sulphite process, or the chemical conversion of wood to pulp, brought about an even greater expansion. In Australia, however, the industry has developed slowly, for owing to the absence of suitable indigenous material, nearly all the pulp has had to be imported. Experiments have been carried out (*Australian Journal of the Council for Scientific and Industrial Research*, vol. 1) with the view of utilising indigenous eucalypts, etc., in order to establish the industry on an independent footing. It has been found that by employing certain modifications of the soda process a pulp suitable for the important type of papers classed as 'book and fine printings' can be produced from the eucalypts. The quick-growing candlenut *Aleurites moluccana* is also promising, but since the pulp is bleached with some difficulty, it is recommended for use in the manufacture of brown paper. There seems little prospect of being able to utilise the indigenous grasses or sedges. With regard to other methods of pulping, the sulphate process has hitherto been considered uneconomic in Australia, but it is of great importance in the production of strong (kraft) pulp. Laboratory and mill trials, however, have shown that it can be successfully used with exotic conifers such as *Pinus insignis*, the results comparing favourably with the pulp from spruce or firs, for which the climate is unsuitable. The possibility of producing a long-fibred sulphite pulp is still under investigation. It is hoped that in this case also *Pinus insignis* will prove suitable, or that the process can be so modified as to allow of its use, in the event of which the paper industry in Australia would be almost self-contained. Further, trials are in progress regarding the manufacture of newsprint from short-fibred eucalypts instead of from the longer fibred spruce and fir. Under special grinding conditions, immature eucalypts have yielded very promising results on a laboratory scale, a paper stronger than the standard newsprint being obtained.

ARCTIC ICE IN 1927.—The *Annual Report* by the Danish Meteorological Office on the state of the ice in Arctic Seas in 1927 has recently been published. In the Barents Sea the most noteworthy features were the congestion of ice off the entrance to the White Sea from March until May, and the open sea up to Franz Josef Land in September. The west coast of Novaya Zemlya was clear in July, and the Kara Sea was almost clear in August and quite clear in September. Around Spitsbergen there was much less ice than usual, except in October and November, when a broad belt of pack lay off the west coast. Bear Island, however, was not clear of ice from the autumn of 1926 until the end of May. On the east coast of Greenland the belt of ice seems, on the whole, to have been wider than usual, but the coasts of Iceland were free throughout the year. In Davis Strait there was less ice than usual, and on the Newfoundland Banks the ice season was short and had ended entirely by August. In Baffin Bay and the channels of the Canadian Arctic Archipelago, ice was scarcer than in most years. Davis Strait was almost clear in July, but Wrangel Island was not approachable until August. The report is furnished with the usual ice distribution charts for the spring and summer months.

THE TASMANIAN TEKTITES.—Sir Edgeworth David, Dr. H. S. Summers, and Mr. G. A. Ampt have made a very valuable study of the remarkable variety of tektite known as Darwin Glass (*Proc. Roy. Soc. Victoria*, vol. 39, pp. 167-190; 1927). The mode of occurrence in what are probably outwash gravels from a Pleistocene ice sheet suggests that a 'hailstorm' of small meteorites fell on the ice, which transported the fragments to the margin. It is shown that the schonite of Sweden, the moldavites of Moldau, the billitonites of Banca, Billiton, and Borneo, the australites of Australia, and the Darwin glass of Tasmania, all occur close to a single great circle. By means of variation diagrams, the genetic relationship between the various tektites is convincingly brought out, and a comparison of the graphs with those for the common acid igneous rocks indicates that the latter are quite distinct in composition. Two fresh analyses of Darwin glass are recorded; they show 86-87 per cent. of SiO_2. Such a percentage is higher than that for any analysed australite, but is approached by some of the moldavites. Various hypotheses of the origin of tektites

—artificial, volcanic, fulguritic, dust fusion by lightning, etc.—are discussed, and by a process of elimination the conclusion is reached that the mysterious fragments are of meteoritic origin.

MAGNETIC MEASUREMENTS.—The September and December (1927) quarterly issues of *Terrestrial Magnetism and Electricity* have recently appeared together under one cover (103 pp.). The principal article is one on earth-resistivity measurements in the copper country, Michigan, by W. J. Rooney, in which interesting details are given of the survey, which proved very successful in locating bodies of copper ore, as tested in cases where direct data obtained by boring were available. The conditions under which magnetic methods of prospecting for underground discontinuities are likely to be of service are discussed. The journal contains also many reports, reviews, and short articles, one of the latter being on magnetic observations made in Spitsbergen in 1927 by a Cambridge expedition, while others deal with questions of computation. In an article by D. Stenquist on the diurnal variation of the normal earth-current in southern Sweden, attention is directed to the fact that in his memoir "Étude des courants telluriques," 1925 (see also NATURE, Feb. 18, p. 242), the values given on pp. 21-23 of that paper are ten times too great.

DEVELOPMENT OF NATURAL GAS.—On Mar. 13, Col. S. J. M. Auld discussed before the Institution of Petroleum Technologists some of the more complex problems affecting natural gas exploitation. Facilities for utilising the gas produced either simultaneously with oil at the well-head, or afterwards by evolution by reduced pressure, vary to some extent with the environment of the field, *e.g.* climatic conditions, and in many limestone fields, such as parts of Texas, Mexico, and Persia, the matter is complicated by the presence of hydrogen sulphide, sometimes exceeding 10 per cent. by volume. The author dealt with a type of gas-oil separator designed for high gas-oil ratios, most proprietary types being more suited to conditions of low gas-oil ratios. The measurement of quantity of gas released was next considered, various standard equations coming up for critical analysis and comment. Equally important is the duration of gas production and, as pointed out, accurate estimates of reserves are always problems of great difficulty; much depends on the gas-oil system involved, and on the degree to which calculations based on gas laws are applicable in particular cases. An interesting section of the paper dealt with the use of highly sulphurous gas as a fuel which, contrary to expectation, results in no serious trouble with modern boilers equipped with efficient methods of firing. It was also shown by experimental data that the active charcoal recovery process is inapplicable to sulphurous gases; in view of recent interest abroad in the possible use of solid adsorbents for gas extraction and gasoline stripping from such extracted gas, this conclusion is not without significance. The author also discussed many of the conditions affecting the oil absorption process for gasoline extraction, and urged the importance of efficient operation depending on knowledge and application of the gas laws.

METEOROLOGICAL INSTRUMENTS.—The latest instrumental catalogue (No. 548) of Messrs. C. F. Casella and Co., Ltd., gives particulars of a wide range of meteorological instruments. We notice that the various types of cup anemometer do not include any with three instead of four cups, nor is there a cup instrument designed to give direct readings of velocity instead of the number of miles of air that have passed the instrument since its erection. The advantages of having only three cups have been proved experimentally by J. Patterson of the University of Toronto, who published his results about two years ago (*Trans. R. Soc. Canada*, Third Series, vol. 20, Sec. 3; 1926), and the *Meteorological Magazine* for September last contains a photograph of such an anemometer adapted for direct reading by the incorporation of a Stewart magnetic speedometer. It is to be hoped that an instrument of this kind will appear in the next catalogue. Accurate thermometry continues to be an expensive matter. It is, however, possible to purchase an outfit of thermometers—maximum, minimum, 'wet and dry'—with a rain gauge, and with a screen that should give good results if properly mounted, for £7. This outfit is designed for schools. A very handy pocket set, with maximum and minimum, as originally designed for Dr. Livingstone, costs £2 10s., and should continue to be in demand among explorers and mountaineers.

NEW SYNTHESIS OF NICOTINE.—The synthesis of an alkaloid generally involves the closing of a ring system containing a nitrogen atom. In the classical synthesis of nicotine, the molecule of which consists of a pyridine ring and an *N*-methylpyrrolidine ring linked together in the β-position to the former and the α to the latter, Pictet employed comparatively violent means to obtain the second ring system attached in the desired manner to the pyridine ring. The new and simple synthesis described in the February issue of the *Berichte* (vol. 61, p. 327) by E. Spath and H. Bretschneider, of the University of Vienna, is therefore very welcome. Prof. Späth employs the novel method of starting with both nitrogen ring systems already formed, in the shape of ethyl nicotinate and *N*-methylpyrrolidone. These compounds are condensed together under the influence of sodium ethoxide, and a ketone is obtained in which the two ring systems are separated by the carbon atom of the ketone group. There is a second ketone group present in the pyrrolidone ring, and by treatment of the compound with hydrochloric acid this group is removed as carbon dioxide. This opens the ring, which is, however, closed again by converting the first –CO– group into –CH(OH)– and thence into –CHI–, for removal of hydrogen iodide now draws the bridge carbon atom into the *N*-methylpyrrolidine ring to replace the carbon atom which had been lost, and (racemic) nicotine is at once obtained. The yields in the synthesis are good, that of the initial condensation being 70 per cent., that of the ring opening 37·5 per cent., and that of the complete ring closure to give nicotine 31 per cent.

RÔLE OF COPPER SULPHATE IN THE DEACON PROCESS.—The work of Hensgen and others has shown that many metal sulphates are decomposed by dry hydrogen chloride gas with the formation of chlorides and liberation of sulphuric acid. If this is the case, it would appear that when the Deacon process is started with copper sulphate as a catalyst, the mechanism is the same as when copper chloride is used. Experiments to test this view have been made by R. A. Beebe and D. B. Summers and are described in the January issue of the *Journal of the American Chemical Society*. Hydrogen chloride, both in the pure state and mixed with oxygen, was passed over pure anhydrous copper sulphate heated to 450° C. (the temperature used in the Deacon process) and the liberated sulphuric acid determined. In each case the sulphate was completely decomposed after several hours, and copper chloride, $CuCl_2$, or oxychloride, $CuO . CuCl_2$, remained. The use of copper sulphate initially in place of cupric chloride does not, therefore, seem to complicate the mechanism of the Deacon process.

Injury by Fire and Bark-beetle Attack.

ABOUT a quarter of a century has elapsed since bark-beetle infestations following fires in coniferous forests came under serious consideration outside European countries. The ideas and opinions then expressed, based admittedly on investigations which still had to stand the test of future corroboration, were at first treated with more or less open scorn by the professional forester both in the United States and in India, the two countries where attention was first paid to the matter. In the former country the commercial lumberer also regarded the scientific worker as a faddist. Of recent years, opinions have undergone a drastic change in both countries, and the present position and opinions held on this important subject are due to the patient work of the entomologist. In India, owing to the difference in climate in the plains, the matter is not confined to the coniferous forests of the mountainous regions, but has to be considered in its relation to the forests of broad-leaved deciduous species. The problem here, however, save perhaps in the native States, has not been complicated during the period alluded to above by the operations of the lumberer and his felling methods in the forest.

Recently two small but important monographs have been issued in the United States. The first, entitled "Preliminary Studies on the Relation of Fire Injury to Bark-Beetle Attack in Western Yellow Pine (*Pinus ponderosa*)," by Messrs. J. M. Miller and J. E. Patterson (*Journal of Agricultural Research*, Washington, April 1927), and the second, "The Relation of Highway Slash to Infestations by the Western Pine Beetle in Standing Timber," by J. E. Patterson (*U.S. Dept. of Agric.*, June 1927). The latter paper has a closer connexion with the danger of infestation from slash in the neighbouring standing forest than with previous damage by fire.

The literature available on the effect of fire in the pine forests of the Pacific slope region is considerable. One phase, the effect of bark-beetle infestations following the fires, has previously received scant treatment. It has been generally recognised that there is a direct relation between fire injury and later insect damage on burned-over areas. Two types of loss are involved—destruction of the marketable value of fire-killed trees by wood-boring insects, and the actual killing by bark beetles of trees that survived the fire. Such damage follows as a result of the sporadic local increase of bark-beetle population within the fire area, which can be explained only by the assumption that numbers of beetles fly into the area from the surrounding forest. The authors hazard the following hypothesis: "Because of fire injury certain trees become especially attractive to the beetles. The physiological basis of this attraction is but vaguely understood. The odour of fire-scorched foliage and cambium may be an attractive influence, or the insects themselves may possess an instinctive ability to select those trees in which sap resistance has been weakened by fire injury, but whatever the influence, it is evidently a very strong one of determining the behaviour of Dendroctonus beetles." The explanation would seem to rather lie in the unerring instinct possessed by the bark beetles, and one may add to these many species of the longicorns and buprestids, which leads them to choose out trees the vitality of which for whatever reason is impaired for the time being. For example, these groups of beetles exhibit the same instinct in infesting wind-blown or snow-broken trees. The heavy windfalls which occurred near Gerardmer in the Vosges in the late autumn of 1903, to quote but one European example, were followed by a heavy concentration of bark beetles on the wind-blown trees the following year. So serious was this attack that a considerable area of forest had to be felled before it was stamped out.

The various aspects of the inter-relation of fire and insect damage raise many questions that are pertinent to the protection of pine forests. The authors set themselves the following questions: What type, and what degree of fire injury make trees attractive to bark-beetles? Are such trees capable of recovery if not attacked by insects? Do bark beetles 'breed up' in fire areas, increasing their numbers to an epidemic status, and then become aggressive in uninjured trees in and around burned areas? As they correctly state, the answers to these questions, of extreme importance to the forester, can only be obtained by a careful study on the ground.

The monograph by Messrs. Miller and Patterson is a most valuable piece of work and merits the careful study by all interested in this matter. Briefly, the authors' conclusions are as follows: Forest fires of sufficient severity to scorch the bark and foliage of yellow pine trees produce types of injury which make certain trees especially attractive to the Western pine beetle. Many trees which have been only moderately injured by the fire and are apparently capable of recovering, are attacked and killed by the beetles after a fire of this character. The attraction of fire-injured trees often causes a concentration of beetles within a burned area which lasts for one or two seasons following the fire. This attraction may extend for a distance of two or three miles from the burn. The concentration of bark-beetle attacks in fire-injured trees within a burned area does not develop into an epidemic condition. The loss from bark-beetle attacks in trees not injured by the fire either within the area of the burn or in the surrounding forest is not materially increased as a result of this concentration. Trees which have been defoliated by the fire are not favourable breeding places for the beetles, the resultant mortality amongst the latter, owing to the abnormally moist condition of the inner bark, being high. Finally, the authors' studies show that fires can be of but little benefit in reducing beetle losses through killing the beetles unless the fires are sufficiently severe to kill the trees. They add, in conclusion, "bark beetles supplement and increase timber losses initiated by forest fires, while fires have but little influence in permanently increasing the losses caused by bark beetles."

The second brochure here under review, by Mr. Patterson alone, deals with the inter-relation of slash (lop and top, etc., of trees) and insects, especially bark beetles and borers. In the United States three types of slash are recognised, and the definition is not without its value in Great Britain, namely, logging slash, the waste left in bulk on the ground after logging; line slash resulting from clearing roads, power lines and telephone lines (occurring in narrow strips); and wind-blown slash, *i.e.* wind-blown or snow-broken trees left unremoved. Both foresters and lumbermen have come to recognise, for the matter has been widely discussed, that if only to minimise the danger of fires originating in the slash and spreading into valuable standing forest, its disposal is advisable. The problem is further complicated by insect infestation, the green material being in the condition most suited to the beetles for oviposition.

The study undertaken by Mr. Patterson was to determine definitely whether the insect infestation of the slash threatened the value of adjacent standing timber, the species investigated being in line slash of the Western yellow pine in Southern Oregon. The following are the conclusions arrived at. The line slash of this species is very attractive to the bark beetle (*Dendroctonus brevicornis*). The attack in the slash is not so heavy as in mature standing timber. The broods developing in slash are characterised by abnormal mortality (64 per cent. increase of beetles as compared with 135 per cent. in adjacent standing timber). Bark beetles from the surrounding standing timber are attracted to the slash at the time of attack, and a temporary concentration of infestation occurs in its immediate vicinity. Normal distribution of the infestation is resumed within the year. The concentration in the slash and the resulting beetles therefrom have little influence on infestations in the surrounding forests. Concluding, the author considers that the infestation of line slash by this beetle is not a serious menace to neighbouring mature timber, and may be disregarded when the problem of slash disposal is under consideration.

These two monographs merit the consideration of those interested in these matters. They exhibit a praiseworthy amount of careful research and experiment, undertaken in the forest, yielding results of practical utility.

Fisheries and their Products.

THE twentieth meeting of the Conseil Permanent International pour l'Exploration de la Mer took place in May 1927 at Stockholm. The report[1] marks the twenty-fifth anniversary of the foundation of the Council, which, mainly through the efforts of Sir John Murray, Prof. Cleve, Dr. Otto Petterson, and Dr. Fridtjof Nansen, owed its existence to the initiative of the late King Oscar II. of Sweden, who summoned in 1889 at Stockholm the first of the two conferences leading up to the foundation of the Council in 1902. The programme of international exploration had for its object the study of the hydrography and biology of the North Atlantic, North Sea, and Baltic, including statistical and industrial problems. With the recent inclusion of Italy, the Mediterranean is now added and fifteen countries are involved.

During the twenty-five years in which the Council has been in existence much work has been done, but most of the problems are so large that they need many years to show any results. Even now, however, in the infancy of the researches, definite results and promises of important results are seen. Direct research on fishes (especially food fishes, but also others indirectly related), with particular reference to their life histories, migrations, fluctuations, food, and environment, come first, and side by side the hydrography and plankton work with bottom sampling. At the same time statistical investigations, comparisons of various nets and methods of fishing, as well as research into the over-fishing of certain areas, are in progress, whilst the work on the whale fisheries is planned to fit in with that of the *Discovery* Expedition.

The hydrographers, continually active in all the countries concerned, maintain regular observations on temperatures and salinities, with special studies of currents and ice conditions. Plankton work in connexion with hydrography and its relation to fish food is undertaken in most of the countries, bottom sampling chiefly in the southern North Sea area. The most important fishes investigated are herring, cod, haddock, and plaice. A large amount has been done on the herring, in the North Sea, particularly the young stages (the main problems of its life history now being known), with regard to races, migrations, and fluctuations. Great Britain, France, Denmark, Norway, Sweden, Germany, and Poland all help in the herring work. The north-eastern area is mainly responsible for the cod. This includes sending specialists on board trawlers for the study of statistics, age, and food. A result of this is found in the comparison of fish from the coast of Finmarken and from the White Sea, showing that they belong to a common stock. Research on the haddock, chiefly in the southern North Sea area, has resulted in important work, carried on at Aberdeen, on age determinations; whilst the plaice, also in this area and in the north-western area, has been investigated particularly in Denmark and the Baltic. It is reported that there is a very large increase in the Baltic fishery in the last few years, and the red tunny has appeared in numbers in the North Sea in connexion with the herrings. Work on salmon and sea trout, together with the study of river pollution, is also being carried on.

The general conclusions to be drawn from this report are that the main facts relating to the spawning areas, life histories, food, age, and migrations of the most important food fishes (especially plaice and haddock, and to a less extent, herring and cod) are now known, and there is a general knowledge of hydrographical data, plankton distribution and bottom communities, especially in the North Sea, all of which form a foundation on which to carry on the enormous amount of detailed work still to be done. The statement of the North Sea Combined Committee that "there are certain features in the life histories of our most important commercial fishes . . . which are still obscure," whilst suggesting special attention to these, only voices the opinion of the Council as a whole, when recommending continuance of the existing programme in all areas and in all sections rather than beginning work on new lines.

A large amount of important and interesting information dealing with sea fisheries and suggestions for their improvement, with regard especially to those products which largely enter into the food of the people of the British Isles, has been published in a recent report of the Imperial Economic Committee on Marketing and Preparing for Market of Foodstuffs produced within the Empire.[2]

The main fishing grounds are almost wholly confined to water of less than 200 fathoms depth, situated in all parts of the Empire, but the North Atlantic and the North Pacific are the only two parts of the world where the fishing industries have been developed on a large scale, the North Atlantic being the most important. There is no evidence pointing to a shortage in the total fish supplies of the world, although the amount of fish on the fishing grounds may vary and some of them may have been overfished. There are many valuable grounds at present only partially worked, because they are difficult of access and the present methods of preserving are not suitable for prolonged sea voyages. Nevertheless, the tendency is to go farther and farther afield.

In the British Isles, the demand is chiefly for 'white fish,' that is to say, such fish as cod, whiting, and sole, as distinct from 'pelagic' fish such as herring and mackerel, the two divisions representing fish of different habit and therefore requiring an entirely different method of catching, resulting in two almost separate trades. Since the War there has been a marked change in the demand for white fish rather than for herring, and the herring trade is faced by a loss of markets both at home and abroad, whilst there is a very large and increasing market for white fish, and almost all that is landed in Great Britain is consumed locally. To meet this demand the vessels must make longer voyages, which necessitate better methods of preservation.

---

[1] Conseil Permanent International pour l'Exploration de la Mer, *Rapports et Procès-Verbaux des Réunions*, vol. 45. (Copenhague. Andr. Fred. Høst et fils, 1927.)

[2] "The Report of the Imperial Economic Committee on Marketing and Preparing for Market of Foodstuffs produced within the Empire." Fifth Report: Fish. (London. His Majesty's Stationery Office, 1927.)

The storage of fish after landing is most important, as at present the fish must be sold directly it is brought in, hence the great fluctuations in the quantities marketed and high prices. If it could be stored in 'live condition' more regular prices could be obtained. High prices limit consumption. This is particularly noticeable in affecting the British market of fresh and refrigerated fish caught off the Newfoundland and Canadian coasts, and discourages this branch of inter-Imperial trade. It follows that anything that will stabilise wholesale prices must have a healthy effect on the trade—the first essential is a better method of preservation at an economic cost. With better methods of preservation a larger consumption would be probable, and it is suggested that economy would be affected if the public were trained to buy filleted fish rather than whole, all the waste parts then being disposed of at headquarters; also that an improved and different method of curing herring would probably reinstate it as a favourite fish.

With regard to by-products, the most important are fish oils, especially cod-liver oil, and fish meals. The British and Newfoundland cod-liver oil is probably superior to foreign oil in essential vitamin content, but at present further research is needed as to methods of refinement. Fish meals are extremely valuable for feeding live stock and should be more fully used.

The recommendations of the Committee are wholly on the industrial side, the most important being that research should be instituted with the view of preserving fish from the moment when it has been caught to the moment when it reaches the consumer. This should be based on two central stations, one in Great Britain and one in Canada, a specially constructed vessel or 'factory ship' being established on which the most essential preliminary parts of the oil and meal industries could be carried on at sea. Other recommendations include the services of a biochemist to determine the scientific problems of economic importance attached to the preservation and curing of herrings, researches into the causes of variation of vitamin content in cod-liver oil and into refining methods, so that the full vitamin content may be retained, and further use of fish meal. With regard to the extension of tropical fisheries, the favourable position of the Malay Government for this purpose is suggested.

University and Educational Intelligence.

Cambridge.—Mr. W. C. D. Dampier-Whetham, Trinity College, has been appointed by the University a member of the Council of the National Institute of Agricultural Botany. E. J. H. Corner, Sidney Sussex College, has been appointed Frank Smart student in botany, and W. L. Edge, Trinity College, has been awarded the Allen Scholarship.

St. Andrews.—The Senatus Academicus has resolved to confer the honorary degree of LL.D. upon Prof. E. P. Cathcart, Gardiner professor of physiological chemistry in the University of Glasgow, and upon Prof. William Darrach, Dean of the Medical School, Columbia University, New York.

An election of Beit Memorial Junior Fellows for medical research will take place in July. The annual value of the fellowships is £400 each, and the usual tenure is for three years. Applications, in writing, should be sent to Sir James K. Fowler, Honorary Secretary, Beit Memorial Fellowships for Medical Research, 35 Clarges Street, W.1.

Applications are invited for a Busk studentship in aeronautics for 1928–29, to be awarded towards the beginning of next July. This studentship, established in memory of E. T. Busk, who lost his life in 1914 while flying an experimental aeroplane, is awarded to provide opportunity for whole-time research on stability problems in aeronautics, and is open to British subjects of less than twenty-five years of age. Applications must reach Prof. B. Melvill Jones, Engineering Laboratory, Cambridge, before May 12 next.

The Prince of Wales' Royal Indian Military College, Dehra Dun (United Provinces), was established in 1921 for the education of Indian boys in preparation for entry into the Royal Military College, Sandhurst, and eventually for a military career as officers. The number of pupils is at present seventy, and further expansion is contemplated. The normal age of entry is 11-13 years, and the standard at entry that of the higher primary school. The course extends over six years. The College is controlled by the Army authorities under the Government of India, and the staff includes a Commandant (Lieutenant-Colonel, Indian Army), a headmaster, and five assistant masters. Applications are now being invited for an assistant master, well qualified in mathematics and able to teach elementary physics and chemistry. Candidates must be public school men, preferably with an honours degree and experience of teaching in public schools. They should normally be from 23 to 30 years of age, and good at games. Unmarried men are preferred. Particulars of the pay, leave, and pension can be obtained from the Secretary, Military Department, India Office, S.W.1.

From the Universities Bureau of the British Empire we have received a list of "Students from other Countries in the Universities and University Colleges of Great Britain and Ireland: Session 1927–28." The total number is 4875, which is 6 per cent. greater than the total number given in the corresponding list for the session 1926–27. The number of students from each of the countries contributing substantially to this increase is as follows, the increase per cent. on the preceding year's figures being given in brackets: Egypt 384 (14), Canada and Newfoundland 183 (17), United States 487 (9), India, Burma, and Ceylon 1501 (10), France 61 (45), Germany 121 (30), Switzerland 60 (54), Australia 234 (20). Of considerable interest for comparison with these statistics is a tabular statement, published on p. 864 of the American Council on Education's new handbook, "American Universities and Colleges" (Charles Scribner's Sons, 1928), giving the number of foreign students in the colleges and universities of the United States during the past five years. The total number for the last year of the series (1925-26) is 5806, the countries chiefly contributing to this total being China (1317), Japan and Korea (808), Canada (733), Philippines (571), Russia (515), South American States (244), British Isles 310 (England 202, Scotland 52, Ireland 49, Wales 7), Mexico 188, Porto Rico 183, India, Burma, and Ceylon 182, Hawaii 141, British West Indies 125, Germany 124, Italy 117. Germany shows a steady increase during the five years—49, 63, 79, 121, 124; South Africa a decrease—146, 137, 97, 76, 63.

Calendar of Customs and Festivals.

April 15.

Low or White Sunday.—Said by a seventeenth-century writer to be so called because in the primitive Church neophytes baptised and clothed in white garments at Easter Eve put off their white clothes on this day and were admonished to remember that they were made *low* as little children of Almighty God such as ought to retain in their lives and manners the memory of the Paschal feasts they had accomplished. An alternative was that it was the lowest or latest day for satisfying the Easter obligations.

In the Highlands of Scotland, 'Old Men's Easter' was a repetition of the Easter feast if on a lesser scale. In the Greek Church its popular observance is a continuation of the Easter festivity. In Macedonia on Easter Tuesday the people repair to the open country where the girls dance, in more or less ceremonial dances, and the youths amuse themselves with contests in shooting at a mark, wrestling, jumping, running, and the throwing of heavy stones. On the following Sunday, known as St. Thomas's Day, a similar celebration, but on a more elaborate scale, takes place. Prizes are given for the principal events —for running and wrestling a kid or a lamb, the winners in these events being acclaimed and marching off with their prizes over their shoulders to the accompaniment of shouts and the firing of guns.

It is evident that in the popular observances throughout Lent and at Easter we are dealing with festivals connected with both seed-time and the advent of spring which took place originally on no fixed date, but were observed at different times in different localities, or perhaps even on various occasions within the same community.

That the two classes of festival are not necessarily coincident or immediately consecutive appears in the popular religion of India. The Holi festival in veneration of fire and lights is a spring fertility festival celebrated in northern India in the month of Phālgun (February-March). Fire is lighted on the night of the full moon, fuel being taken from all the villagers for the purpose, or a tree is set on fire. Processions are made round the fire, men and women jump through the fire, and offerings are thrown into the flames. Foul obscenities of act and word are used, and sometimes there is a procession of a mock king—an Easter ceremonial which survived in Cornwall at Lostwithiel, but as a solemn observance. In contrast, the agricultural new year begins with a festival in later April, which is a time of great solemnity. Both plough and seed are consecrated, small portions of the latter being sowed ceremonially; and cutting the first sods in ploughing or digging—evidently an act of peril—are performed by a holy man. Among the Nagas the transplanting of the first five rice plants is done by the village priest, and a libation made. Such a solemn rite is almost necessarily made the occasion for mourning lost relations. Omens are taken of the coming harvest, and ceremonial contests such as mock fights or tug of war between the women and girls on one side and the men and boys of the village on the other, promote fertility or foretell the harvest.

Among the Malabars, in the earlier half of April, but usually between April 10 and April 14, the vernal equinox is celebrated, marking the agricultural new year. The first thing seen on Vishu day is an omen of fortune for the whole year, judicious prearrangement usually securing a desirable object. Presents of money are made to the junior members of the family and the servants. The spade furrow is laid and an offering made to the elephant god. The Chál is the most important of these agricultural ceremonials, though not now often observed. It demanded the services of a professional astrologer to fix the propitious time and place for cutting the first furrow. A new ploughshare was fitted and a handful of seed was thrown ceremonially into the first furrow. A coconut was cut on the ploughshare to foretell the character of the harvest, in accordance with the direction of the cut and the part at which the nut was divided. The actual seed is not sown until May.

April 17.

St. Peter Gonzalez or St. Elmo: *b.* in the town of Astorga in Spain, 1190, *d.* 1240. He accompanied King Ferdinand in the expeditions against the Moors and was present at the capture of Cordoba. Afterwards he went on evangelical missions among the degraded peasantry and among sailors. He is especially associated with the protection of the latter. In art he is represented as holding a blue candle, and the confraternities of St. Elmo carry blue candles in their processions. This is in reference to the corposant (*corpo santo*), the blue electric discharge which in the Mediterranean appears on the tops of masts of ships under certain conditions of weather, and is taken to ensure the safety of the ship.

Virtues have been added to St. Elmo to which he is not entitled in making him responsible for this light, for the belief is much older. Several other saints have had the protective light assigned to their province—St. Anselm of Lucca or St. Erasmus, names of which, it is suggested, St. Elmo or St. Telmo may be corruptions. Frequently the saint is duplicated, hence St. Cosmas and St. Damian or St. Crispin and St. Crispian, the last-named pair being especially connected with the protection of sailors and ships in the English Channel, and more particularly in Kent, owing to the proximity of the Goodwin Sands. St. Nicholas is also popular there for the same reason. The twin cult, and its association with maritime activities, however, antedates Christianity. The Dioscuri and other pairs of brothers, such as Romulus and Remus, from whom the name St. Elmo may really be derived by amalgamation, were specially connected with navigation and the protection of sailors as part of a great protective cult.

April 21.

St. Maelrubius or Maelrubha, a member of the Clan Cinel-Eoghain of Co. Londonderry and a descendant of the famous Niall of the Nine Hostages. He passed over to Scotland, becoming a zealous apostle among the Picts and founding the church of Aporcrossan or Applecross in A.D. 672 or 673. He was patron saint of all the coast from Applecross to Loch Broom. His cult has evidently subsumed a number of local cults, and his name appears in a number of varying forms. Partly for this reason his festival has been identified with others occurring later in the year. His relation to paganism is suggested by his association with a well on Inis Maree noted for the cure of insanity, and by his patronage of several fairs in August and September. For neglect of his festival in August at harvest-time men's houses were burnt, while those of the men who observed it were preserved. The saint's influence has not waned. When the present manse at Applecross was building, the builder was warned in a dream to desist from using a fragment of the saint's tombstone. Later he was thrown from the scaffolding and his skull fractured on this very stone.

Societies and Academies.

London.

Geological Society, Mar. 21.—**F. B. A. Welch**: The geological structure of the Central Mendips. The Central Mendips comprise a rectangular area measuring roughly 80 square miles, lying between Shepton Mallet and Cheddar on the east and west respectively. As a whole, the Mendips consist of a west-north-westerly to east-south-easterly ridge, the structure being that of four periclines arranged *en échelon*. The cores of these periclines are of Old Red Sandstone age, with the Carboniferous Limestone Series succeeding. The Central Mendips include the North Hill, the Pen Hill, and part if the Beacon Hill periclines. Of these, North Hill and Pen Hill are more or less anticlinal in structure; but the Pen Hill pericline has been much disturbed by extensive earth movements. A large syncline, which extends from Cheddar to Wells, has been thrust from the south against the southern limb of the North Hill pericline, while at one point a 'window' occurs in this syncline, revealing beds of the main hill-mass beneath the thrust. Parallel to this thrust, at Ebbor, a second great thrust is developed, isolated remnants of which are seen in the small hills north of Wells. Earth movements seem to have been directed mainly from the south, at first producing the ridge with periclines *en échelon*, and separated one from the other by normal synclines. Pressure continued, and appears to have been greatest in the Pen Hill region, where overfolding was developed. Finally overthrusting resulted, and large blocks of beds, bounded by extensive north-and-south faults, formed at the time of the thrusting, were driven northwards.

Paris.

Academy of Sciences, Mar. 5.—**G. Ferrié**: The operation of world longitudes (October-November, 1926). An account of work done by the international committee. Fifty-two stations belonging to thirty nations took part in the work, and forty-five of these have already sent to the president accounts of their observations. Twenty-two of these have furnished data bearing on the fundamental triangle, Algiers—Li Ka Wei—San Diego, for which results are given.—**C. Sauvageau**: The development of two Asperococcus.—**Luigi Fantappié**: The calculation of matrices.—**S. Stoilow**: A class of continued transformations with limited variation.—**Henri Cartan**: A theorem of M. A. Bloch, and questions of unicity in the theory of meromorph functions.—**G. Vranceanu**: Completely stable periodic solutions.—**Jacques Mesnager**: The theory of equilibrium of heavy massifs submitted to pressures from below and its bearing on the stability of barrages.—**Mesnager**: Remarks on the preceding communication.—**Henri Mémery**: An important recrudescence of sunspots on Feb. 2, 1928.—**Marcel Dufour**: The refraction of the astigmatic pencil. The third equation of Sturm.—**M. Ponte**: The various spectra of mercury. Details of the spectrum obtained in a tube fitted with a single electrode and submitted to high frequency discharge with very short wave-length (about 12 metres).—**W. Kopaczewski**: The buffer action of the serum in relation with immunity.—**Jacques Bardet** and **Arakel Tchakirian**: The preparation and properties of some germanous salts. Two direct methods are given, one based on the reduction of germanic salts by zinc and sulphuric acid, the other by reduction with hypophosphorous acid in hydrochloric acid solution. Germanous oxide is soluble with difficulty in solutions of sulphuric or hydrochloric acid, and after filtering and rapidly drying, is stable at the ordinary temperature.—**G. Allard**: The determination of the crystalline network of microcrystalline substances by means of radiograms taken with powders. The method described is general, and is not, like Hull's method, limited to substances crystallising in the cubic, quadratic, hexagonal and rhombohedric systems.—**Henri Termier**: A hypothesis concerning the Permian and Trias of Morocco.—**Marcel Martz**: The anomalies of the androecium in a hybrid of the genus Digitalis.—**A. Jullien**: The significance of the eosinophil granulations of the blood cells of *Sepia officinalis*.—**Maurice Caullery** and **Mlle. Marguerite Comas**: The determination of sex in a nematode (*Paramermis contorta*), a parasite of the larvae of Chironomus. From determinations of the number and sex of parasites present on single worms, it was found that the sex depends largely on the number of parasites on each worm, and hence is probably a question of nutrition.—**Charles Pérez**: The evolution of the apparatus for attaching the abdomen to the thorax in decapods (Dromia, Homola).—**Angel Establier y Costa**: Hyperallantoinuria in artificially produced polyuria and diabetes in man. In all the cases examined the polyuria was accompanied by a large increase in the amount of allantoin excreted.—**Marcel Duval**, **Paul Portier**, and **Mlle. A. Courtois**: The presence of large quantities of amino-acids in insects. Analyses of seven different species showed a very high proportion of amino-acids, ranging from 13 to 36 times the amounts present in the blood of mammals.—**C. Levaditi** and **T. E. Anderson**: The neurotropism of *Spirochæta Duttoni*. From experiments on mice inoculated with *Sp. Duttoni*, the brain was found to be virulent long after the blood was sterile. No typical spirochæte could be detected in the brain in these cases. As in the experiments described by Nicolle, Levaditi, Sanchis-Bayarri, and Schoen, the parasites appear to undergo a cycle of evolution, one of the phases of which is invisible and non-filtrable.—**S. Nicolau**: The histo-pathological modifications of the suprarenal capsules and the salivary glands of rabbits killed by experimental enzootic encephalomyelitis (Borna's disease).—**V. Chorine**: The influence of the hydrogen ion concentration of the culture medium on the virulence of the Coccobacillus of the Pyralis of maize.

Rome.

Royal National Academy of the Lincei, Dec. 18.—**G. Armellini**: Measurement of double stars.—**S. Baglioni**: (1) Action of quinine, eserine, pilocarpine, digitonine, sparteine, and atropine on the nervous centres. Experimental investigations on a preparation of *Bufo vulgaris*. None of the poisons named, when applied locally to the dorsal or ventral face of the posterior intumescence of this preparation, causes increase in the excitability or tetanic or clonic convulsions. An apparent exception occurs with digitonine applied to the dorsal face, this resulting, after the lapse of some hours, in tetanic reflexes similar to those produced by strychnine; such action is, however, almost certainly due to a decomposition product of digitalin which has an action resembling that of picrotoxin. (2) Physiological doctrine of the action of poisons exciting the nervous centres. Consideration of the available experimental data seems to justify the enunciation of the following general theory: All poisons acting selectively by enhancing the excitability of the central co-ordinating elements of the posterior corna of the spinal medulla, cause the abnormal increase in the reflex activity which culminates in the typical tetanic convulsions of central origin (strychnine type), whereas those which act selectively by raising the excitability of the central elements of the anterior corna (motor neurones) cause increase in the reflex excitability, resulting finally in clonic convulsions of central origin (phenol type). This selective action of different poisons is, moreover, a proof that the neurones of the posterior corna and of the anterior corna are endowed with specifically different functional properties.—**F. Tricomi**: The equation $y\partial^2z/\partial x^2+\partial^2z/\partial y^2=0$.—**U. Crudeli**: The elementary geodesic displacement.—**G. Sansone**: The apiristic resolution of the biquadratic congruences.—**Giuseppe Scorza**: Partial minima and maxima for functions of several variables.—**V. Hlavatý**: Complements to the theorem of reduction of orthogonal differential systems.—**G. Krall**: Variation of the field in the equations of elastic motion.—**D. Graffi**: Magnetic induction. A mathematical treatment is given for the problem of magnetic induction for ferromagnetic bodies in the case when the variations in time of the electromagnetic field are so small that the phenomena accompanying such variations may be neglected.—**E. Fermi**: A statistical method for the determination of certain properties of the atom (1). A process is described for calculating statistically the distribution of the electrons round the nucleus. The results obtained render it possible, first, to calculate the energy necessary to ionise the atom completely, that is, to strip it of electrons, and secondly, to determine the variation in potential at different distances from the nucleus and hence to ascertain the electric field in which the electrons of the atoms occur.—**L. De Caro**: The production of lactic acid and of phosphoric acid in 'rigor from thawing.' Quantitative experiments made by Fletcher on the production of lactic acid in striated mammalian muscle subjected to low temperatures showed that, during the freezing of the muscle, there takes place no formation of lactic acid, but some change which disposes it to a more rapid formation of the acid when thawing begins. The results of the author's experiments on muscle from the frog, toad, and dog show that the production of phosphoric acid in the muscle at low temperatures follows a course parallel to that of lactic acid and that this behaviour remains unchanged even after the suppression of the morphological structure of the muscular tissue. 'Rigor from thawing' is accompanied by the same chemical changes as are encountered in the other normal or experimental forms of muscular contraction.—**Camillo Artom**: Effects of cooling the spinal ganglia.—**N. Passerini** and **P. Galli**: Experiments on the action of the sodium chloride contained in irrigation water on certain plants. Under the conditions of pot tests, various annual and perennial plants exhibit for some time marked tolerance towards moderately concentrated sodium chloride solutions, but, owing to the rapid evaporation of the liquid and to consequent accumulation of salt in the soil, even dilute solutions result ultimately in death or damage to the plants. Although such accumulation of salt is not to be feared in the open ground, it is not advisable to employ, for irrigation, water containing more than 1 part of combined chlorine per 1000. For the spontaneous growths of established meadow-land or for arable land with permeable subsoil, this limit may be increased to 2 or, in some instances, 3 parts per 1000.

VIENNA.

Academy of Sciences, Jan. 19.—**W. Figdor**: The influence of light on the form of *Bowiea volubilis* and the increase and structure of its bulbs. Both in the light and in the dark, the main and the side axes show opposite tendencies as to growth in length.—**K. Menger**: Notes on theory of dimensions (4). The dimensions of irreducible continua.

Jan. 26.—**A. Franke** and **E. Gigerl**: Researches on the formation of benzal in glycols.—**A. Franke** and **R. Stern**: Glycol from methylethylacetaldehyde and benzaldehyde.—**F. Schweda**: Calculation of the transversal end frame of open bridges.—**K. Menger**: Metrical researches: (1) Theory of convexity, (2) Euclidean metric, (3) n-dimensional metric.—**A. Methlagl**: Trombidioses in Austrian alpine countries. Various species of Trombicula are reported.—**L. Lämmermayr**: Further contributions to the flora of magnesite and serpentine soils.—**A. Kieslinger**: Geology and petrology of the Kor Alps. (5) Marble outcrops in the region of the map sheet Deutschlandsberg-Wolfsberg.

Diary of Societies.

SATURDAY, April 14.

Institute of British Foundrymen (Lancashire Branch) (at College of Technology, Manchester), at 4.—J. Hogg: A Foundry Problem.—W. Holland: Refractories.

Institute of British Foundrymen (West Riding of Yorkshire Branch) (at Technical College, Bradford), at 6.—W. H. Poole: What has Science done for the Foundry?

Institute of British Foundrymen (Lancashire Branch—Junior Section) (Annual General Meeting), at 7.—C. F. Brereton: Some Observations on Metallurgical Practice in the U.S.A.

Hull Association of Engineers (at Municipal Technical College, Hull), at 7.15.—L. Rowland: Rubber as a Shock Absorber.

MONDAY, April 16.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Rev. Charles Boutflower: Sennacherib's Invasion of Judah 701 B.C.

Institution of Electrical Engineers (Informal Meeting), at 7.—E. H. Shaughnessy and others: Discussion on Wireless Reception.

Institution of Electrical Engineers (Mersey and North Wales (Liverpool) Centre) (at University, Liverpool), at 7.—Annual General Meeting.

Ceramic Society (at North Staffordshire Technical College, Stoke-on-Trent), at 7.30.—W. H. Box: The Recent Development of Special Electro-magnetic Separators and Applications of Interest to the General Pottery Trade.—Dr. G. Martin: Researches on the Theory of Fine Grinding, Parts 9, 10, and 11.

Railway Club (25 Tothill Street, S.W.1), at 7.30.—B. M. Basley: South American Railways.

Royal Society of Arts, at 8.—A. G. Huntley: Applied Architectural Acoustics (Dr. Mann Lectures) (L.).

Chemical Industry Club.

TUESDAY, April 17.

Electrical Association for Women (at Institution of Electrical Engineers), at 11.15 A.M.—Annual General Meeting.

Royal Statistical Society (at Royal Society of Arts), at 5.15.

Royal Society of Medicine, at 5.30.—General Meeting.

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.

Zoological Society of London, at 5.30.—J. H. Lloyd: Abnormalities of *Rana temporaria*, chiefly relating to the Vascular System.—Dr. J. G. Myers: Morphology of the Cicadidæ (Homoptera).—Dr. H. G. Jackson: The Morphology of the Isopod Head. Part II. The Terrestrial Isopods.

Institution of Civil Engineers, at 6.—C. P. Taylor and Dr. O. Faber: Deep-water Jetty at Bevan's Cement-Works, Northfleet.

London Natural History Society (at Winchester House, E.C.), at 6.30.—C. L. Collenette: Mothing in the Tropics (Bacot Memorial Meeting).

Royal Photographic Society of Great Britain (Scientific and Technical Group), at 7.—Dr. D. A. Spencer: Photographic Applications of Diazo Compounds.—H. H. Horton and O. Bloch: A Mechanical Developing Appliance for Sensitometric Work.

Society of Glass Technology (at University, Sheffield), at 7.30.—W. Butterworth, sen.: Stained Glass of the Renaissance Period.

Royal Anthropological Institute, at 8.30.—Rev. F. R. Bishop: Native Life in the Mandated Territory of New Guinea.

WEDNESDAY, April 18.

Research Association of British Paint, Colour, and Varnish Manufacturers (at Paint Research Station, Waldegrave Road, Teddington), at 2.30.—R. A. Coolahan: Cellulose Lacquers, illustrated by a film entitled Modern Lacquers.

Society of Glass Technology (at University, Sheffield) (Annual General Meeting), at 2.30.—(Ordinary Meeting), at 3.—Dr. S. English, Prof. W. E. S. Turner, and F. Winks: Some New Facts arising from a Study of the Casing of Colourless by Coloured Glass.—A. Cousen, H. W. Howes, and F. Winks: The Control and Distribution of Temperature in Lehrs.

Electrical Association for Women (at Institution of Electrical Engineers), at 3.—Capt. P. P. Eckersley: Technical Problems of Broadcasting.

Royal Meteorological Society, at 5.—C. K. M. Douglas: Some Alpine Cloud Forms.—N. K. Johnson: A Strong Wind of small Gustiness.—T. N. Hoblyn: A Statistical Analysis of the Daily Observations of the Maximum and Minimum Thermometers at Rothamsted.

Geological Society of London, at 5.30.—Dr. G. H. Mitchell: The Succession and Structure of the Borrowdale Volcanic Series in Troutbeck, Kentmere, and Long Sleddale (Westmorland).—L. J. Chubb: The Geology of the Marquesas Islands (Central Pacific).

Institute of Metals (Swansea Local Section) (at Thomas' Café, Swansea), at 7.—Annual General Meeting.

Institution of Electrical Engineers (Sheffield Sub-Centre) (at Royal Victoria Hotel, Sheffield), at 7.30.—D. B. Hoseason: Squirrel-Cage Induction Motors.

Royal Microscopical Society, at 7.30.—Dr. K. F. Bélař: The Separation of Protoplasm in the *Mycomycete Didymeum* by Stimuli.—B. R. Johnson: Some Introductory Experiments dealing with a Quantitative Method of Determining the Resolving Power of Microscope Objectives.

Royal Society of Arts, at 8.—A. C. Bossom: American Architecture.

Folk-Lore Society (at University College), at 8.—W. J. Perry: The Dramatic Element in Ritual.

Electroplaters' and Depositors' Technical Society (at Northampton Polytechnic Institute), at 8.15.—G. B. Hogaboom: Effect of Carbonates in a Silver Solution.

Institute of Brewing (Burton-on-Trent Section) (at Queen's Hotel, Burton-on-Trent).—C. F. Wade: Fuel Economy.

Institute of Chemistry (London Section).

THURSDAY, April 19

Institution of Mining and Metallurgy (at Geological Society), at 5.30.

Institution of Electrical Engineers, at 6.—Sir Oliver Lodge: The Revolution in Physics (Kelvin Lecture).

Royal Photographic Society of Great Britain (Colour Group, Informal Meeting), at 7.—F. T. Hollyer: Some Aspects of Colour Printing.

Royal Society of Medicine (Neurology Section) (Clinical Meeting at West End Hospital for Diseases of the Nervous System), at 8

British Institute of Radiology, at 8.30.—C. Wainwright: The Coolidge Cathode-Ray Tube and its Applications.—J. E. Schall: Lantern Slide Projection of Stereoscopic Radiograms.

Institution of Civil Engineers (Birmingham and District Association) (Annual General Meeting) (at 6 Corporation Street, Birmingham).—R. A. Robertson: The Sandfields Filters of the South Staffordshire Waterworks Company

Institution of Mechanical Engineers (Bradford Branch).—Prof. G. F. Charnock: Mechanical Transmission of Power.

FRIDAY, April 20.

Royal Astronomical Society (Geophysical Discussion), at 4.30.—Dr. de Graaf Hunter, A. R. Hinks, Sir Gerald Lenox-Conyngham, Capt. G. T. McCaw, and H. L. P. Jolly: Some Applications of the Geoid. Chairman, Sir Charles Close.

Institution of Mechanical Engineers, at 6.—Dr. H. J. Gough and A. J. Murphy: The Causes of Failure of Wrought-Iron Chains and Cable.—Third Report of the Wire Ropes Research Committee.

North-East Coast Institution of Engineers and Shipbuilders (at Mining Institute, Newcastle-upon-Tyne), at 6.—Dr. S. H. Long: W/T Direction Finding for Marine Purposes.

Royal Photographic Society of Great Britain (Pictorial Group, Informal Meeting), at 7.—A. Cocking: The Development of Cut Film.

Junior Institution of Engineers, at 7.30.—Re-Exhibition of Slides and Discussion on Paper by W. M. Hurrell on An Outline of the Distribution of Petroleum.

Society of Chemical Industry (Chemical Engineering Group) (Jointly with Birmingham Section), at 7.30.—Dr. C. M. Walter: The Heat Treatment of Ferrous Metals

Royal Society of Medicine (Obstetrics Section), at 8.—R. H. Paramore: Eclampsia and its Treatment: an Experience with Spinal Anæsthesia in one case.—Prof. W. Blair Bell: The Malignant Functions of the Chorionic Epithelium.

Royal Institution of Great Britain, at 9.—Col. Sir Henry G. Lyons: Heirlooms of Industry in the Science Museum.

Society of Dyers and Colourists (Manchester Section).—Annual Meeting.

SATURDAY, April 21.

North of England Institute of Mining and Mechanical Engineers (Newcastle-upon-Tyne), at 2.30.

CONFERENCE.

April 13–16.

Geographical Association (at Oxford).

April 14.—Sir Halford Mackinder: The British Empire in Relation to the Geography of the World (Lecture).

April 16.—Col. C. H. D. Ryder: Surveys from Air Photographs (Lecture).—Dr. L. Dudley Stamp and others: Discussion on Practical Steps in Regional Survey Work and Local Studies.

SATURDAY, APRIL 21, 1928.

Problems in Human Nutrition.

IN the acquirement of knowledge by the experimental method, with the attention to minute detail which accurate and successful work demands, it is sometimes useful to pause a while and raise the eyes from the task in hand, and to take a general survey of the field—what has already been accomplished and what still remains to be done. Some reflections on problems in nutrition are suggested by perusal of the thirteenth annual report of the Medical Research Council, more especially as one chapter of our knowledge of the elusive, but extremely important, accessory food factors appears closed, even though the next may be already partly written. The discovery that ergosterol is the precursor of vitamin D, and is converted into it on irradiation by ultra-violet light or by exposure to sunlight, has already been referred to in these columns (NATURE, vol. 120, p. 955; 1927): it is now possible for the first time to produce a vitamin from a pure chemical compound in the laboratory or even in the factory, so that an ample supply should be readily available for all.

Advances made, however, in one branch of nutritional studies, striking though they are, should not lead us to forget the importance of the other elements of the diet, the salts, the proteins, fats, and carbohydrates, or even the water. All constituents of the diet are worthy of study: scientific knowledge of them is of especial importance to a country which imports the major portion of its food supply. Thus it is known that proteins differ in their 'biological value'; that is, animals can maintain nitrogenous equilibrium on smaller quantities of some proteins, usually of animal origin, than of others which are usually derived from vegetable sources. What is both the most suitable and also the most economical source or sources of protein for human dietaries? Again, it is possible for human beings to live on much smaller quantities of protein than are usually consumed, but it is doubtful if this minimum is also the optimum. Another problem of extreme importance is the relationship which the different constituents of the diet should have to one another. Thus the quantity of vitamin B must bear a certain ratio to the amount of protein present: and vitamin A can only exert its full effect on growth in the presence of vitamin D.

The practical application of some of our recently acquired knowledge is mentioned in the Medical Research Council's report and has also been referred to in Nature (vol. 120, p. 440; 1927) by O. Rosenheim and T. A. Webster. The supply of milk fat is inadequate for the minimal needs of our population, partly owing to the greater cost of animal fats as compared with vegetable. The chief sources of vitamins A and D have so far been animal fats: in this respect vegetable fat products cannot replace animal. Heretofore, the richest known supplement has been cod-liver oil, but its unpleasant flavour has made it more of a medicine than a dietary supplement to most people. Vitamin D can now be supplied by irradiation of ergosterol, and vitamin A has been found to be present in large amounts in the livers of herbivorous animals, from which it can be easily extracted together with the fat. The supply of liver, fresh or frozen, should be sufficient to meet the requirements of our population for vitamin A; and the fat has the advantage that it is without the unpleasant flavour of the fish oils, so that it can be easily added to vegetable fats or other articles of the diet.

A knowledge of correct nutrition has also a direct bearing on certain medical problems and the prevention of disease. It is only necessary to mention that inadequate intake, relative or absolute, of the appropriate vitamins, is the ultimate cause of scurvy, rickets, beriberi, and pellagra, and probably plays an important part in the initiation of dental decay. It is impossible to say what light future advances in nutritional problems may throw upon certain aspects of preventive medicine.

Much of our knowledge on this subject has been derived from animal experiments: the conclusions drawn can frequently be applied directly to mankind. But it must not be forgotten that results so obtained have another aspect and may throw light on problems facing those who have to breed and maintain animal stock. In the case of the domestic animals, the problem comes back to human nutrition again, in the fattening of stock or in the production of milk of high nutritive value.

Many questions, both of general scientific and practical interest, still await investigation and solution. The nature of the change that occurs in ergosterol under the influence of light, leading to the formation of vitamin D, the further change resulting in the destruction of the vitamin when the irradiation is long continued, and the wavelengths which are the most active in producing these effects, are still undecided The solution of these questions has a practical bearing on the optimum conditions for effecting the transformation. Of more academic interest, perhaps, are such problems as the source of the vitamin D which is found in the liver of the cod, or the reason for the absence of this vitamin from mammalian liver. Leigh Clare has shown that the diatom *Nitzschia closterium* contains none of it, so that presumably the cod obtains it from the plankton and smaller fish it consumes, since it is unlikely to be exposed to enough light to synthesise it for itself (*Biochem. Jour.*, vol. 21, p 368; 1927). Again, the body fat of fish is usually free from vitamin A, though it contains vitamin D, but the body oil of eels is rich in both these vitamins; thus does scientific investigation confirm man's empirical selection of certain of his articles of diet. The prospects of the improvement in human well-being which may be expected to result from better knowledge of the influence of diet in the prevention of disease or ill-health make research work on nutrition and its application of prime importance and worthy of generous support from the State and the public.

Czechoslovakian Cytology.

Structure and Development of the "Living Matter." By Prof. F. Vejdovský. (Published with the Assistance of the Ministry of Education of the Czechoslovak Republic.) Pp. vii + 360 + 24 plates. (Prague: Royal Bohemian Society of Sciences; Fr. Řivnáč; London: James Smith, 1926–7.) 147*s*.

THIS volume is one of the largest contributions to cytology published by a single author in recent years. It is written in fairly good English, though in certain more technical parts the translator has not got the equivalent English terminology. Prof. Vejdovský's publications go back at least to 1888, when he brought out his first study on the "Reifung, Befruchtung und Furchung" of the Rynchelmis egg. He is to be congratulated on being at work forty years after.

There are six chapters devoted respectively to the spermatogenesis of the crayfish, the development of the cleavage spindle of Ascaris, and of Rhynchelmis, the structure and development of the somatic cells of Angiospermous plants, the spermatogenesis of the rock kangaroo, and finally a general discussion of the cell constituents. The book contains 360 pages, and the plates are nearly all in colour.

It should be said at once that Prof. Vejdovský's cytology has much in common with that of the celebrated German cytologist F. Meves—perhaps with not so much of the latter's remarkable powers of observation, for Meves, within the limits of his technique, never made a mistake. Prof. Vejdovský makes many mistakes, and he is a little querulous with those whose views do not coincide with his own. In justice to Prof. Vejdovský, it should, however, be mentioned that the book was meant for publication before the War. As he himself says, he took two years reading up the periodicals he could not get during or just after the War. He has endeavoured to superimpose the results of his reading on his own pre-War cytological views.

The book serves to throw into relief the extensive advances both in microscopical technique and general cytology made by non-continental workers in recent years. Prof. Vejdovský has not kept abreast with modern advances, and in some ways one even feels that he has not learnt what he might have done from the work of Jan Hirschler, F. Meves, and Duesberg, whose publications must have been accessible to him before he went to press.

F. Meves was, in his later years, dominated by the idea that the cytoplasmic inclusions are bearers of the hereditary factors of the cytoplasm. This view is not acceptable nowadays, except in a very moderate form, but Meves's theory never injured his powers of observation. Prof. Vejdovský, on the other hand, allows his theories to lead him into misinterpretations of descriptive cytology.

The book is dominated by two theories—that the acrosome of mammalian spermatogenesis is derived from 'nuclear liquid,' and that the Golgi bodies are a 'mitotic apparatus.' Now there is probably no field in cytology which has been more thoroughly searched than that of the formation of the mammalian sperm from the spermatid. Benda, Niessing, Lenhossék, Hermann, Meves, Moore, Walker, Brown, Duesberg, Papanicolaou, and Stockard, and Woodger and the reviewer, to mention only a few workers, have brought out papers on this subject. In recent years, work by Schütz, Bowen, Voinov, Hyman, and the reviewer has been brought into line with the results of the workers on mammalian spermatogenesis, and confirmed by work in lower vertebrates and invertebrates. Yet Prof. Vejdovský attempts to show that the acrosome is formed as a sort of coagulum from "Karyochyme or nuclear liquid" poured out of the nucleus on to the region of the "mitotic apparatus" (Golgi apparatus). This view is at variance with the careful observations of past and present cytologists. The author has failed to study the spermatocyte and spermatid stages properly, and it is regrettable that he should have devoted so much space to this undoubtedly mistaken interpretation. Perhaps if Prof. Vejdovský had chosen an insect or a mollusc instead of a crayfish for his study of invertebrate spermatogenesis, his views would have changed.

Before the War, and when he was nearly ready to publish his book, Prof. Vejdovský had found the Golgi bodies both in supravitally stained cells and in prepared sections. He was impressed by the fact that in much of his material these bodies hovered near the asters during mitosis. Not being aware of the newer homology of the Golgi apparatus of nerve cells with these bodies, he considered them to be a 'mitotic apparatus.' This quite natural mistake vitiates much that is good in his accounts of mitosis. We cannot definitely claim that the Golgi bodies in these cases do not contribute in some way to the amphiaster, but we do know that the amphiaster can form without Golgi bodies stuck on it, and the idea that the Golgi apparatus is a 'mitotic apparatus' is unacceptable. It seems a pity that Prof. Vejdovský has not familiarised himself with recent work on dictyokinesis, such as that of Ludford, Bowen, Da Fano, *et alia*.

Prof. Vejdovský has observed both mitochondria and Golgi bodies *intra vitam*. There is much in his work of importance to the younger men, and his observations on plant cells should be taken into consideration by those who are now investigating plant tissues so successfully.

The original coloured drawings of Prof. Vejdovský are very beautiful, yet it is interesting to note that the three methods which are most used by modern workers, modified Kopsch, Da Fano, and chrome-osmium hæmatoxylin, all give 'black and white' preparations, and the necessity for coloured plates to illustrate cytological articles is no longer so apparent.

Zoologists who may be interested in cytology are advised to procure Prof. Vejdovský's most interesting publication. J. Brontë Gatenby.

Acoustics of Buildings.

The Acoustics of Buildings. By Dr. A. H. Davis and Dr. G. W. C. Kaye. Pp. ix+216+22 plates. (London: G. Bell and Sons, Ltd., 1927.) 15*s.* net.

THE high standard of care in preparation and the wealth of illustration which are such notable features of Royal Institution lectures are paralleled in this volume, which is based on the Tyndall lectures of 1926. The account of the lectures already given in Nature (vol. 99, pp. 603-606) indicates the scope of the book.

The subject is full of fascinating problems, for so much is demanded of a public auditorium. In many towns the same hall has to be used for speech, chamber music, or a full symphony orchestra and choir. When we realise the minute amount of energy in a human voice, it seems remarkable that a speech in a large hall can be heard at all. R. L. Jones has calculated that if a million persons were to talk steadily, and the energy of their voices were to be converted into heat, they would have to talk for an hour and a half to produce enough heat to make a cup of tea (even if they were all politicians)! The minute amount of energy is, however, compensated for by the remarkable sensitivity of the ear, which can hear a sound of amplitude equal to the wavelength of a penetrating X-ray. Then again the smooth rigid parts of the walls of a hall act as better reflectors of sound than do the best mirrors for light. If, however, these reflecting parts are too far away, the time lag between the direct and reflected ray will cause confusion, and the reflecting power has to be reduced.

The book admirably illustrates that the subject has reached a stage when an architect submitting to experts at, say, our National Physical Laboratory, plans and details of materials for a proposed hall, could be given trustworthy particulars of its acoustics. The principles and necessary details are so clearly set out that he might even make the necessary calculations himself. It should be added that the mere act of consulting experts will not, however, lead to the production of a satisfactory hall if their advice is not followed. This may seem a facetious remark, but it is based upon the reputed facts of a recent famous case when a hall was found, when built, to be quite unsuited for speech, although experts had been consulted.

Whilst prevention is better than cure, the correction of acoustical defects is now so well understood that the acoustics of a faulty hall can always be improved, and in many cases the defects can be entirely removed. One method which will make no appreciable difference is in use in our largest auditorium, the Royal Albert Hall in London. Across the ceiling is draped some half-dozen lengths of ordinary wide-mesh wire netting, no doubt a relic of darker ages. This eyesore should be removed out of consideration for the feelings of musical scientists who visit this monument of defective acoustic design.

The use of draping or porous acoustic plaster for rendering hospital wards less reverberant would no doubt be unhygienic. In this and similar cases, such as in typewriting rooms or underground tube railways, the initial generation of sound should be reduced by suitable insulation of the vibrating objects.

The book is admirably produced, and the authors have succeeded in giving all necessary quantitative details in such form that they can be readily understood and applied, even by those with only an elementary knowledge of acoustics. Although there is no bibliography, adequate references are given in the text.

W. H. George.

A Revised Physical Chemistry.

Outlines of Theoretical Chemistry. By Dr. Frederick H. Getman. Fourth edition, revised and partly rewritten. Pp. xiii + 728. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 18*s.* 6*d.* net.

The principal value of a review of a new edition of a well-known book is to inform the reader of the review of the features in which the new edition differs from the old. In the present instance the author claims: "a fuller treatment of limiting densities and vapour pressures; a brief description of the latest and most accurate method of measuring heats of vaporisation; a more comprehensive treatment of crystal structure and the methods of X-ray analysis; an enlargement of the section treating of the absorption of light and its bearing on chemical constitution; a thorough revision of the chapter on the elementary principles of thermodynamics; a more discriminating treatment of the phenomena of osmosis; the inclusion of the concepts of fugacity and activity in connexion with the subject of vapour pressures of dilute solutions; a fuller discussion of the theories of emulsification and gel formation; an enlargement of the sections devoted to adsorption and the methods of preparation of colloids; a more detailed account of the theories of catalysis; the treatment of the more important practical applications of conductance and electrometric methods in separate sections in the respective chapters devoted to electrical conductance and electromotive force; the simplification of the treatment of hydrolysis; the adoption of a uniform and consistent system for the representation of galvanic cells, thereby connecting their polarity with the direction of current-flow; a fuller treatment of both the hydrogen electrode and oxidation and reduction cells; the rearrangement and enlargement of the chapter on electrolysis and polarisation; a brief presentation of the quantum theory together with its application to the principle of photochemical equivalence; an outline of Baly's fascinating and suggestive researches in the field of photosynthesis; and lastly, the complete revision of the chapter on atomic structure."

There can be little doubt that further changes will have to be made in the near future when the author has considered in fuller detail how far he intends to maintain his hold upon Arrhenius's theory of reversible ionisation and how far he proposes to admit the later theory of complete ionisation, since it is obviously unsatisfactory to devote a large part of one chapter to expounding one view and a considerable part of another chapter to demolishing the foundations on which that view rests. The optical sections of the book will also require revision, in order to conform to the modern physical view that absorption of light of given frequency does not depend on a vibratory oscillation of given frequency in the molecule, but on the possibility of some form of activation in which quanta of energy of suitable magnitude are taken up.

These two points serve to illustrate the difficulty that is experienced by every writer of books on physical chemistry in this transition period, and they are particularly acute when a book of well-established merit falls due for revision. The author has not spared himself in the work of revision, and, if further changes have to be made in the near future, this will only be a further proof of the vitality of the subject which he expounds with no mean skill.

Our Bookshelf.

Allen's Commercial Organic Analysis. Vol. 5: *Tannins, Writing Inks, Stamping, Typing and Marking Inks, Printing Inks, Amines and Ammonium Bases, Analysis of Leather, Colouring Matters of Natural Origin, Colouring Substances in Foods, Benzene and its Homologues, Aniline and its Allies, Naphthylamines, Pyridine, Quinoline, and Acridine Bases.* By the Editors and the following Contributors: M. Nierenstein, C. Ainsworth Mitchell, John B. Tuttle, H. E. Cox, A. E. Caunce, W. M. Gardner, Walter E. Mathewson, J. Bennett Hill, A. B. Davis. Fifth edition, revised and in part rewritten. Editors: Samuel S. Sadtler, Dr. Elbert C. Lathrop, C. Ainsworth Mitchell. Pp. xii + 700. (London: J. and A. Churchill, 1927.) 30*s*. net.

IN the period of sixteen years since the publication of the corresponding volume in the fourth edition of "Allen's Commercial Organic Analysis," there has been a considerable advance in our knowledge of practically all the sections under review. In spite of the enormous amount of data to be included on a great number of subjects in a limited space, the editors have presented a readable and connected book. They have avoided the temptation of presenting their material in the usual dull dictionary form now so common in many comprehensive treatises on specialised branches of science.

Benzene and its homologues have been introduced as a first step on the road to coal-tar dyes, and are considered before dealing with amines and other dye intermediates. As natural dye colours are used largely as foundation material for the after treatment with coal-tar colours, they are included in this volume. Tannin materials and inks are considered in conjunction with natural colours which are rich in tannin products. Nearly one-third of the whole volume deals with the subject of tannin, and the qualitative and quantitative examination of tannin materials is treated exhaustively. The constitution of acacatechin, as set forth by Nierenstein, is given, and while it is stated that this is not in agreement with the views of Freudenberg, it is left to the reader to look up the original papers, to which references are given, to examine the points of difference.

Much of the material in the sections on amines and ammonium bases, benzene and its homologues aniline, naphthylamine, etc., will be found in general text-books on organic chemistry. If this material was restricted, more place might be given to the more specialised sections on natural colouring matters, inks, and leather analysis.

The volume shows signs of careful editing, and only a small number of errors have been noted. The standard of the previous volumes has been maintained generally, and the subject index has been greatly improved.

J. REILLY.

(1) *Manual of British Birds.* By H. Saunders. Third edition, revised and enlarged by Dr. William Eagle Clarke. Pp. viii + 834. (London and Edinburgh: Gurney and Jackson, 1927.) 30*s*. net.

(2) *The Birds of the Island of Bute.* By J. M. McWilliam. Pp. 128 + 8 plates. (London: H. F. and G. Witherby, 1927.) 8*s*. 6*d*. net.

(1) CLOSE field observation and keen discrimination of racial differences have brought the number of British birds from 384 to 500 since the second edition of this famous "Manual" appeared twenty-eight years ago. Fortunately, the bulk of the third edition has not kept pace with the increase, for although all the additions are described and many are illustrated, the editor has properly distinguished between rare visitors and regular British birds by allotting less space to each of the former. The essential plan is as in earlier editions: the occurrence in Britain, characteristic appearance, nesting habits, and migrations of each species are set out in a description which, with an illustration in woodcut or half-tone, occupies roughly two pages.

Great care has evidently been taken in compiling the accounts of occurrences and breeding in the British Isles, one of the most useful features in the book, since records are brought down to the year of publication. Its compactness in a single volume, its accurate, full and readable descriptions, and its definitive illustrations of every species, make this the most suitable of British bird books for the ordinary ornithologist and naturalist.

(2) Island faunas offer many points of interest to the naturalist, and although the viability of birds discounts the significance of many species, there remains a substratum of 'residenters' which illustrate, more clearly than can be done on the mainland, the history of the fauna. Mr. McWilliam fully appreciates this significance, and in his historical introduction and remarks about several species, points out how the island of Bute has suffered a gradual reduction. In all, 168 species have been recorded from this limited area, and a general survey shows that the avifauna is closely comparable with that of the mainland, although island life has sometimes impressed new habits. Thus of rooks, jackdaws, and starlings, it is noted that they make daily migrations to the mainland over the Firth of Clyde, setting out in the morning and returning at dusk, notwithstanding that Bute itself apparently contains abundance of suitable feeding ground. It is estimated that in the autumn the sixty square miles of the island may contain as many as 400,000 birds.

A Treatise on the British Freshwater Algæ, in which are included all the Pigmented Protophyta hitherto found in British Freshwaters. By the late Prof. G. S. West. New and revised edition, in great part rewritten by Prof. F. E. Fritsch. Pp. xviii + 534. (Cambridge: At the University Press, 1927.) 21*s.* net.

More than twenty years have elapsed since the late G. S. West published his "British Freshwater Algæ." The edition was soon exhausted, and the lack of a similar volume has since been acutely realised. Prof. Fritsch has, therefore, done botanists in general a very real service in undertaking a revision of the earlier work. He has successfully tried to retain the character of the original volume, but the vast increase in every branch of our knowledge of the algæ has necessitated the addition of an enormous mass of material, and the result is an entirely new work, which has gained also an added personality.

Point is given to the general treatment of algal morphology in the emphasis laid on the development of parallel stages of morphological complexity in widely separated groups, a useful chart being given in illustration. The chief changes in arrangement occur in the Isokontæ. The Cladophorales and Sphæropleales are now removed from the Siphonales and grouped with Ulothricales, presumably on account of their metabolic similarity. The treatment of the Chlorococcales follows that of Brunnthaler in distinguishing Autosporinæ and Zoosporinæ. A considerable number of flagellate forms are added, these being grouped along with the appropriate coccoid and filamentous forms. The Peridineæ are also now included. No freshwater Phæophyceæ are recognised, the forms which were formerly described here having been more suitably transferred to the Chrysophyceæ.

The figures include one, at least, of every genus. Generic keys are given, and indications of the characters of at least the commoner species, while the valuable indications as to habitat have been retained and amplified. The book will be of great value not only to the algologist, but also to the teaching botanist, the student, and the amateur naturalist. W. H. P.

Foremanship Training. By Lieut.-Col. Hugo Diemer. Pp. viii + 230. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1927.) 12*s.* 6*d.* net.

The *flair* for business which is so typical of Americans is peculiarly noticeable in their methodical consideration of the problem, how to get the most effect out of men and materials. This does not imply that the American seeks to take advantage of his fellow-citizens; it is rather that he desires to use human effort (as he strives to use mechanical effort) to the last ounce of advantage, so that the end in view may be achieved in the most practically economical way. Col. Hugo Diemer's treatise upon foremanship training considers one—and a very important—aspect of this urge for maximum effect. In a series of fourteen chapters he discusses that responsible cog in the machine, the foreman, with the view of making evident the necessity for training him so as to be, in fact, something more than a mere part of a machine—to be a man with intelligent general grasp of the whole of the work involved, and having a human faculty for bringing out what is best in the employés over whom he has to exercise a measure of control. The author drives home his arguments with a skill that is beyond dispute. P. L. M.

A Book of Words: Selections from Speeches and Addresses delivered between 1906 and 1927. By Rudyard Kipling. Pp. vii + 299. (London: Macmillan and Co., Ltd., 1928.) 7*s.* 6*d.* net.

The addresses which compose the "Book of Words" were delivered in many lands to varied audiences through a period covering almost a quarter of a century. Occasional speeches, however, especially when delivered in lighter vein, only have value outside the circumstances in which they are made when they contain, hidden it may be by phraseology peculiar to the occasion, ideas of general interest. Such, in a measure, are these speeches. Almost every conceivable theme is touched upon from "The Spirit of the Navy" to the "Virtue of France," from "Independence" to the "Handicaps of Letters." Here and there, at greater length, occur other types of topics such as the contribution of prehistoric man to modern military practice and naval science, in which imagination and a kindly regard for half truths have resulted in charming narratives. The delight of the book is in the reading.

Letters to the Editor.

Lecture Experiments on the Hydrogen Ion Concentration Changes in the Rusting of Iron.

FOR the rusting of iron, oxygen, water, and a trace of acid are required. In the process oxygen is used up, also a certain amount of water, but the acid may be said to act as a catalyst. It is, in fact, regenerated when the ferrous salt first formed is oxidised to the ferric state, as was shown previously (*Trans. Faraday Soc.*, **18**, 310-317; 1923). This is at once evident when we consider that, on making solutions of ferric or ferrous salts less acid, ferric hydroxide is first precipitated, at *p*H 3·5 to 5·5, and ferrous hydroxide comes down later, at *p*H 5·1 and onwards, a trace being still in solution at *p*H 7·6. Oxidation, therefore, must result in a liberation of acid, accounted for by the ferric being hydrolysed to a greater extent than the ferrous salt.

The reaction may be demonstrated as follows: Adding four drops of 0·04 per cent. brom phenol blue to each 10 c.c. of a dilute solution of a ferric salt, the yellowish colour of the indicator denotes acidity equivalent to *p*H 3·2 or less, namely, equivalent to a solution at least as acid. A similar solution of ferrous sulphate gives a purple colour with this indicator and can accordingly be no more acid than *p*H 4·2. It is in reality at about *p*H 4·8. On standing for some days the change to the ferric condition is accompanied by a change in reaction, as shown by the indicator. For lecture demonstration, however, it may be brought about instantaneously. By adding a few crystals of 'hyperol' to distilled water, a solution of hydrogen peroxide may be prepared which is no more acid than *p*H 5·6. It is accordingly alkaline towards the indicator mentioned and gives with it a good purple colour, as does also the freshly prepared ferrous solution. On mixing these two alkaline solutions, the result is a solution acid to the indicator, namely, at about *p*H 3·2, which is a clear yellow. This somewhat paradoxical behaviour is accounted for by the regeneration of acid from the hydrolysis of the ferric salt. Were metallic iron present, this acid would be free to attack it.

The action of carbon dioxide in solution can also be demonstrated. Bright iron wire is carefully washed free from the lime in which it is stored, being finally dipped in dilute acetic acid and thoroughly washed with distilled water. It is then placed in a test tube with distilled water to which brom thymol blue (0·04 per cent.) has been added. The full yellow colour of the indicator denotes the presence of free carbonic acid, so that the water is at least as acid as *p*H 6. This indicator changes to a clear green at *p*H 7·0 and is blue by *p*H 7·3. To demonstrate the rapidity of the change, one must work near the neutral point and in an unbuffered solution; the water is therefore brought to a yellowish green colour, *p*H 6·6–6·8, by the addition of either a trace of pure sodium bicarbonate or a few drops of sea water. On standing, the very low acidity, *p*H 6·8, is reduced by the attack on the iron; within two minutes the reaction has become noticeably less acid; within five minutes the change is readily recognised. For lecture demonstration the experiment may be started an hour beforehand, when the green colour of the indicator will have been changed to an intense blue round the wire. On shaking up, the whole tube becomes blue, but on allowing to stand, a green colour reappears in the parts remote from the wire, especially near the surface, owing to the oxidation of the ferrous salt, with regeneration of acid. Inasmuch as increase in acidity appears to slow down the rate, there are reasons for thinking that the constituent most readily oxidised is the fraction of the ferrous salt which is hydrolysed to hydroxide. By its oxidation the equilibrium is upset and more ferrous bicarbonate hydrolysed to hydroxide, the equivalent of acid being set free. The changes occurring round the wire may be projected on a screen and so made visible to the audience.

With solutions which are alkaline at the start, namely, those containing fewer hydrogen ions than does *pure* water, the change proceeds, though more slowly. Using 0·02 per cent. phenol red, a pink colour may be obtained, increasing to a good red, indicating *p*H 8. Using xylenol blue, a light blue may be obtained, showing a reaction as alkaline as *p*H 8·4–8·6. Beyond this I have not succeeded in going, for the change being much slower, the liberation of acid through oxidation prevents further increase in alkalinity. Were care taken, however, to remove all oxygen, it seems likely that a greater alkalinity could be reached.

On standing in a tube with distilled water, iron wire in rusting continues to absorb carbon dioxide from the air to such an extent that when the acid is set free by 'hyperol' solution, as previously described, the solution, originally no more acid than *p*H 5·6–6·0, will give a good red colour with methyl red, showing that it is nearly saturated with carbon dioxide and is somewhere near *p*H 4·6.

Control tubes without the iron wire were used throughout and the tubes were of British resistance glass. The water was freshly distilled in a room free from chemical fumes.

The explanation given here of the mechanism of the rusting of iron is, I believe, that which is now generally accepted, and the hydrogen ion changes revealed by the indicators support it. It naturally follows that the experiments described are against the view that an oxidation of the iron is the first stage in rusting.

W. R. G. ATKINS.

Marine Biological Laboratory,
Plymouth, Mar. 13.

The Disintegration of Radium E from the Point of View of Wave Mechanics.

ELLIS and Wooster (*Proc. Roy. Soc.*, A, **117**, p. 109) have shown recently that in the disintegration of radium E the single β-particle emitted has an *initial* energy which may vary from 40,000 to 1,050,000 volts. This means that the result of disintegration is in some way indeterminate, a conclusion difficult to reconcile with the usual ideas of radio-activity.

Some such result, however, is to be expected on the new wave mechanics, if the ejection of a β-particle is produced by anything like a sudden explosion. In such a case one would expect that the wave-group which accompanies, and on some views actually constitutes, the electron, would be of the nature of a single pulse, that is, the damping factor of the amplitude would be of the order of the wave-length. Such a wave-group, being very far from monochromatic, would spread rapidly lengthwise owing to the large dispersion of the phase waves, and so the distance within which the electron may occur becomes large, implying a marked 'straggling' in velocity. Similarly, if the waves pass through a magnetic field, which is for them a refracting medium, the group will split into monochromatic waves going in different directions, just as white light is split up by a prism. Thus an observer who forms the magnetic spectrum of the β-rays will find electrons in places corresponding to paths of various curvatures, that is, he will find a spectrum continuous over a wide range.

This view can be checked numerically. Darwin has shown (*Proc. Roy. Soc.*, A, **117**, p. 258) that if we assume, for convenience of calculation, a distribution of 'intensity' (chance of the presence of an electron) in the initial wave of $\exp - (x - x_0)^2/\sigma$, that is, an 'uncertainty of position' σ, then there is an 'uncertainty of momentum' in the group of amount $h/2\pi\sigma$ and conversely. This is, of course, Heisenberg's 'uncertainty relation' in wave dress. I find that a fair fit to Ellis and Wooster's result is got by taking the number of β-particles with momentum g proportional to $\exp - \left[\frac{g - 1{\cdot}25m_0c}{0{\cdot}65m_0c}\right]^2$. Hence the uncertainty in momentum is $0{\cdot}65\ m_0c$, and that in position is $\sigma = h/2\pi \times 0{\cdot}65m_0c$.

The mean wave-length by de Broglie's relation is $\lambda = h/1{\cdot}25m_0c = 2 \times 10^{-10}$. Thus, $\lambda = 3{\cdot}3\sigma$ and the wave is heavily damped, the amplitude at the first minimum being only 7 per cent. of that in the middle of the group. The group in fact looks like a typical pulse such as may be formed in a stretched rubber cord by a sharp blow. It should be noticed that the value of σ is much larger than the diameter of the nucleus, which might at first sight be expected to govern the uncertainty of position.

The Form of the Carbon Atom in Crystal Structure.

A. Gerstäcker, H. Moller, and A. Reis have published an account of the crystal structure of pentaerythritol tetra-acetate (*Zeitsch. f. Kryst.*, **66**, 355; Jan. 1928), in which they assign the crystals to the space-group C^3_{4h} with a simple tetragonal lattice (Γ_t). There are two molecules of pentaerythritol tetra-acetate to the unit cell and the space-group C^3_{4h} with a Γ_t lattice requires eight asymmetric molecules per unit cell. Therefore the molecules of pentaerythritol tetra-acetate must have some kind of fourfold symmetry. There are two types of fourfold symmetry possible in this space-group—either a simple fourfold rotation axis or a fourfold alternating axis. Messrs. Gerstacker, Möller, and Reis have chosen the former, since it leads to a molecule which can be built into a chain-like structure, and the latter does not.

The authors base their expectation of a chain structure on the prismatic habit of growth and on the shortness of the c-axis compared with the a-axis ($c : a = 0{\cdot}458$), and claim that a chain structure, when present, has the length of the chain parallel to the axis of highest symmetry of the crystal. Now experience goes to show that prismatic growth and chain structure are not necessarily associated, either in the tetragonal system or in any other. There are many thin tabular crystals, which have a chain structure in which the chains are perpendicular to the plates, as, for example, the many long-chain carbon compounds, which have been investigated by X-rays. Moreover, in these long-chain compounds the direction of the chains was found to be perpendicular and not parallel to the axis of highest symmetry. Again, the interesting group of metallic tetraphenyl compounds (W. H. George, *Proc. Roy. Soc.*, A, **113**, 585; Jan. 1927), which crystallise in the tetragonal system, are prismatic in their habit of growth, but show no suggestion of a chain structure.

The form of the molecule of pentaerythritol tetra-acetate proposed by the above authors is shown in Fig. 1 (reproduced from Fig. 1 of their paper). It will be seen that the molecule is polar, and that the four bonds from the central carbon atom must be directed away from it towards a square base. It does not appear that the authors have put forward any evidence which could justify the adoption of a molecular form departing so completely from what would be expected from physical and chemical considerations.

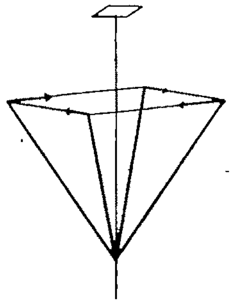

Fig. 1.

In May 1927, in a private communication to the Council of Girton College, I gave an account of an X-ray examination of pentaerythritol tetra-acetate carried out in this laboratory. My results led to the space-group C^4_{4h} and not to C^3_{4h}. The distinction between the two space-groups depends on the absence or otherwise of all odd order reflections from the (001) plane. I have been able to find only a second order reflection from this plane, after making a most careful search for other orders both on the ionisation spectrometer and by photographic methods. In a rotation photograph about the [100] axis, using copper radiation, a weak spot is found on the zero layer line, which, from its position, might be due either to the first order reflection from the (001) plane for copper $K\alpha$ rays or to the first order reflection from the (011) plane for copper $K\beta$ rays. However, in a rotation photograph about the [110] axis, the spot did not appear on the zero layer line. The conclusion is that it is not due to reflection from the (001) plane, for if it were, it should still be found in the same position as before.

In their paper, Messrs. Gerstäcker, Moller, and Reis state that they find a first order reflection from the (001) plane and are thus led to the space-group C^3_{4h}. Their only mention of this reflection is in an oscillation photograph in which [100] is the rotation axis, but neither the range of the oscillation nor its angular relation to any plane appears to be stated. It is not possible to say with certainty, therefore, to what plane the observed reflection is due, or that it is not due to the $K\beta$-reflection from the (011) plane. It is not evident that the authors have taken any particular care to establish the presence of the first order (001) reflection, upon which their space-group and, moreover, the molecular symmetry which they propose, depend. For if, as I believe, the space-group is C^4_{4h}, there is no longer any possibility of a molecule with a simple fourfold axis of symmetry, the only possible molecular symmetry then being a fourfold alternating axis, the molecule having the form shown in Fig. 2. On this view, therefore, the carbon atom plays the part expected of it.

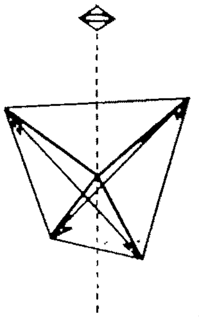

Fig. 2.

My measurements of the dimensions of the unit cell differ from those of the German workers. They find $a = 12{\cdot}34$ A., $c = 5{\cdot}56$ A., while the values I find are $a = 11{\cdot}98$ A., $c = 5{\cdot}47$ A. The density of the substance is 1·273. In a previous paper of mine (*Jour. Chem. Soc. Lond.*, **123**, 77; 1923) an overlooked printer's error made it 1·213. With my figures and the correct value of the density, the number of molecules in the cell works out at 1·99. I. E. Knaggs.

Science and Nature.

It is undeniable that the attitude towards Nature which inspired the author of Nature's motto, is implicitly repudiated by many of its readers. For that spiritual intimacy between Nature and man, which formed the substance of Wordsworth's poetry, is questioned and even rejected by a large body of investigators. To them Nature is the sphere of essentially impersonal energy and law, which are either absolutely indifferent or actively hostile to human ideals. Huxley, for example, regarded the 'cosmic process' as everywhere antithetic to 'social progress,' thus unconsciously destroying the continuity of evolution just where it becomes of supreme value to humanity; and in precisely the same spirit Mr. Bertrand Russell foresees the ultimate extinction, by natural agencies, of everything for which he himself bids us strive.

The validity of such a viewpoint is plainly a matter of the highest scientific importance. For since science is the investigation of Nature, any interpretation of Nature must reflect itself in the interpretation of science itself. Conversely, the implications of science must illuminate the character of Nature; so that quite apart from that fatal breach of evolutionary continuity postulated by Huxley, both the content and the expansion of modern science yield ample material for controverting his conclusion. From the strictly psychological viewpoint, all functions of the human mind are fully as natural as those of the brain. It follows, therefore, that reason, logic, and science are just as natural as the cerebral processes which sustain them; and even if any of these are 'emergent,' still this involves no essential loss of continuity. Thus Nature is not only the *object* of science, but also the sole and primal *source* of science; and this, still further, not in any merely passive nor indifferent way, but dynamically. For it matters not whether man's intellect is the result of heritable acquired characteristics or of natural selection, since in both respects alike it is the culmination of the age-long interplay of Nature's own agencies. Reason, then, is in no degree foreign to Nature; Nature therefore cannot be foreign, much less hostile, to reason and all that reason involves—to science, art, and morals. Only thus, in fact, can Nature's motto be accepted in anything beyond a purely metaphorical sense.

Turning next to the specific content of science, it is clear that the logic of science reflects an order of Nature. This remains true even if we regard scientific principles as mere formulæ which enable man to utilise and control Nature; the sole alternative being the abdication of thought in favour of Bergsonian 'intuition,' which is plainly suicidal so far as science itself is concerned. The truth surely is that science yields an insight, slowly growing in clarity and coherence, into the structure of Nature alike on its physical, vital, and psychical levels. To what degree these are continuous with one another is an important, but here subordinate, problem, since it cannot affect the conclusion that Nature, not partially but throughout its whole extent—from electron to galaxy, from space-time to Shakespeare—is coterminous both with human reason and, so far as man dominates Nature, with human purpose.

It may still be argued that this reciprocity is approaching its final limits, beyond which lies Nature not merely as unknowable, but as inimical. This suggestion, however, definitely contradicts the incessant *expansion* of modern science. For in all its details alike, scientific progress exemplifies the single fundamental principle that Nature possesses a structure and order so systematic and intricate, so delicate and precise, that all current theories are far too simple to be at all adequate for their understanding and explanation. The solution of every problem without exception reveals fresh problems of ever-increasing difficulty; but in spite of this, increased knowledge shows these to be, in principle, soluble problems. In other words, they are not, essentially, intractable to human reason as such, but only to the limited data with which reason, at any given stage, is condemned to operate; so that as these data slowly multiply, to that degree can more of Nature's riddles be read. Reason thus proves itself to find an ever-widening and favourable habitat within Nature's inmost realm, which thus reveals itself to be no hostile region, but rather thought's highest native sphere.

Nevertheless, the relation between science and Nature must always remain asymptotic; it can never become exhaustive. But this again is no occasion for pessimism and despair. Rightly understood, on the contrary, it plainly implies that Nature, far from mocking and defying human thought, beckons it ever onward to more intimate contact with herself. For her last secrets will be disclosed only to a reason and a science which transcend our own to the same degree that we transcend Eoanthropus.

J. E. Turner.

Light and Sight.

I have read Sir John Parsons' article in Nature of Jan. 21 and the letters of Mr. Smith and Sir John (Nature, Feb. 18) with great interest. Perhaps I may be allowed to make a few comments on them. Sir John's supposition was that since the retinal sensation curve reaches its maximum not far from that of the energy curve, and since the two curves are not unlike in shape, there may have been some evolutionary process at work. Mr. Smith's criticism is that only on a wave-length basis would this be the case. If, as is preferable, frequencies be taken, then the shapes of the two curves are quite different.

Now we cannot be sure that Mr. Smith's criticism is justified until we have considered the conditions present in the eye. Until we have done that, have we a pertinent reason for claiming one set of arbitary units (wave-lengths) to be better or worse than another set (frequencies)?

Now on a wave-length basis, equal wave-length differencies occupy equal areas and all wave-lengths have equal access, since the slit remains fixed in size to give equal wave-length purity. On a frequency basis, on the other hand, equal wave-length differencies do not occupy equal areas, since those of long wave-length are more condensed and those of shorter wave-length more spread out. Neither have all wave-lengths equal access, since the slit has to be narrower for short wave-lengths than for long, to give equal frequency purity.

In the eye, on the other hand, owing to the presence of chromatic difference of magnification, shorter wave-lengths are less spread out, and the pupil is slightly wider for short wave-lengths than for long. That is, the conditions present are far removed from the frequency basis and approximate fairly closely to the wave-length one. In view of this, I can see no reason to prefer the frequency basis or to criticise Sir John's suggestion as being impossible. With regard to Mr. Smith's alternative suggestion that the use, on one hand, of the near ultra-violet rays has been avoided in vision because of want of contrast, and of the near infra-red rays, on the other, because of the blackness of the shadows: if there were such difficulties in the use of these rays, one would expect ordinary non-colour-sensitive photography to be adversely affected on one hand, and for these black shadows to become visible when the eye is made sensitive to rays between 6800 and 7100 A. on the other.

Yet in my experience such is not the case. Is it not conceivable that the blackness of the shadows was due in R. W. Wood's photographs to slight under-exposure, seeing that only recently have fast infra-red sensitive plates been available. To my mind, it is more likely that the exclusion of ultra-violet rays was due to the difficulty in producing living media transparent to these rays, and that the non-utilisation of the near infra-red rays (which do in point of fact reach the retina) is due to the absence of a suitable retinal pigment which will absorb and will undergo photochemical change as a result of the incidence of these rays. Now I will refer to the resolving power of the eye. Mr. Smith suggests that there are ocular powers of discrimination that are more refined than the coarser features of retinal structure—the rods and cones—would lead us to expect. This is a question to which I have given a great deal of thought, and the conclusion to which I have come is that if we are prepared to grant that the cones in some way are able to register increases or decreases of intensity of, roughly, 10 per cent. (which we should not find difficult, since we can prove by experiment that moderate sized areas of retina can register increases or decreases of intensity of less than 1 per cent.), then we can adequately account for all the finer ocular powers. We can explain on this basis how, for example, the eye that can just recognise the 'twoness' of two point sources when they subtend at the eye an angle of not much less than 50″, can see a black line when its width subtends at the eye an angle of only 3·1″; with cones, moreover, the diameters of which subtend at the nodal point of the eye an angle of about 44″.

Lastly, with regard to Mr. Smith's letter in NATURE of Feb. 25 on "An Optical Paradox," would not any method of measurement depending on comparisons break down if put to a similar test? I would propose that the word 'optical' be omitted lest it suggest to the uninitiated the idea that the paradox only applies to visual measurements.

H. HARTRIDGE.

The Density necessary to Produce the Nebular Spectrum.

IN a recent letter to NATURE (Jan. 7, p. 12) C. T. Elvey attempts to calculate the density, ρ, of the expanding gaseous shell of a nova at the moment when the nebular lines first appear. It is easily shown that $\rho=\rho_0 r_0^2/v^2t^2$ where ρ_0 is the original density of the shell when coincident with the stellar atmosphere, r_0 its original radius, v its velocity of expansion, and t the time elapsing between the outburst and the appearance of the nebular lines. The above equation involves the additional and somewhat questionable assumption that the thickness of the expanding shell does not change. Elvey takes v from velocity displacements on nova spectrograms. For Nova Aquilæ 3 this is about 1700 km./sec. and $t=19$ days. Hence he finds,

$$\rho=12\cdot 7\times 10^{-20}\rho_0 r_0^2 \text{ gm./c.c.}$$

(r_0 in km.). Since figures for eight additional novæ give coefficients for $\rho_0 r_0^2$ of the same order of magnitude, Elvey concludes that "the novæ originate from stars of similar physical conditions and that there is a limiting density above which the conditions are unfavourable for the production of the nebular spectrum."

It is my opinion that the experimental evidence is far too meagre to draw any further conclusions than those just quoted. Up to this point the assumption of constant thickness for the gaseous shell has been unnecessary. It would have been sufficient merely to suppose that it varies at the same rate for all novæ.

I think that Elvey's attempt to calculate an absolute value for ρ is not justified. Taking $\rho_0=10^{-8}$ gm./c.c. (corresponding to a pressure of some 10^{-4} atmosphere) and $r_0=6\times 10^5$ km., he finds for the mean density, critical to the nebular lines, $1\cdot 8\times 10^{-17}$ gm./c.c. Elvey's use of $\rho_0=10^{-8}$ gm./c.c. is equivalent to the assumption that the phenomenon of the nova originates in that particular layer of the star's atmosphere. There is no *a priori* reason why a value of ρ_0 of 10^4 or more times the above should not have been employed in the calculation; the expanding shell would still be essentially atmospheric. It is true that the value, 10^{-4} atmosphere, is the pressure at which the stellar atmosphere is becoming opaque to visible radiation and hence marks a more or less definite layer, but this fact does not demand that all atmospheric phenomena originate there.

Bowen (*Publ. A. S. P.*, **39**, 295; 1927) has identified the nebular lines with metastable transitions in the atoms of singly, doubly, and triply ionised oxygen. These transitions, at one time spoken of as 'forbidden,' are presumably allowed in the very tenuous nebulæ, where the time between atomic collisions is extremely long. Ordinarily the time spent by an electron in an excited level is only about 10^{-8} sec. The time it would remain in a metastable state is much greater—so long, in fact, that before the natural atomic transition can occur, a collision with another atom (impact of the second kind) will knock the electron from its metastable orbit. Hence the 'forbidden' electron jumps should occur only when the time between collisions is longer than the excited time, that is, in gas of low density. A determination of the critical density, at which the metastable transitions begin to occur, would furnish valuable information regarding their life-time, but Elvey's value for it—a hundred seconds—is almost valueless for the reasons stated above.

The only fact that recommends Elvey's computed densities appears to be the close correspondence between them and the calculated values[1] for the planetary nebulæ (5×10^{-18} gm./c.c.). If the latter be assumed approximately true for the novæ, the more correct interpretation of Elvey's work is that the phenomenon of a nova originates in the star's atmosphere at a layer where the pressure is 10^{-4} atmosphere or less. When more data regarding the life histories of novæ have been obtained, and when the physicists have determined the metastable life of the atoms under consideration, these facts may be used to solve the nova problem. One should not neglect, however, to take into account photo-electric ionisation of the gas by the intense stellar radiation. Recent work by Bowen (*Astrophys. Jour.*, **67**, 1; 1928) shows that conclusions derived without considering this influence may be devoid of physical meaning.

An Apparent Failure of the Hund Theory.

The Hund theory of spectra includes, as an essential part of it, a prediction of the individual levels of an ion to which component term sequences will converge. The evidence supporting the predictions seem reasonably good in cases of spectra the character of which is determined by less than half-filled electron groups. On the other hand, the following two items of evidence seem to indicate that the theoretical predictions are not fulfilled in spectra determined by nearly completed electron groups.

1. The Paschen *s* terms in Ne I are, without doubt, the ^3P and ^1P, which arise from an electron structure $2p^5ns$ $(n \geqq 3)$. The $1s$ terms can be arranged unambiguously from both position and Zeeman effect as follows:

$$^3P_2 = 1s_5,\ ^3P_1 = 1s_4,\ ^3P_0 = 1s_3,\ ^1P_1 = 1s_2.$$

Consequently, if one accepts Paschen's series, $^3P_2$ and $^3P_1$ converge to one limit; and $^3P_0$ and $^1P_1$ to a higher limit, the two limits together being the $^2P(p^5)$ of Ne II. This is in definite disagreement with the theory, which would reverse the limits of $^3P_1$ and $^1P_1$. Since the nature of the terms is determined empirically in this case by the first members only and the limits by the higher members, it is possible to reconcile observation and theory, as Hund has done, by associating $1s_4$ with the s_2 series as its first member; and $1s_2$ in the same way with the s_4 series. But there is now evidence against such a change. The series of s_2 and s_4 terms combine with the lowest term of the spectrum $^1S_0$ $(2p^6)$ to give a far ultra-violet series of pairs $^1S_0 - ns_2$, $^1S_0 - ns_4$. In this series the line $^1S_0 - ns_4$ is the stronger of each of the pairs. This statement is based not only on the published material, but also on personal observation of plates taken in this laboratory. Such a regularity of intensities is incompatible with Hund's distortion of the series and leads definitely to the conclusion that the theoretical prediction is not satisfied for such sequences as the *s*-terms of neon. The whole argument applies equally to the corresponding terms of argon.

2. The second item of evidence is contained in the spectra of atoms and ions, of which the structure is based on 9 *d*-electrons. Ni I, Cu II, Pd I, Ag II all show sequences of ^3D, ^1D terms of origin d^9s converging to the $^2D(d^9)$ of the higher ion. In Cu II, Ni I, and Ag II only two series members are known, but they are well verified in every case by intensities and in Cu II also by Zeeman effects. In all cases the calculated limits of $^3D_3$ and $^3D_2$ fall close together, as do those of $^3D_1$ and $^1D_2$, contrary to the theory, which predicts coincidence of the limits in pairs $^3D_3$, $^1D_2$; $^3D_2$, $^3D_1$. In Pd I the evidence is more striking, since three series members are present. To pick them correctly, it is necessary to identify consistently all the terms of the spectrum from intensities. This leads to an identification of the middle set of terms exactly as given by Bechert and Catalan and in disagreement with McLennan and Smith. The second member of the d^9s sequence is then McLennan's with $^3D_2$ and $^1D_2$ interchanged. In the third member, this interchange is again necessary, and also the addition of McLennan's $^3G_4$ as $^3D_3$. These identifications are unambiguous. The limits calculated from a Ritz series formula lead to the same disagreement with theory as the similar two term series. The separation of the two limits $^2D_3$ and $^2D_2$ of Pd II, is so great (more than 3500 wave-numbers) that there can scarcely be any doubt of the reality of the coincidences of the real limits even though the calculated limits differ by 80 units in one case ($^3D_3$ and $^3D_2$) and 20 units in the other ($^3D_1$ and $^1D_2$).

The disagreements with the Hund theory here pointed out are the only ones of which I am aware. More evidence is certainly advisable and it is being sought in this laboratory.

I cannot offer any explanation of these apparent failures of the theory. It seems that the operations with the electron vectors which lead to the predictions may be carried out in a great variety of ways and lead always to the same result so long as they are treated consistently in both series and limit terms.

A Change of Wave-length in Light Scattering.

Further observations by Mr. Krishnan and myself on the new kind of light-scattering discovered by us have been made and have led to some very surprising and interesting results.

In order to convince ourselves that the secondary radiation observed by us was a true scattering and not a fluorescence, we proceeded to examine the effect in greater detail. The principal difficulty in observing the effect with gases and vapours was its excessive feebleness. In the case of substances of sufficient light-scattering power, this difficulty was overcome by using an enclosed bulb and heating it up so as to secure an adequate density of vapour. Using a blue-violet filter in the track of the incident light, and a complementary green-yellow filter in front of the observer's eye, the modified scattered radiation was observed with a number of organic vapours, and it was even possible to determine its state of polarisation. It was found that in certain cases, for example, pentane, it was strongly polarised, while in others, as for example naphthalene, it was only feebly so, the behaviour being parallel to that observed in the liquid state. Liquid carbon dioxide in a steel observation vessel was studied, and exhibited the modified scattering to a notable extent. When a cloud was formed within the vessel by expansion, the modified scattering brightened up at the same time as the ordinary or classical scattering. The conclusion is thus reached that the radiations of altered wave-length from neighbouring molecules are coherent with each other.

A greater surprise was provided by the spectroscopic observations. Using sunlight with a blue filter as the illuminant, the modified scattered radiation was readily detected by the appearance in the spectrum of the scattered light of radiations absent from the incident light. With a suitably chosen filter in the incident light, the classical and modified scatterings appeared as separate regions in the spectrum separated by a dark region. This encouraged us to use a mercury arc as the source of light, all radiations of longer wave-length than 4358 A. being cut out by a filter. The scattered radiations when examined with a spectroscope showed some sharp bright lines additional to those present in the incident light, their wave-length being longer than 4358 A.; at least two such lines were prominent and appeared to be accompanied by some fainter lines, and in addition a continuous spectrum. The relation of frequencies between the new lines and those present in the incident light is being investigated by photographing and measuring the spectra. The preliminary visual observations appear to indicate that the position of the principal modified lines is the same for all substances, though their intensity and that of the continuous spectrum does vary with their chemical nature.

Limits of Form and Magnitude in Desert Dunes.[1]

By Dr. VAUGHAN CORNISH.

REVIEWING in the light of later publications, particularly Sven Hedin's "Scientific Results" and Dr. W. F. Hume's "Geology of Egypt," vol. 1, the observations of sand dunes which I made more than a quarter of a century ago, I have been led to recognise the dynamical significance of the peaked structure which is so marked and picturesque a character in the sand seas of the Gobi, the Tarim basin, and western Egypt.

On the sea shore, loose, dry sand is arranged by the wind in little waves, which travel and keep station with one another as they move. They are a few inches from crest to crest, with short, steep front and long, gentle slope to windward. These little æolian waves, or ripples as they are called, are remarkably level-crested and long-crested, these characters being much more pronounced than in the waves which travel on water during the action of a breeze (Fig. 1).

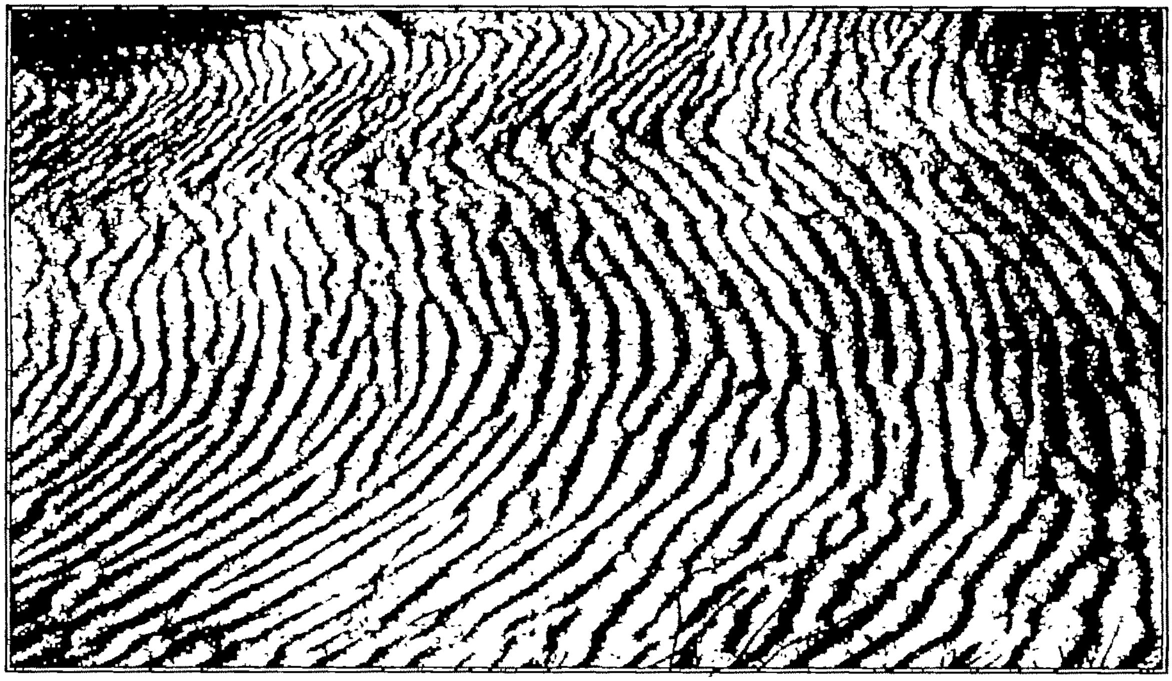

FIG. 1.—The level crests of æolian sand ripples.

In the extensive deposits of dry sand which are called sand seas, these long- and level-crested ripples pattern the slopes of the larger waves, called dunes. The average steepness, or ratio of height to length, of the dunes is comparable to that of the ripples but generally rather less. The profile of the large waves, or dunes, is of the same general character as that of the ripples, a short, steep front and a long, gently-sloping back; but the section at right angles to the wind is very different. A manikin viewing a landscape of æolian sand ripples would see a succession of peaks when looking across the direction of the wind, but a level sky-line when looking up- or down-wind. The drawings of M. Binosi in the western desert of Egypt, of Dr. Sven Hedin in the Takla Makan, and that made from the notes of Sir Francis Younghusband in the Gobi ("The Heart of a Continent," p. 98) show that, in whatever direction we look, the sky-line is punctuated by sharp peaks, all of which attain about the same height. Thus, whereas the little sand-waves or ripples are normally level-crested and long-crested, the large sand waves or dunes which rise from a sea of sand subject to stormy winds are usually peaked and frequently short-crested.[2] The peaked form has been ascribed to a breaking of the level-topped ridges by wind from a direction inclined, or at right angles, to that by which the ridges were built. It is evident that such seasonal change of wind would furrow the ridges and make them otherwise irregular, but from observations which I made in Egypt in 1899 I infer that peak-and-saddle form can be produced by strong wind constant in direction, and that this is in fact the form of the maximum sand waves produced by such wind in a sand sea.

On a dried-out sandbank of the Nile near Helwan, where the sand is finer and more mobile than that of the desert, I watched a group of many little dunes, about twenty inches high and thirty feet in wave-length, during the process of transformation from the level-crested to the peak-and-saddle crested form, the direction of the wind remaining constant. It can easily be understood that if the wind increase after the ridges have attained their maximum steepness the crest will collapse here and there, but the natural expectation would be that the parts then left upstanding would soon give way, thereby levelling the crest, whereas in fact the undulation of the crest rapidly increased. It follows that if any lowering at the peaks occurred, it must have been less rapid than at the saddles, but in point of fact there was no indication that any lowering had occurred at the peaks. The action of the wind, as well as I could ascertain, was as follows. In passing through the notches or saddles it neither conformed to the profile of the surface nor circulated round a horizontal axis, but swirled spirally. It is significant that the ripples at the saddles were larger and the sand coarser than elsewhere. Under the lee of the peak the right- and left-handed spirals met. When the dunes were losing more sand than they received, and the wind was strong, the action of these converging currents under the lee of the peak was to scoop out the loose sand, lowering the trough, sometimes down to the bare floor. When, however, there was no depletion, a longitudinal bank of sand was piled against the lee of the peak where the converging currents met.

---

[1] See paper on "Waves in Granular Material Formed and Propelled by Winds and Currents," *Monthly Notices of the R.A.S.*, Geophysical Supplement, July 1927.

[2] The term 'short-crested' has been introduced by Dr. H. Jeffreys for "wave systems in which the distance between consecutive maxima of elevation is of the same order of magnitude in whatever direction it is measured."

I measured the height and wave-length of a long series of these dunes which had level crests, and of another series the crests of which had marked peak-and-saddle form, and found that the average steepness was the same, a result which points to the conclusion that as much sand is piled on the peaks as is eroded at the saddles.

When I crossed the Suez Canal at Kantara and went east along the El Arish route to view the sand sea of northern Sinai, I found the western edge of the buried country, where the sand is not deep, was all in rounded, billowy undulations like those of gently rolling chalk downs; but farther on, where the deposit was thicker, the dunes had the characteristic desk-shaped profile. Their ridges, however, although of considerable crest-length, were neither level nor merely undulating, but punctuated by peaks the height of which above saddle was comparable to the height of saddle above trough. The moderate breeze which was blowing daily at the time of my visit was in the reverse direction to that of the wind by which the dunes appear to be formed, not oblique or at right angles thereto. As the height of peak above trough is sometimes as much as three hundred feet, it is evident that the force of the wind at the crests must be considerably greater than that to which the sand on the shallow margin of the sand sea is exposed. This would account for the more pronounced form of profile. It is evident, however, that the increased force of wind due to vertical deflexion must set a limit to the growth of peaks: there will be a certain height at which the top will collapse.

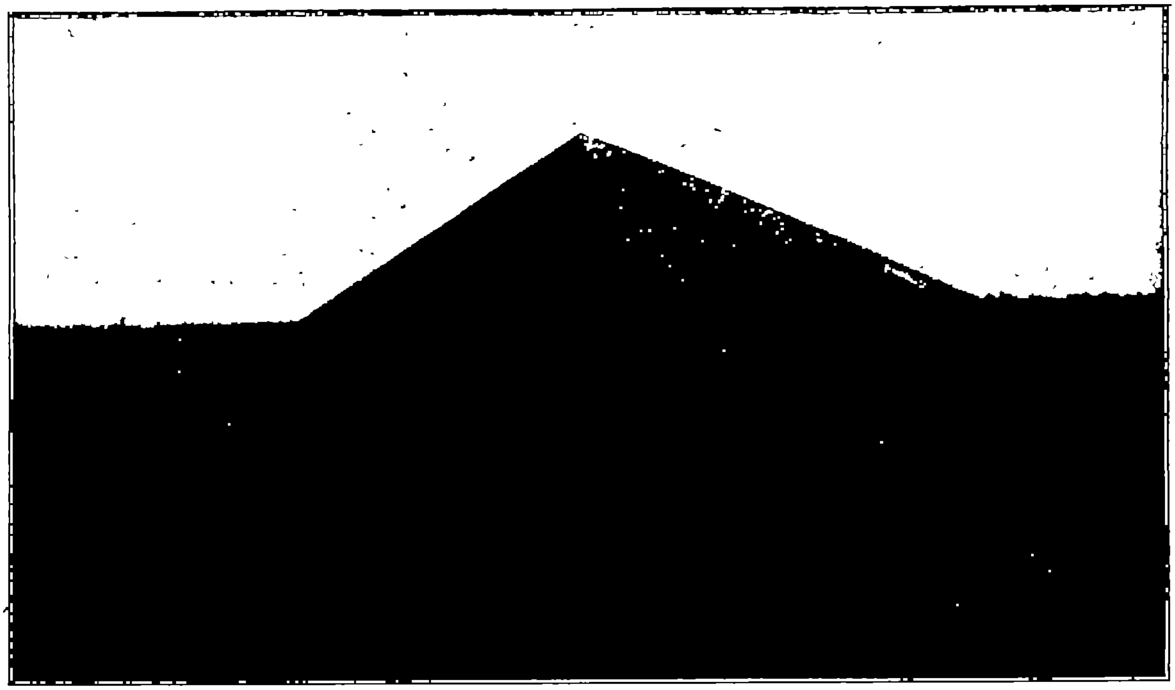

Fig. 2.—A peak on the crest-ridge of a sand dune.

On the west side of the Suez Canal, near Ismailia and close to Lake Timsah, was a transverse ridge of dune from which rose a pyramidal peak so sharp that its appearance recalled the monumental pyramids of Egypt (Fig. 2). As I approached the peak from the lee side in order to obtain a nearer view, the vibration of my step caused a considerable landslide, the soft sand of the lee side breaking away from the crest-line where it abutted on the more compact sand of the weather slope. The accompanying photograph was snapped at the moment when slipping began. The occurrence emphasised the conclusion that such peaks are forms of accumulation, not erosion.

From the foregoing observations I infer that if a country be silted with loose, dry sand under the action of strong wind constant in direction until the dunes attain maximum height, the sky-line will be serrated by peaks not only when viewed at right angles to the wind but also when looking up- or down-wind; that these peaks are not remnants of erosion, but accumulations; and that the normal crest-line of maximum dunes in a sand sea subject to strong wind of constant direction is not level, but peaked.

Dr. Sven Hedin records in his "Scientific Results" that in the eastern part of the desert of Lop, the windward part of the Tarim basin, small dunes are formed during the dying-down of a storm, but when the wind gathers force in the next storm are dispersed. Mr. A. E. Douglass[3] and Prof. S. I. Bailey[4] record that in the windward part of the Peruvian desert of Islay the sand, which is derived from an extraneous source, collects in isolated dunes less than four feet high which are not permanent, being dispersed after a time, blown to pieces by the wind. As soon as a height of four feet is attained, permanence is assured, but does not occur nearer than twenty miles from the windward edge of the desert. From this position the moving mounds grow during a very short course of travel from four feet to fifteen feet in height, which is the characteristic maximum throughout the remaining twenty-five miles of desert plateau. The dimensions and movement of a dune near La Joya railway station have been recorded for several years. The rate of progress was remarkably uniform, 62, 57, 63, 63, 63 feet in successive years, and the height and breadth of the crescentic mound was almost constant. The length and direction of the tapering cusps or horns varied, but the quantity of sand added to or subtracted from the cusps was very small in proportion to the total mass of the dune, not, I think, greater than the quantity contained in one of the rudimentary dunes which form and disperse in the windward part of the desert according to the vicissitudes of weather.

It is well to bear in mind that most of the recorded observations of the movement of sand-grains in deserts have been made during moderate breezes, when the effect of a mound of sand is to provide shelter to leeward. During storms the atmosphere in a sand sea is usually so blinding and suffocating that no precise observations are made, but in this weather the increased force of wind at the summit of the dune is sufficient to cause dispersal, a reversal of the mode of action which we commonly observe.

High Frequency Sound Waves of Small Intensity and their Biological Effects.

By Prof. E. Newton Harvey, Princeton University,
and Alfred L. Loomis, the Loomis Laboratory, Tuxedo Park, New York.

R. W. WOOD and one of us (Loomis) have described (*Phil. Mag.*, **4**, 417; September 1927) certain physical and biological effects observed with high frequency sound waves of great intensity. To obtain this great intensity, high potentials (of the order of 50,000 volts) are required, and the oscillating piezo-electric quartz crystal must be operated in an oil bath. This method is not suitable for observing biological material under a microscope.

For this purpose we have constructed a special device which can be attached directly to a microscope and operated by an oscillator of relatively low power but must be accurately tuned to resonance with the quartz crystal. The entire oscillator (Fig. 1) is very compact and weighs only eighteen pounds. It takes current directly from the 110 volt A.C. lighting circuit and employs a 75 watt tube (Radiotron 852) with two small transformers (one giving 8 volts for the filament, the other 1100 volts for the plate). The microscope with quartz crystal is set up about three feet from the oscillator and connected through a shielded lead, so that movements of the operator will not materially vary the capacity and thus the frequency. Two controls which connect with the oscillator are operated from the microscope, one varying the plate and filament current and the other the frequency.

The crystal mounting consists of a bakelite ring which is placed directly on the microscope stage. Fastened to the top of this ring is a thin foil electrode connected to the high tension lead. The quartz crystal is placed on top of this electrode. The crystal is 54 mm. in diameter and 7·02 mm. thick. It is cut with its electric axis perpendicular to the plane of the disc. Its natural frequency is 406 kilocycles per second. The specimen to be examined is placed on the centre of the upper surface of this disc and protected with a cover glass. On top is placed the upper electrode, which is earthed. The frame of the microscope is also earthed. A small hole through the centre of the lower electrode permits adequate illumination of the specimen, and a similar hole through the upper electrode permits the light from the specimen to enter the microscope objective.

Observing under a high-power microscope, it has been possible to follow the progressive destruction of frog blood corpuscles. The oval cells at first become warped and twisted. Strained areas appear and the colour fades, leaving a pale distorted shadow. Human blood corpuscles are likewise twisted and sometimes broken up into many small globules like an emulsion of oil. Individual bacteria can be studied, but while they can be violently agitated, we have not yet been able to observe their destruction under the microscope.

If a fine emulsion of oil is examined, an individual droplet of oil can be singled out and made to rotate rapidly in either direction at speeds that can be accurately controlled by varying slightly the frequency of the oscillating circuit.

An excellent material to illustrate the effects of these waves is a leaf of Elodea, two cell layers in thickness. The protoplasm with suspended chloroplasts forms a thin layer about the cellulose cell wall enclosing the vacuole of cell sap. High frequency sound waves of low intensity passed through these cells cause the protoplasm to rotate very much as in the normal rotation or cyclosis of Elodea. Increasing the supersonic intensity increases the movement until the whole cell is a rapidly whirling mass of protoplasm, fragments of which are torn loose and rotate as small balls in the vacuole. The effect is very striking and might almost lead one to conclude that the normal cyclosis of this plant was caused by high frequency vibrations. The normal protoplasmic rotation of Elodea is stopped by the waves unless they are of very low intensity. Rotation begins again provided the irradiation has not been too strong. Sugar-plasmolysed Elodea cells are affected in the same manner as are the unplasmolysed ones, the whole protoplasm rotating rapidly, until, with increasing intensity, the mass finally bursts and scatters the chloroplasts, still whirling, throughout the cell. Nitella cells when exposed to radiation have the chloroplasts torn from the walls of the cell and whirled rapidly, leaving a clear area which had originally been a uniform green colour.

This stirring of the cell contents is one of the most characteristic effects of supersonics. The smaller the cell, the more difficult it is to stir, but we have observed the rapid rotation of the chloroplasts in moss cells the diameter of which averages 12μ. The phenomenon is not connected with living cells only, but may be observed in Elodea killed by heating or by chloroform, although a greater intensity is necessary since the protoplasm is coagulated on death, and the coagulated mass is only churned with some difficulty.

This microscopic method offers a promising means of attack upon the problem of influencing the development of eggs of various species, as forces can thus be applied inside an egg at different stages of its development without the necessity of puncturing the cell wall or enveloping membrane. The results immediately suggest the interesting possibility of converting an egg with determinate cleavage into an indeterminate one by thoroughly mixing and redistributing the organ-forming substances of its interior. We are now engaged upon this and allied problems, the results of which we expect to publish in due course.

No effects of the waves have been noted that could be clearly traced to an influence on chemical processes in cells, although it is known that high intensity waves influence certain chemical systems, especially metastable ones (W. T. Richards and A. L. Loomis, *Jour. Am. Chem. Soc.*, **49**, 3086; 1927). The phenomena in living organisms, apart from temperature rise, are connected with mechanical effects, the most striking of which might be best described as 'intracellular stirring.'

In certain biological studies where great intensity is desired, and it is not necessary to observe under the microscope, a high-powered oscillator is required.

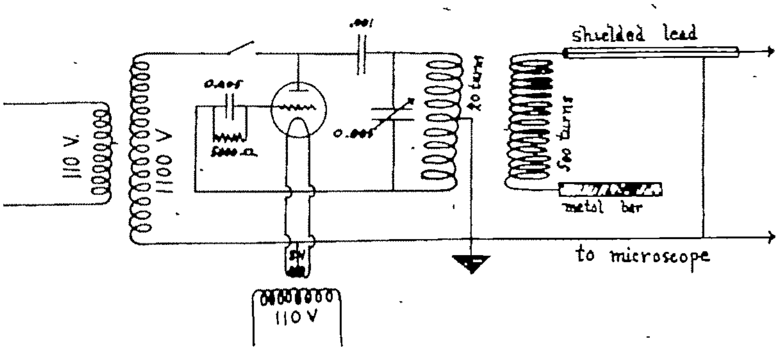

FIG. 1.

Using such an oscillator and placing the material to be treated in test tubes which were subjected to the vibrations, Wood and Loomis caused the rupture of filaments of Spirogyra, the tearing of Paramœcium and the laking of red blood corpuscles. This latter effect is very striking, defibrinated mammalian blood corpuscles in physiological salt solution laking completely in one minute before the average temperature of the fluid had risen to 37° C. They also noted the killing of small fish and frogs, but the cause of death was not determined. Using the same high-powered oscillator, we have taken small organisms like Euglena or Paramœcium and enclosed them in capillary tubes sealed at the ends. When one end of such a tube is subjected to intense vibrations the organisms are thrown in piles regularly spaced (about 2 mm. apart, depending on the diameter of the capillary) along the tube, from which they are unable to swim. These piles represent nodes of *transverse* vibrations set up in the capillary. It is not that the organisms swim into these nodes but they are passively carried into the nodes, and fortunately so, for between the nodes they would be subjected to mechanical tearing that would disintegrate them. Thus, red blood corpuscles in a capillary tube are thrown into the nodes and quite unharmed by ten minutes' exposure to radiation, whereas the same corpuscles in a test tube, where convection currents carry them about, are laked in one minute. Even luminous bacteria and particles of gamboge form striæ in capillary tubes, but colloidal particles (as of benzo-purpurin, arsenic sesquisulphide, or ferric hydroxide) do not.

An emulsion of luminous bacteria in sea water in a test tube, exposed to radiation until the temperature rose from 1·5° to 21·5°, luminesces considerably less brightly than a control tube heated from 1·5° to 21·5°. The turbidity is also less in the irradiated tube, indicating that some of the bacteria have undergone cytolysis. Control experiments showed that the dimming was not due to the electric field. The luminescence of a mixture of Cypridina luciferin and luciferase was unaffected by irradiation in any way that could not be accounted for by rise in temperature.

One might expect that high frequency mechanical vibrations, carrying as much energy as they do, would be capable of stimulating muscle or nerve tissue. All attempts to demonstrate a stimulating action have failed. The sciatic nerve of a frog connected with the gastrocnemius muscle may be touched (either nerve or muscle) to a test tube violently oscillating or be immersed in a salt solution in such a test tube without stimulation and without injury. Both nerve and muscle are later found to be quite irritable to electrical stimuli. The high tension field is unable to stimulate because of its high frequency. A bull frog's heart mounted in Ringer's solution in a test tube touching the oil and connected with a heart lever for recording movement, shows no peculiarities of the contraction, but an irregularity and usually a slowing of the rate, despite the rise in temperature that accompanies the irradiation. Further observations will be necessary to analyse these peculiarities.

Obituary.

MR. W. B. CROFT.

WILLIAM BLEADEN CROFT died at Winchester on Mar. 23 at the age of seventy-six years. Born in 1851, the sixth son of a surgeon, Mr. C. I. Croft, he went to Christ's Hospital, and thence as a scholar to Pembroke College, Oxford, and obtained first classes in the schools of mathematics and natural science, besides rowing bow in the Pembroke boat at the head of the river.

Croft was a very remarkable man. He was appointed mathematical and then science master at Winchester College in 1874, but for the last twenty years of his service he taught only physics. He retired in 1915. During all this time he never missed an hour's teaching through ill-health. He was a fellow of the Physical Society, at the meetings of which he was a regular attendant, and was elected to the council in 1903. He served several times on the committee of Section A of the British Association, and examined for the final honours school in natural science at Oxford.

Croft took little interest in chemistry, but he was a born physicist. Had he been trained in one of the great university schools of to-day, he would have achieved a fame far beyond that which fell to his lot. He had the gift of a vivid scientific curiosity, an uncanny power of pitching upon the first hint of a new discovery before others were fully awake to its importance, and a talent for experiment that almost amounted to genius. He was a constant reader of NATURE and other scientific periodicals, and he carefully cut out articles and pasted them into scrap-books, which he filled with comments and annotations. If anything struck him as likely to lead further, he at once got into touch with the writer of the article or letter, and repeated for himself any experiments that could be compassed in his laboratory, developing them in promising directions. Thus, for example, it came about that he was the first man in England to make a Branly coherer and to perform further experiments with Hertzian waves.

Croft was always at work on phenomena of common occurrence, and never rested until he, and some special pupils, understood its physical significance. Did a question arise about bells or fiddles? Croft set to work immediately upon the fundamentals and harmonics of college bells, and called in the assistance of the musical staff. His photographs of diffraction phenomena were extraordinarily good, and still enrich the pages of Edser's "Light for Students." Light and sound were perhaps his chief interests, but he did good work in electricity also.

A teacher for the few rather than the many, to those of his pupils who by diligence and aptitude proved themselves worthy of the meticulous care which he bestowed upon his lectures, Croft imparted all that they could receive of his knowledge of and reverence for science, and his gift of seeing the essential and planning an experimental approach; and he kept touch with them in after years. A permanent memorial of him is left in the collection of interesting apparatus which he gathered in the College laboratory; but above all, he will be remembered by his pupils, his colleagues, and his many friends for infinite courtesy and thoughtfulness. He leaves a widow, three sons, and a daughter.

WE regret to announce the following deaths:

Prof. Wilhelm von Branca, emeritus professor of geology and palæontology in the University of Berlin, distinguished for his work on the evolutionary history of man and other animals and for work on the development of flight, on Mar. 12, aged eighty-three years.

Prof. Elmer E. F. Creighton, of the General Electric Co., Schenectady, a well-known consulting electrical engineer, on Jan. 13, at the age of forty-nine years.

Mr. Alexander E. Outerbridge, of the William Sellers Company, professor of metallurgy at the Franklin Institute, known for his work on the molecular physics of iron, on Jan. 13, aged seventy-seven years.

Mr. E. A. Reynolds-Ball, author of many travel and guide books, including "Mediterranean Winter Resorts," aged sixty-nine years.

M. Emile Senart, president of the Société Asiatique of Paris and an honorary fellow of the Royal Asiatic Society of Great Britain, and author of "Les Castes dans l'Inde," on Feb. 21, aged eighty years.

Mr. G. Chisholm Williams, a distinguished pioneer in the medical use of X-rays, on April 10, aged sixty-three years.

Supplement to NATURE

No. 3051 APRIL 21, 1928

The Physical Basis of Light Therapy.[1]

By Prof. F. Ll. Hopwood.

The Spectrum of Radiation.

THE visible spectrum is only a small portion of the complete spectrum of ethereal waves. Beyond the violet with progressively decreasing wave-lengths, come successively the radiations called 'ultra-violet,' soft X-rays, hard X-rays, the gamma rays of radium, and the very penetrating radiation, the so-called cosmic rays, which have only recently been proved to be of extra-terrestrial origin. Similarly, beyond the red, in progressively increasing wave-lengths, come in turn infra-red and the Hertzian waves used in radio communication.

Table I. gives the approximate wave-lengths of the various radiations, but it must be noted that the divisions are quite arbitrary and that the various regions may overlap ; differences in properties arise solely from differences in wave-length.

Table I.

Type of Radiation.	Approximate Range of Wave-lengths.
Hertzian waves	40 kilometres to a few centimetres.
Infra-red	A few millimetres to 7000 A.
Visible spectrum	7000 to 4000 A.
Near ultra-violet	4000 to 3000 A.
Middle ultra-violet	3000 to 2000 A.
Far ultra-violet	2000 to 1000 A.
Soft X-rays	100 to 1 A.
Medium and hard X-rays (used in diagnosis and therapy)	0·2 to 0·05 A.
Gamma rays from radium C.	0·02 to 0·001 A.
Cosmic rays	0·0005 to 0·0003 A.

Note.

1 A. = 1 Angstrom unit = one hundred-millionth of 1 cm. $= 10^{-8}$ cm.

$1\mu = \frac{1}{1000}$ millimetre

$1\mu\mu = \frac{\mu}{1000} = 10$ A.

Light used in Therapy.

Both natural and artificial sources of light are used for therapeutic purposes, and considerable differences of opinion exist as to their relative merits. These differences arise very largely from the fact that the relative distribution of energy amongst the infra-red, visible, and ultra-violet portions of the spectra of the different sources varies over wide limits.

Numerous observers have noted the close parallelism between pigmentation due to exposure to light and beneficial therapeutic results. Experiment has shown that the solar radiations which are most active in producing pigmentation of the skin and hæmobactericidal effects are those between 2900 and 3000 A., or, in other words, those which are situated in the middle ultra-violet part of the spectrum. Infra-red and visible radiations may certainly influence the rate at which these effects are produced, but in general cannot themselves produce them.

On account of the spectral region used and the effects produced, light therapy is often called 'ultra-violet light treatment,' 'phototherapy,' or 'actinotherapy.' More often these terms are used in connexion with artificial sources of light to distinguish such treatment from 'heliotherapy,' or sunlight treatment.

Sunlight.

The natural source of ultra-violet radiation is the sun. The spectrum of sunlight after filtration by the earth's atmosphere extends continuously from the infra-red to the middle ultra-violet regions (30,000 to 2900 A.), but its limits are influenced by the seasons, height of the sun above the horizon, altitude of the place of observation, water vapour content of atmosphere and atmospheric pollution. The lower the sun is in the heavens, the greater is the length of path through the earth's atmosphere that its radiations have to traverse, and the resulting absorption considerably shortens the range of the spectrum. The intensity of its ultra-violet radiation reaches its maximum about one hour after midday on a clear day. Dull, cloudy weather, coupled with atmospheric pollution due to smoke and chemical fumes, may practically reduce to zero the intensity of these active rays in the neighbourhood of a large city.

It is important to note that the total ultra-violet radiation from the sky is more than that from the direct sun. Even with the sun at its zenith the ultra-violet radiation from it does not exceed 90 per cent. of that from the blue sky, whilst with a low sun the sky yields far more. This addition to the amount of ultra-violet radiation which a patient receives from the direct sun is due to the scattering of the sunlight by the smallest particles of the atmosphere. The effect is the more pronounced the shorter the wave-lengths involved. As Rayleigh has shown, the amount of energy scattered by a particle of given size varies inversely as the fourth power of the wave-length, and consequently the phenomenon exhibits itself more in the ultra-violet than in the visible spectrum. Thus—a fact of great practical importance—it is not essential to be exposed to the direct sun in order to receive the benefits of heliotherapy.

---

[1] Reprinted, after revision and with additions, from *St. Bartholomew's Hospital Reports*, 1926.

The above considerations show us that treatment by natural sunlight (heliotherapy) is intimately associated with geographical and climatic conditions. In the Alps, at altitudes of above 5000 ft., pure, fresh, dry air and an almost constant daily supply of sunlight are easily obtainable, whereas in England the sun appears only erratically, and its ultra-violet component varies rapidly within wide limits, rendering dosage difficult and regular treatments impossible. For these reasons, artificial sources of radiation have been developed by which constancy of output can be strictly controlled.

ARTIFICIAL SOURCES OF ULTRA-VIOLET RADIATION.

All the artificial sources of light used for therapeutic purposes are heterochromatic (that is, emit a broad band of wave-lengths), since, up to the present, no one has designed a practicable source of monochromatic radiation of sufficient intensity to be of definite therapeutic value.

The chief sources of ultra-violet radiation are electric arcs. Incandescent electric lamps with their bulbs made of fused quartz or of glass manufactured for its special transparency in this region of the spectrum (such as vita-glass) are occasionally used for some purposes, but their low energy output makes their general use impracticable.

The arc-lamps usually employed are of two types, namely, (*a*) open arcs, and (*b*) enclosed arcs.

(*a*) Open arcs have electrodes of iron, tungsten, metallic alloys, or carbon. Carbon electrodes may be either solid, 'neutral cored,' or 'impregnated.' Neutral cored carbon electrodes have a soft core of carbon powder mixed with a small amount of some substance such as potassium silicate to ensure quiet, steady burning. Impregnated carbon electrodes have mixed with the carbon powder, either salts of various metals, powdered metals, or a central wire core. Thus 'white flame' carbon electrodes usually contain the fluorides of the rare earths obtained as residues from monazite sand; 'blue flame' carbons contain iron. The ultra-violet radiation emitted by these arcs varies greatly with the chemical composition of the electrodes and the current between them. A high current density is necessary for high efficiency.

(*b*) Enclosed arcs are mercury vapour lamps with fused quartz (not glass) envelopes.

All these lamps produce ultra-violet radiation of sufficient intensity and satisfactory quality for therapy. Each differs from the rest in spectral range and has its special advantages and defects.

One of the varieties of carbon arc is usually employed in institutions when group treatment is given, and a mercury vapour lamp for individual or localised treatment. The order of the maximum relative percentage of ultra-violet radiation of wave-lengths less than 3200 A. in the total radiation emitted by the above sources, is

Mercury arc.
Impregnated carbon arc.
The sun.
Neutral cored carbon arc.
Incandescent electric lamp.

The radiation from the neutral cored, or solid electrode carbon arc is similar to that of the sun, in that it is relatively weak in radiation of wave-lengths less than 2900 A. It is, however, strong in infra-red radiation of wave-lengths longer than 30,000 A., which the earth's atmosphere has eliminated from the solar rays.

Special dispositions are required to maintain metallic arcs on an alternating current supply.

We know that radiations from the middle ultra-violet region can exert marked bactericidal properties *in vitro*, and also 'activate' certain substances such as ergosterol, etc., in such a manner that when ingested they tend to cure rickets. We also know that the bactericidal power of the blood is enhanced, and the mineral metabolism promoted, when the living animal is subjected to these rays. Some effects, such as the erythema following irradiation, only appear after an interval of time—called the 'latent period'—has elapsed since the exposure terminated. How these effects are produced is not known with certainty, and light therapy is still mainly empirical.

PHOTO-ELECTRICITY.

For every substance there are radiations which will cause some of its atoms to eject electrons and consequently leave the stripped atoms positively charged. This phenomenon is called ionisation or photo-electric emission. For it to occur, it is only necessary that the wave-length of the incident radiation should be less than a critical or threshold value, which is characteristic of the atom ionised. For most substances the critical wave-length lies in the ultra-violet spectral region, but for some it occurs in the visible spectrum, and for cæsium is actually in the infra-red region (see Table II.). The wave-length which will cause maximum emission of electrons from any element is approximately two-thirds of the critical wave-length for that element, and for sodium, potassium, and cæsium lies in the visible spectrum. The velocity of emission of photo-electrons depends on the wave-length of the exciting light, whilst the number emitted depends upon the intensity of the light.

TABLE II.

Element.	Critical Wave-length in A. for Photo-electric Effect.
Graphite . . .	2615
Copper . . .	2665
Selenium . . .	2670
Iron	2870
Cadmium . . .	3130
Zinc	3425
Sodium . . .	6000 (about)
Potassium . . .	7000 ,,
Cæsium . . .	8000 ,,

As the emission of photo-electrons from an illuminated surface is very susceptible to the presence of condensed surface films of gas or vapour, it is necessary for reproduction of photo-electric effects that the surfaces be prepared, and maintained, in high vacua.

FLUORESCENCE AND PHOSPHORESCENCE.

Certain substances, when stimulated by radiation of one wave-length, emit radiation of a different wave-length. If the emission only appears whilst the stimulus is being applied the phenomenon is called fluorescence, but if it persists after the stimulus has ceased it is called phosphorescence.

Phosphorescence is only exhibited by solids: fluorescence by solids, liquids, and gases. Although Stokes stated that fluorescent light was always of longer wave-length than the exciting light, we now know that this rule, though generally valid, is not invariable.

Fluorescence is caused by the return to a more stable position in an atom, of, electrons displaced by the exciting radiation.

PHOTO-CHEMICAL ACTION.

That chemical action can be brought about by light has been known for a very long time, and is familiar to everyone through photography. Photo-chemical actions are usually divided into three classes, namely:

(*a*) Photo-catalytic actions in which light only accelerates an irreversible process. Here the light cannot be regarded as stored up in the transformed substance as chemical energy. The action only occurs in the presence of a catalyst. Thus, in the presence of colloidal uranium, formaldehyde may be synthesised from carbon dioxide and water, by exposure to sunlight. Without the uranium no formaldehyde is formed.

(*b*) True photo-chemical equilibria in which the equilibrium of some reversible reactions is altered by light, and again brought back to the initial state on standing in the dark. (Compare the behaviour of a selenium cell which conducts electricity better when illuminated than in the dark.)

(*c*) False chemical equilibria, which are irreversible processes composed of two or more photo-catalytic reactions.

In certain cases the initial action of radiation is to decompose some substance (called a 'negative catalyst') which hinders the chemical action which takes place some time after the irradiation of the system has proceeded (cf. erythema and pigmentation).

Photo-chemical actions are subject to the following two laws:

Grotthus's Law.—Radiation must be absorbed in order to bring about the reactions which it produces.

Bunsen-Roscoe Law.—The amount of substance decomposed by radiant energy is proportional to the amount of radiant energy absorbed—that is, is proportional to the product of the intensity of the radiation, by the time for which it is applied.

In connexion with the above, it should be noted that radiations of different wave-lengths may produce different actions on one and the same substance. It appears to be a fairly general rule that of two radiations which produce opposite effects, it is the longer wave-length which produces the oxidising action and the shorter wave-length the reducing action. The decoloration, by infra-red rays, of glass which has been coloured by ultra-violet rays, illustrates this.

Several writers have claimed that they have detected a similar opposing action, or physiological interference, of infra-red and ultra-violet radiations in the production of erythema of the skin, or the immobilising action on bacteria *in vitro*. These observations, which have not yet been confirmed beyond doubt, are of great interest from the point of view of choice of an artificial source of radiation and the measurement of dose.

Unlike most chemical reactions, in which rise of temperature produces a marked increase in the velocity of reaction, the effect of temperature on photo-chemical reactions is usually very small.

ABSORPTION, TRANSMISSION, AND REFLECTION.

Certain substances strongly absorb light corresponding to some parts of the spectrum, and transmit the remaining light unchanged. This phenomenon is called selective absorption. It produces dark bands, called absorption bands, in the spectrum of the transmitted light.

Absorption bands are characteristic of the absorbing substances and serve to identify them by examination with a spectroscope, for example, the bands of hæmoglobin and chlorophyll.

By making use of the selective absorption bands of different substances, it is possible to make light filters which will transmit narrow bands of wave-lengths in chosen parts of the spectrum.

The reflecting, transmitting, and absorbing powers of a substance for light in the visible spectrum give no trustworthy indication of these properties for radiations in the infra-red or ultra-violet regions.

The percentage penetration of *dead* human skin by ultra-violet radiation is given in Table III., which records some measurements by Hasselbalch.

TABLE III.

Thickness of dead skin in mm.	Wave-length in A.						
	4360.	4050.	3660.	3130.	3020.	2970.	2800.
	Per cent	Per cent.	Per cent	Per cent	Per cent	Per cent	Per cent.
0·1	59	55	49	30	8	2	0·01
0·5	7·0	5·0	3·0	0·3	—	—	—
1·0	0·5	0·3	0·08	0·006	—	—	—

The practically negligible penetrative power of the biologically active ultra-violet rays indicated by this table is very marked. Definite clinical evidence is available, however, which shows that ultra-violet radiation of wave-lengths shorter than 2900 A. can produce marked physiological effects. The difficulty of explaining these effects by any direct or indirect action has recently been considerably lessened by the work of Macht and his co-workers. These investigators have shown that the penetration of ultra-violet radiation into *living* tissue is greater than for dead tissue. This is brought out by comparing the figures in Table III. with those published by Macht and summarised in Table IV.

TABLE IV.

(Transmission of monochromatic ultra-violet radiation through living animal tissue, 1·175 mm. thick.)

Wave-length in A.	4050	3660	3130	3025	2800	2650	2537
Transmission (per cent.)	16·3	11·4	19·5	27·2	56·3	23 8	42·8

Infra-red and luminous rays can penetrate more deeply than ultra-violet rays. Sonne has shown that the luminous rays can produce a greater elevation of temperature below the skin than the infra-red rays, and asserts that this heating effect due to absorbed luminous rays assists in the destruction of toxins and formation of antibodies.

Ordinary window glass transmits a portion of the ultra-violet nearest the visible region of the spectrum, but cuts out completely all wave-lengths less than 3100 A. It thus absorbs all the solar radiation which produces pigmentation, etc. Fused quartz and water transmit ultra-violet radiation quite freely down to wave-lengths of about 2000 A. Corning glass 980 A. transmits all solar radiation almost as freely as the more expensive fused quartz. Vita-glass resembles Corning glass 980 A. in its properties, but is not so transparent for equal thicknesses, and also exhibits some deterioration in transmission after exposure to sunlight.

'Wood's' glass, which cuts out most of the visible spectrum, transmits a band of wave-lengths in the near ultra-violet region about 3600 A. and is therefore useful for fluorescence experiments.

Snow is a good reflector of ultra-violet radiation, and snow-blindness is due to the reflection by it of the short waves of sunlight.

Polished surfaces of magnalium, nickel, and aluminium make the best reflectors of the middle ultra-violet region of the spectrum for ordinary purposes; silvered mirrors are much poorer.

The biological effect produced by uninterrupted exposure to ultra-violet radiation appears to be directly connected with, and in proportion to, the energy absorbed (Bunsen-Roscoe Law). The intensity of the incident radiation and the time of exposure are the external quantities, and the absorption coefficient of the skin the internal quantity, which determine the quantity of energy absorbed, and therefore the biological effect.

It has already been pointed out that all sources of radiation used in light therapy are heterochromatic, and that radiation from them is absorbed differentially by the skin. Reference has also been made to

Sonne's assertion concerning the effects of luminous rays, and also to the possibility of antagonistic action between infra-red and ultra-violet rays. Throughout this article it has been assumed that exposure to *ultra-violet* radiation is essential for the production of the recognised benefits of light treatment. This assumption seems to be perfectly in agreement with experience. What is not yet satisfactorily settled is whether (and if so, what) other wave-lengths are also useful or harmful.

It is this lack of knowledge which renders the physical measurement of the therapeutic efficiency of an arc-lamp uncertain.

DETERMINATION OF QUALITY.

The quality of the radiation emitted by a given source may be determined by passing the radiation through a spectroscope and examining the emergent beam. As glass absorbs both infra-red and the middle and far ultra-violet rays, it cannot be used for this work, and therefore the prisms and lenses used are of quartz or rock-salt.

For the visible and ultra-violet regions down to wave-lengths less than 2000 A., this examination may be done by direct observation, the rays in the ultra-violet being detected by the visible fluorescence caused either in uranium glass or in a smear of vaseline. Alternatively, these regions may be recorded on a photographic plate. For the infra-red spectrum we must use one of the methods mentioned later. When examined by any of the above methods, it will be found that whereas the spectra of tungsten and mercury consist mainly of bright lines, that of pure carbon is practically a continuous one, being similar in character to the solar spectrum. From the known constants of the apparatus, or by making use of reference lines of known wave-lengths, it is possible to determine the range of wave-lengths in a spectrum and the wave-lengths of any bright lines in it.

DETERMINATION OF INTENSITY.

In determining the intensity of radiation proceeding from a source and falling on a surface, we have to decide which of the following three quantities we wish to measure:

1. The total intensity.
2. The intensity of a group of radiations of differing wave-lengths.
3. The intensity of the radiation of a single wave-length.

In measuring the total intensity, no preliminary analysis of the radiation is required. To measure the intensity of a group of radiations, either colour filters must be used to isolate it, or some instrument employed which is only sensitive to radiations in the given region.

For the measurement of the intensity of the radiation of a single wave-length, the total radiation is first resolved by means of a spectroscope and the particular radiation caused to pass through a narrow slit to the measuring instrument.

Whichever of the three intensity measurements is to be made, the following methods are available: (*a*) Thermal, (*b*) fluorescent, (*c*) chemical, (*d*) electrical.

THERMAL METHODS.

Either a thermopile or bolometer may be used.

The thermopile consists of a number of thermocouples or pairs of electrical conductors of different metals, and is used joined in series with a galvanometer. Whenever one junction of a thermocouple has its temperature raised above that of the other, an electric current will flow through the galvanometer. By allowing the radiation to fall on the junctions of a thermopile which have been covered with lamp-black and by using a sensitive galvanometer, measurements may be made over the complete range of wave-lengths used in light therapy.

The bolometer consists essentially of a blackened fine metallic wire the rise in temperature of which, when radiation falls upon it, alters its electrical resistance. This change in resistance, when measured by suitable means, gives the intensity of the absorbed radiation. The sensitiveness of both thermocouples and bolometers is increased by mounting them in evacuated vessels to reduce the cooling effect of the surrounding gas.

FLUORESCENT METHODS.

In practice these methods are only applicable to measurements made in the ultra-violet region. They depend upon the fact that the intensity of the fluorescent light emitted by such substances as barium-platino-cyanide and zinc sulphide is directly proportional to the intensity of the exciting radiation.

CHEMICAL METHODS.

A great variety of photo-chemical reactions have been proposed and used for measuring either total or ultra-violet radiation. The effect most frequently used is the reduction of silver chloride as in photography. Here, instead of weighing the silver liberated, the resulting blackening is used as a measure of intensity, either by finding the time necessary to produce a standard blackening, or the blackening produced in a definite time.

Leonard Hill has devised a system of measurement of the ultra-violet radiation of wave-lengths shorter than about 3600 A. by making use of their bleaching effect on a solution of methylene blue in acetone.

The standard solution is exposed in a quartz tube and the 'exposure' measured by comparing its tint with some standard tints calibrated in terms of the lethal effect on infusoria. The scale adopted is quite an arbitrary one.

Janet Clark has suggested using the blackening effect of ultra-violet radiation on lithopone (a pigment containing zinc oxide, zinc sulphide, and barium sulphate) for intensity measurements. This substance, when moistened with water, darkens under the influence of rays of wave-lengths less than 3200 A. It thus appears to afford a simple colorimetric method of measuring those rays which can produce an erythema of the skin.

ELECTRICAL METHODS.

These generally make use either of the photoelectric property of some metal—generally zinc or cadmium—or the fall in electrical resistance of selenium when illuminated. A glance at Table II. will show what metal is best suited to the particular radiation to be measured. In principle, a photoelectric cell consists of an insulated plate of metal connected to an electrometer or gold-leaf electroscope, the system being negatively charged. Under the influence of a suitable radiation, the plate loses its charge at a rate dependent upon the intensity of the radiation.

The action of a 'selenium cell' is somewhat different. As ordinarily used, the change of resistance of the cell when illuminated is measured by the change in current through a microammeter connected in series with the cell and an energising battery. This effect can be produced by infra-red, visible, ultra-violet, Röntgen, and gamma radiations, and is not the normal photo-electric effect.

It is easily seen that any of the instruments described above can readily be used to give a trustworthy check on the emission of a given source at different times. Their value in comparing the different emissions of different sources is not quite so certain.

INVERSE SQUARE LAW.

The intensity of the radiation falling on a surface can only be assumed to diminish according to the law of inverse squares (1) when the active dimensions of the source are small compared with its distance from the surface, and in addition (2) when no reflector is used.

DANGERS AND PRECAUTIONS.

Three common sources of danger in connexion with the use of artificial sources of ultra-violet radiation, and the precautions necessary to avoid them, are :

(1) The production of a severe conjunctivitis, through looking directly at an arc. Operators and patients should always wear protective goggles or shades.

(2) Over-exposure through continuing a course of treatment after replacing an old mercury vapour arc-lamp by a new one, or substituting different electrodes in an open arc. An intensity measurement should always be made when using a new source.

(3) Electric shock through touching 'live' electrical conductors. Several fatalities have occurred through the use of electrical apparatus in bath-rooms, where the conditions for short circuiting the supply through the body are almost ideal.

No installation should be set up in such a position that a patient can touch a 'live' electrode and a water-pipe or 'earthed' conductor at the same time. It is advisable to use a floor covering of linoleum or carpet.

CONTRA-INDICATIONS TO LIGHT THERAPY.

In addition to the purely physical dangers mentioned in the last paragraph, there are many physiological and pathological conditions—such as menstruation in women, low blood pressure, fever, hyper-photo-sensitiveness, etc.—which are contra-indications to the therapeutic use of ultra-violet radiation. The discussion of these lies outside the scope of the present article.

Biological Action of Ultra-Violet Rays.

By Prof. LEONARD HILL, M.B., F.R.S.

RADIATIONS from sources of energy—sun, stars, etc.—are conducted by waves in a hypothetical ether with a velocity of 186,000 miles per second in the case of light. Ether radiations include the Hertzian waves used in radio with wave-lengths extending to a thousand metres or more, then the infra-red, with wave-lengths from 60,000 to 700 $\mu\mu$, then the visible with wave-lengths from 700 $\mu\mu$ (red) to 400 $\mu\mu$ (violet). Beyond the visible lie the invisible ultra-violet rays with wave-lengths from 400 $\mu\mu$ to 100 $\mu\mu$, and beyond these come the soft X-rays and then the hard X-rays and the rays of radium with wave-lengths so short as 0·01 $\mu\mu$.

The body of a man is screened by the horny layer of the epidermis, varying in places from some 0·02 to 0·5 mm. thick, beneath which lie the living cells of the epidermis in layers of corresponding thickness to the thin horny layer. These cells are myriad in number, and are naturally exposed to the influence of light in wild naked men. Beneath these comes the derma or true skin, in which circulates the blood through close woven networks of capillaries, in streams some 0·01 mm. thick. Among the living cells of the epidermis and in the derma are nerve endings. The epidermis reflects and scatters a part of the rays which fall upon it, but some of the visible rays penetrate and are absorbed by the blood beneath, warming this. The infra-red rays, on the other hand, are absorbed by the least layer of water; caught therefore by the wet layer of the epidermis, they warm this and warm the blood in the derma indirectly by conduction. The biologically active or middle ultra-violet rays are also very largely absorbed by the epidermis, and exert their effect there. The shorter ultra-violet rays, powerful to kill microbes, fail to penetrate the horny layer and so have no action on the skin. The longer ultra-violet rays, like the visible rays, reach the blood in the capillaries of the derma and are converted into heat.

The skin screens itself from excessive light by its horny layer and by pigment. The horny layer is thickened by ultra-violet rays killing the living cells of the epidermis, and protection is thus quickly afforded from sun burning. Pigment lying in the deeper cells of the epidermis, by absorbing visible and ultra-violet rays, screens these deeper cells and the blood in the derma. It converts visible rays into heat, and this heat, stimulating the nerve endings in the skin, may reflexly lessen body heat production while increasing body heat loss by provoking sweating and dilatation of cutaneous blood-vessels. Increased transpiration of water is the chief method of warding off excessive radiant heat when shade is not available. The increase of heat and transpiration by the visible rays is important in the treatment of wounds, etc.

The sterilising power of the ultra-violet rays, first established by Downes and Blunt (1877), is not nearly so important as has been thought, for the rays can only kill the surface bacteria; they cannot penetrate into filth any more than through the epidermis. Tubercle bacilli rotated in serum in a quartz flask under a mercury vapour lamp are not killed, so great is the protection afforded by the proteins of the serum which absorbs the ultra-violet rays (Eidinow). In the case of tissues or infusoria screened by mesentery, there is a partial, by the skin complete, protection from the lethal action of ultra-violet rays. The penetration of the biologically active ultra-violet rays is not more than 0·25 mm. in an organ exposed to the mercury vapour lamp for an hour or two, as is demonstrated by the depth of the lesion thereby produced.

The intensity of illumination received from a point source of light is inversely proportional to the square of the distance from the source. The law is only accurate from a source sufficiently small or far enough off to be treated as a point. It does not hold for sources with reflectors behind or lenses in front of them. Only those rays which are absorbed exert an effect. When light passes through a layer of absorbing substance, the fraction transmitted depends on the nature and thickness of the substance and the wave-length; the transmission coefficient is the fraction transmitted by a layer 1 cm. thick.

If light passes two absorbing layers successively, the final fraction transmitted can be calculated by multiplying together the fraction transmitted by each layer alone. Thus, if each layer transmits 1/10th, two in succession transmit 1/100th. Epidermis 0·1 mm. thick transmits about 1/10th, and therefore epidermis 0·2 mm. thick transmits only 1/100th of the amount of active ultra-violet rays.

The biologically active region of the ultra-violet rays is round about 300 $\mu\mu$. Hausser and Vahle, using equal energy values, found the maximal erythema effect at 297 $\mu\mu$. Four per cent. of this effect was found at 313 $\mu\mu$ and 16 per cent. at 256 $\mu\mu$. The longer ultra-violet rays are little absorbed by the epidermis, and so have little action; the shorter ones are very active, but are absorbed by the horny layer of the epidermis and so do not reach the living cells. Owing to the absorption by the horny layer of the epidermis and its screening action, the living cells beneath are protected from the short ultra-violet rays of artificial sources which penetrate into and are most powerful in killing microbes, infusoria, and ciliated cells of the wind-pipe. The ultra-violet rays of the sun extend scarcely beyond 300 $\mu\mu$, and the sun exerts its sun-burning action by ultra-violet rays longer than those of artificial sources such as the long flame metal cored carbon arc or mercury vapour lamp, the active rays of which are mostly of wave-length shorter than 300 $\mu\mu$. Vita-glass lets 75 per cent. of the active ultra-violet rays of the sun through, but largely reduces the active rays of the mercury vapour lamp, so that the lethal exposure for infusoria is made much longer when this screen is interposed. The rays which activate ergosterol and form vitamin D are in the region of about 280-300 $\mu\mu$; it is, then, clear skies and high sunlight, which afford rays about 300 $\mu\mu$, having this effect.

Mist, smoke-pollution, glass windows, walls and roofs, and clothes, cut out the sunlight and deprive us of the effect which the sun naturally exerts on naked wild men and animals, for example, on ergosterol, which, eaten in the food, is present in the skin, and there awaits activation into vitamin D by sunlight. It must be borne in mind that the bright sky shine is a source of ultra-violet rays, affording more (from the whole sky) than the high sun affords directly. Owing to this fact, cool ultra-violet treatment can be had from the sky without exposing febrile patients to the direct hot sun. Skyshine and earlier morning sun can be used by febrile cases of tuberculosis. To heat such patients is a disadvantage, hence the excellence of the alpine climate. Exposure to cold air stimulates the tone of the muscles and the appetite, and works, under proper control, as much good on the naked body as light does.

Rickety, weakly children kept in an open-air shed without artificial heat throughout the winter do wonderfully well, and become robust and full of life and energy. The clean cool air, absence of crowd-infection, and indoor dust, heat, and noise, work their good effects as well as light. It must always be borne in mind that the open cool air is at least as important as light in treatment of tuberculosis, wounds, etc.

We can take in vitamin D from cod-liver oil, or nowadays eat it in tabloids, the product of laboratory irradiation of ergosterol.

Not only rickets, but also osteomalacia, prevalent in the purdah women of Kashmir (Vaughan), is due to want of sunlight and vitamin D. With rickets go decay of teeth, liability to catarrhal and low infections. Open-air treatment and ultra-violet irradiation are powerful to prevent these troubles. In fowls kept under glass, ultra-violet irradiation improves the egg laying and hatching, and prevents leg weakness of chicks. Similarly, it improves the stamina and milk of cows kept in byres.

In the treatment of surgical tuberculosis and wounds, carbon arcs have advantages in yielding abundantly visible and infra-red rays as well as the ultra-violet rays. The mercury vapour lamp is relatively a cold source, but incandescent lamps can be added to it so as to make good the deficiency. The monkeys, iguana lizards, and tortoises at the Zoo do well under incandescent lamps. The monkeys are also given access to open air. The conversion of visible light into blood heat is most important to all these animals. The lizards, heated up by the visible rays of the lamps, become active, hot-blooded animals as they naturally do by day under the tropical sun. Babies exposed naked under incandescent lamps and given also exposure to cool open air, would thrive as well as the monkeys do, the diet chosen being of course one fully provided with the necessary vitamins, and those other qualities required for growth and health.

The ultra-violet rays reaching the living cells of the skin and absorbed therein, cause change in atomic structure (displacement of electrons from their orbits with consequent rearrangement of molecules), which result in chemical changes ending in coagulation and death. The increasing granulation of the protoplasm of infusoria can be observed under the microscope when these animals are exposed in a water-cooled quartz chamber to the mercury vapour lamp. The same sort of change is produced whether longer or shorter wave-lengths of the active region of ultra-violet rays are used to kill. There is no evidence of specific changes set up by one or other of the different wave-lengths absorbed by the skin, other than possibly in the case of activation of ergosterol. There is no evidence that one group of the active ultra-violet rays is more or less harmful to living cells than another; the result depends on penetration and absorption. Given a sufficient dose of rays absorbed, coagulation and death takes place. The damage of the living cells in the skin produced by sunburn provokes secondarily a local hyperæmia, œdema, and leucocytosis, followed by desquamation and pigmentation. The inflammatory reaction increases the power of the blood to kill staphylococci as tested *in vitro*. In some way, as yet unexplained, it provokes better feeling of health and vigour, but overdosage may have the opposite effect. The inflammatory reaction helps the skin to recover from infections such as lupus. This terrible disease is cured by local and general light baths. Surgical tuberculosis is benefited by light and open air.

The ultra-violet rays can be used successfully for certain affections of the eye as well as skin, but all this is the province of the medical practitioner skilled in such treatment. By the general public light baths should only be used in mild doses for taking the place of natural sunlight. The body can conveniently be divided into four parts: 1, front of body; 2, back of body; 3, front of legs; 4, back of legs. One part is bathed at a time. Two baths a week suffice. Using a long flamed arc with iron-cored carbons or a mercury vapour lamp, a 5-minutes' exposure, 2 ft. away, suffices. Large doses result in a thickened horny layer and pigmentation which prevents the reaction of the skin. It may be as well to intermit the light bath for a month at the end of two months, and then start again. If a vita-glass screen is used, the artificial sources are made more to resemble sunlight and much safer to use. Overdosage can do more harm than good.

The Physiological Action of Ultra-Violet Radiation and its Use in the Home.

By W. Kerr Russell, M.D., B.S. (Dunelm).

THE founder of the science of actinotherapy was Finsen, and he published his first paper on the subject of ultra-violet radiation in 1893. His efforts were directed to the cure of lupus (the wolf), that disfiguring disease of the skin caused by the tubercle bacillus, a disease which so often causes those attacked by it to hide themselves away in order to avoid the gaze of their fellows. This new local form of treatment devised by Finsen was a wonderful success, and it was only Finsen's early death, at the age of forty-three years, that prevented him from carrying out other most important applications of the treatment. He left at his death the complete designs for a clinic in which investigations were to be undertaken for the purpose of ascertaining more exactly what affections would lend themselves to treatment by general light baths, and among the diseases in which this treatment was to be used, he expressly mentioned tuberculosis.

Describing his proposed carbon arc bath, Finsen said it consisted of a circular room in the middle of which were two gigantic arc lights of 100 amperes, suspended about six feet from the floor; by numerous radiating partitions, bath chambers were arranged in which the patients could lie naked on couches. It was, however, only after a visit to Switzerland, where Reyn, Finsen's brother-in-law, saw the successful work of Bernhard and Rollier in the cure of extra-pulmonary tuberculosis by regulated exposure to the sun's rays, that he instituted the general light bath treatment at the Finsen Institute in 1913. Then came the War, and though it is true that hundreds of thousands of wounded men were treated by physiotherapy, and that the conflict was largely responsible for bringing physical methods of treatment into prominence, it has only been during the last few years that general ultra-violet treatment has received the recognition in Great Britain which it deserves.

Actinotherapy is still in its infancy, and a great deal of research work is necessary before the reproach of empiricism can be removed. This makes it imperative that it should only be employed with great care and discrimination. One must also remember the cruel fate which has overtaken so many of the pioneers of X-rays, and though, judging by the experience of the Finsen Institute, it is very improbable that a similar catastrophe will befall the actinotherapist, the need for the exhibition of great caution is obvious. Dosage is a very important factor in all forms of medical treatment; we make use of the beneficial action of heat when we apply a poultice to relieve the pain of inflammation, but in excess, those same heat rays can act destructively and cause a painful burn. This is the case with X-rays, where ulceration and even cancer can be caused. Ultra-violet rays, too, are harmful in excess; the same applies to drugs, most of which, given in too great doses, can act as dangerous poisons.

It is obvious that the prevention and cure of disease should principally be the concern of those who have been specially qualified by suitable training to perform this important work. Therefore, the only persons at the present moment who should undertake ultra-violet treatment are members of the medical profession. Unfortunately, anyone can at the present time administer ultra-violet or X-ray treatment to others. It is no longer fashionable for the quack to sell pills in the market-place; he much more probably nowadays administers physical treatment in some fashionable part of the town. It has been said that there is no part of medicine which is so nearly allied to quackery as is physical treatment, and this stricture will last so long as the present chaotic state of affairs is allowed to continue. The quack, with his power to issue blatant advertisements, will continue in his present affluent state, indiscriminately maltreating suffering humanity. It all reminds one strongly of a character in Shaw's sparkling play, "The Doctor's Dilemma," whose procedure was to give his advice free, the fee for the course of treatment to be paid in advance, and cure guaranteed. A correct diagnosis is the essential factor in the satisfactory treatment of any form of disease.

Recently, owing to the ill-advised propaganda of certain manufacturing firms and individuals who have allowed their commercial zeal to outrun their discretion, the tendency has been rather for lay interest to exceed medical in regard to ultra-violet radiation.

There are two ways in which the ultra-violet rays can be utilised for curative purposes—exposure of the body to the sun's rays, or irradiation with an ultra-violet lamp. Ultra-violet treatment can be general, local, or internal, and in the writer's opinion the only form of ultra-violet treatment which should be used at home is general treatment, that is, exposure of the whole body to the rays.

In regard to the most suitable form of ultra-violet lamp for use in the home, the obvious choice is the carbon arc. The extreme power of the quartz mercury vapour lamp, which renders it a most valuable instrument in the doctor's hands, is a source of real danger when it is used in the home, and for the same reason, the home use of the tungsten arc with its short erythema-producing dose is also undesirable. Mercury vapour lamps can, however, be purchased where either the burner is made of translucent quartz, or a screen of the same material, or of vita-glass, is placed in front of the burner; in both these cases the time of exposure is greatly lengthened, and the risks of over-dosage considerably minimised, so that no objection can be taken to the home use of lamps of this kind.

The disadvantages of the carbon arc are the initial cost of a trustworthy model with automatic regulation, and the cost of the electric current necessary for the proper functioning of the lamp, which is considerable. Incidentally, several persons can be treated with one carbon arc lamp simultaneously, so that it seems that one solution of the difficulty is the formation of special clinics where ultra-violet treatment can be administered collectively at a reasonable charge under medical supervision. Special physical treatment clinics are increasing daily, especially in Germany, where there are many excellent establishments for the treatment of rheumatic disorders. However, the careful home use of ultra-violet radiation is justified by intelligent persons in good health who wish to make use of its tonic effects, but the treatment of disease is an entirely different matter, and the great temptation of a layman who has installed a lamp to treat various ailing friends and neighbours, should be firmly resisted. A doctor's advice and supervision are imperative in the treatment of disease.

The dangers of unskilled radiation treatment are very real, and many fatal cases of exfoliative dermatitis have occurred. A few years ago an accident took place in which a patient, who had been in the habit of giving himself ultra-violet treatment with a quartz mercury vapour lamp at home, while lying on his bed, fell asleep. Instead of his usual ten minutes' exposure, he was irradiated for one hour and ten minutes. Marked reddening of the skin occurred and peeling followed. Twelve days later, a general redness of the skin developed, and at the end of another five days, the heart became gravely affected and very irregular; the patient was seriously ill for four days and then gradually he began to improve. Meanwhile the peeling of the skin continued, and after the lapse of a further two weeks, a hæmorrhagic rash appeared all over the body, and afterwards the patient slowly recovered. A short while ago an acquaintance of the writer's bought a mercury vapour lamp, and his first irradiation was so ill-timed that a marked erythema developed, and as a consequence the expensive lamp was promptly laid aside.

Though the ultra-violet rays have very little power of penetrating the skin, they are nevertheless able to produce two striking peripheral effects, namely, erythema or reddening of the skin, and tanning, or pigmentation. Actinic erythema, unlike that produced by the infra-red rays, comes on after a latent period of four to twelve hours, and pigmentation follows the erythema. It must be remarked that the skin exercises an important protective function against excessive irradiation; it is also an insulating medium, an excretory and an endocrine organ, and it contains many arterioles, and is the most extensive sensory organ of the body.

There are many theories regarding the action of the ultra-violet rays. One is that some of the rays penetrate to the capillaries in the vascular layer of the skin, where they are absorbed by the blood and chemical changes occur, leading to a general body effect. Another theory is that the rays have a direct photo-electric effect on the nerve endings in the skin, and yet another that the rays act photo-chemically on the skin fat-producing vitamin D, the bone-forming vitamin. Probably all three theories are partly true. An important action of ultra-violet rays is their power of killing bacteria. Five seconds' exposure to the rays from a mercury vapour lamp is often sufficient to kill some virulent organism. Water, which is probably the most transparent liquid to the ultra-violet rays that we know, can be sterilised readily by them. The sun is Nature's universal disinfectant, and it is only in darkness that the organisms which are harmful to man and other animals can flourish.

Irradiation of the body generally leads to a fall in blood pressure, and Finsen proved that there was a seasonal variation in the numbers of red blood corpuscles, the number being greatest at the end of summer and least at the beginning of spring. So that if the red blood corpuscles are reduced in number, they generally increase after exposure to the ultra-violet rays. The hæmoglobin colouring matter of the red cells also increases in amount, and this proves an analogy with plants which, when grown in darkness, are deficient in chlorophyll. Changes occur also in the white blood corpuscles; the polymorphonuclear cells decrease, and the lymphocytes and, most markedly of all, the eosinophilic cells, become more numerous. There are alterations in the blood serum, and if there is an excessive quantity of blood sugar present, it is reduced. The amount of tyrosin in the blood serum increases, but decreases when pigmentation occurs, and a basic hydrogen ion concentration generally takes place. The vasomotor reflexes of the body are stimulated by ultra-violet irradiation, and this leads to an improved regulation of the body temperature, so that a body habitually stifled by wearing an excessive amount of clothing becomes able to tolerate with comfort greater extremes of heat and cold. It is a common experience that less clothing is often worn after a course of irradiation.

Ultra-violet radiation provokes certain metabolic changes. It has already been mentioned that hyperglycæmia is reduced; fats are also oxidised, particularly by natural sun baths, but the most profound action is on the mineral metabolism, the body calcium, phosphorus, iron, and iodine being all increased in amount. The calcium salts play a very important part in the body economy. They have a tonic effect on the heart, they stimulate the peripheral circulation and decrease the permeability of the lymph and blood-vessels; in bleeding, their presence is essential before clotting can occur. Calcium salts also stimulate the phagocytes in the blood, and play an important part in repairing the local ravages of disease.

Ultra-violet rays probably influence the ductless glands through the medium of the sympathetic or vegetative nervous system. They stimulate the thyroid and sexual glands and cause depression of the suprarenal glands. It has been found experimentally that irradiation diminishes the acidity of the gastric juice. The ultra-violet rays act on the central nervous system, and cause mental stimulation. The cheering effect on our spirits of a bright sunny day has long been realised, and artificially produced ultra-violet rays generally have the same effect. Intelligence tests carried out at the Treloar Cripples' Hospital, Alton, proved that the children there were about a year in advance of crippled children of the same age living in London. Ultra-violet, like the infra-red rays, have an analgesic effect on the peripheral nervous system, thus relieving pain.

The ultra-violet lamp in the home can be installed in a bedroom, or preferably in a large spare room. It is certainly unwise to put it in the bathroom, because here the electrical dangers are very great, and many fatal cases of electrocution have been reported. Moreover, the steam rising from hot water in the bath would condense on the unlit lamp and cause certain metal parts to become rusty, and dampness damages insulation. For home use, a suspension type of lamp would probably prove most convenient; a beam should be found and a pulley securely fixed into it—the lamp should be counter-weighted so as to make it possible to raise or lower it at will. An arc with cored carbons often gives off unpleasant fumes, so that the ultra-violet room should be satisfactorily ventilated—cross ceiling ventilation is the ideal, but the creation of draughts must be avoided, as the open arc is very sensitive to air currents. It should be possible to heat the treatment room to a temperature of about 70°, as general treatment is always given to the nude body. Satisfactory wiring, able to carry the required load, must be installed, and if it is available, the direct current should be chosen. It is generally possible to obtain permission to use the ultra-violet lamp on the power circuit, and power rates are generally much cheaper than the rate for lighting. The polarity of the two terminals must be known, and a three pin, or non-reversible type of plug should always be fitted. There should also be a quick-break type of protected double pole switch to turn on and off the current. The fuses should be of the easy replacement type and some spare fuse wire should always be available. The lamp resistance can be mounted on the wall.

In my opinion the most trustworthy types of carbon arc lamp are (1) the 'short flame' arc taking 20 amperes, made at the Finsen Institute, Copenhagen, which can only be used with direct current (with 240 volts three lamps can be used in series), and (2) the 'long flame' arc (with 240 volts two can be used in series) designed to take 30 amperes.

The disadvantage of the short flame arcs is that the maximum exposure with them reaches 2¼ hours, whereas with the long flame arc it never exceeds an hour, and when two long flame arcs are used simultaneously, one in front and the other behind, the time needed for treatment can be cut down to half an hour. The direction of the radiant emission from these two types of lamp varies considerably. The greatest ultra-violet emission from Finsen lamps is given off at an angle of about 45° to the lower carbon, whereas the maximum emission from the long flame arc is given off by the flame itself, and is therefore greatest in the horizontal direction.

With the Finsen arcs, irradiation is given while the subject is lying on a couch, first in the prone and then in the supine position. The subject should be seated on a chair during exposure to the long flame arc, and first the front of the body and then the back irradiated, the arc flame being on exactly the same horizontal plane as the lowermost ribs. If preferred, irradiation can also be made in the reclining position on a couch, the subject lying on his side and facing the lamp, and then lying on his other side with his back to the lamp. With carbon arc lamps, the distance of the subject from the lamp should be as short as the heat comfortably allows, but not too short, because burning with the infra-red rays can, of course, occur. The initial exposure to each side of the body with the short flame arc should not exceed ten minutes, and should be gradually increased to a total of seventy-five minutes, back and front. With the long flame arc fitted with white flame carbons, an exposure of each side of the body for five minutes, at a distance of approximately four feet from the arc, should be made. This time is gradually increased to a maximum of thirty minutes.

A trustworthy alarm system should be installed to give warning at the termination of the exposure, but it is generally safer for a second person to be present.

During exposure the eyes must be carefully protected with suitable glasses or some other material which is opaque to the ultra-violet rays.

Irradiation is generally carried out every other day, and can be continued regularly for months, though it is only fair to say that many actinotherapists consider that it is advantageous to make an intermission of about a month after every twelve exposures.

Ultra-Violet Radiation for Domestic Use.

By Prof. S. Russ.

It seems very natural for people to want to make use of 'artificial sunlight' in their homes, especially during the rather sunless seasons, but there are some points which should be considered before it becomes a general practice, especially among those who seem to get along very well as they are.

In the first place, how nearly are artificial sources of radiation a copy of sunlight as it reaches most of us, nearly at sea-level? Perhaps the nearest approach to this is given by a high temperature filament lamp, though this will err on the side of having too big a proportion of radiation in the red and yellow part of the spectrum. Such lamps are of course largely used therapeutically, but mainly for the radiant heat which they give in a very convenient form.

All the forms of arc lamps, carbon, carbon-cored, tungsten, titanium, or mercury vapour, give out a composite radiation which is very different from sunlight, as it contains a large proportion of ultra-violet radiation. So that none of these sources which are often described as providing artificial sunlight can be said to do so unless a large part of the ultra-violet is screened off, and the remaining part of the spectrum very carefully compensated so as to resemble sunlight as nearly as possible.

In the second place, even if a source were invented that gave a fairly exact replica of sunlight as it comes into our houses, would it be used to any extent, and if so, for what purpose? This raises the question rather at the root of the matter; Why this quest for body irradiation? Undoubtedly much more attention is now given to housing, particularly to ventilation and lighting; it seems in fact an inevitable part of the hygienic trend which aims at abolishing the smoke pall of big cities, and the basement life which many seem able to survive. But we shall probably not be far wrong in attributing the demand for some source of artificial sunlight rather to a wish for ultra-violet radiation, and this in turn is probably due very largely to the discovery that irradiation with ultra-violet rays can cure rickets in children. It is perhaps not so much this plain fact as the story of its unfolding that has appealed so strongly to the imagination. This discovery has shown how a deficiency disease can be cured by exposing the body to radiation which penetrates but a fraction of a millimetre into the skin. The inferences drawn from this have of course been boldly acted upon, and in consequence the substance in the skin which when irradiated produces vitamin D, the anti-rachitic factor, has been tracked down. The whole sequence of discoveries following on that of Mellanby in 1915, that rickets was a deficiency disease, forms a most impressive example of what well-directed scientific effort can achieve.

The question now before us is whether, in view of the admitted value of ultra-violet radiation in the treatment of rickets and general deficiency diseases in children, it would be a good thing for the general public to make good the deficiencies in diet (which undoubtedly affect a big proportion of the population) by exposing their bodies to frequent, perhaps daily, doses of ultra-violet radiation. The position taken up by the writer is that it is inadvisable on many grounds, and probably nationally uneconomical.

One need perhaps not lay great stress upon the fact that such a daily ray bath would cost an appreciable sum. A source suitable for home installation has to be safe; therefore it would probably have to be some form of closed arc, such as a mercury vapour lamp requiring no handling of leads from the mains. The initial cost of such a lamp, if the demand were on a big scale, might be so low as £5 or £6. Consumption might reasonably be 4 amperes at 200 volts, say 800 watts; if used daily for 10 minutes for one-half of the year, the running costs, apart from breakage and depreciation, would be 12*s.* per annum, taking power at 6*d.* per B.O.T. unit; for many households a cost that need not be taken into account, but on a big scale—a big item.

Some count should be taken of the risks run by repeated exposure of the body to a form of radiation to which it is quite unaccustomed; almost as foreign to it, in fact, as X-rays or gamma rays. Without in any way wishing to become an alarmist on the subject, I think that definite risk would be run by anyone exposing his body to repeated doses of ultra-violet radiation unless he were under proper medical supervision. The various reactions of the skin to ultra-violet radiation, which happen soon after the exposure, are well recognised by medical men, but it is too soon yet to know much about later reactions which may occur as they sometimes do after exposure to X-rays.

One very well recognised feature of prolonged exposures is the pigmentation that occurs in most, though not all, skins. If the thing were carried to extremes and people in the winter months pigmented themselves very considerably, it is open to doubt whether this would be a very good thing. Pigmentation means opacity to radiation generally, ultra-violet or luminous; and it could well be argued that in winter months one is far better guarded against heat losses by having a skin rather devoid of pigment; the general feeling of well-being quite likely depends on the tissues being illuminated to some extent by daylight.

People who spend a good part of their time in the tropics generally appear to lack vitality. There are lots of factors contributing to this, quite apart from the diseases peculiar to these zones; high temperatures and excessive humidity no doubt account for a good deal, but the continual exposure to solar radiation, besides tanning the skin, may set up other changes in the body which react upon the general vitality.

Experimentally it is found that when ergosterol is exposed to the full radiation from a mercury lamp, the amount of vitamin D gradually increases with the exposure up to a certain point, but a stage is reached when this stops. Whether this is due to the gradual formation of a neutralising body perhaps cannot yet be stated, but a recent report on nutrition by the Medical Research Council mentions that there are constituents of diet which appear to nullify the action of vitamins.

The reason for mentioning this here is that it seems a doubtful thing to advise people to install sources of ultra-violet radiation in their homes until more is known about the effects of repeated doses of these rays upon the body.

It is indeed relevant to inquire on what grounds it can be advocated. It is known that these rays can help those on an inadequate diet to avoid some of the consequences of such deficiency, but this can be done equally well by supplying the accessory food factors at much lower cost, and in a far more certain manner than by the population taking such medical matters into their own hands.

It may, however, be argued with considerable weight, that ultra-violet radiation does far more than this for people. There are some who positively hunger for sunlight and feel much fitter for some ultra-violet radiation, and the question is whether there is any valid reason why they should not have it when it can be got so easily.

The enormous sale of patent medicines throughout the country shows how willingly people will do without medical help, especially if they think the ailment a trifling one, so that there is of course nothing to prevent people getting any of the various appliances for generating ultra-violet radiation and using them in their own homes, but surely they should not be *advised* to do so. Suppose, for example, that it were a part of the regular equipment of a household, and normally healthy children were periodically given doses of this radiation, could it be looked upon as anything short of an experiment? If so, are such domestic experiments on a large scale to be encouraged? There are many who will feel that the balance of health is maintained by so many factors, many of which are clearly recognised, that on such slender grounds it is better not to bring into this delicate balance a kind of radiation that no living race has been accustomed to before.

Medical Aspects of 'Artificial Sunlight' in Private Houses.

By P. R. PEACOCK, M.B., B.S.

THOUGH ultra-violet therapy has been practised in an empirical way from the earliest times, the association of sunshine with good health being in the nature of a primitive instinct, it is only during the past thirty years or so that any serious attempt has been made to establish it on a scientific basis.

Systematic clinical observation gradually led to an appreciation of the value of the alpine climate in the treatment of tuberculosis of the bones, joints, and lymph glands, and the establishment of centres for treatment of this crippling disease by heliotherapy in the Swiss Alps was largely a result of the patient work of Bernhard, followed by Rollier and others. The notable extension of ultra-violet therapy by Finsen brought the curative rays within the reach of those in comparatively sunless countries and marked the start of the modern practice of artificial actinotherapy.

The success of ultra-violet treatment for 'surgical' tuberculosis, saving as it has many children from mutilating operations, is undoubtedly one of the reasons for the popular desire for ultra-violet rays, but the more recent and far more spectacular series of discoveries linking the demonstration by Mellanby of the nature of rickets with the subsequent rapid strides of research, culminating in the synthesis of vitamin D from ergosterol by Rosenheim and Webster, probably constitutes an even stronger influence.

It is as well to have a clear idea of the real justification for ultra-violet therapy before considering the type of pseudo-medical publication or manufacturers' advertisement, from which it might be concluded that ultra-violet rays will not only prevent and cure all known diseases, but will also regulate even minor variations from the physiological standard of normality. Such one-sided propaganda has been much in evidence in recent years, and that it has borne fruit is easily judged from the number of hairdressers and beauty specialists who make a fine thing out of ultra-violet and 'violet-ray' treatments, not to mention the bottles of 'ultra-violet lubricant' and 'radioactive' bath salts, for both of which commodities the writer has been assured that there is a good demand.

In addition to the specific cure of rickets and the successful treatment of surgical tuberculosis, the value of ultra-violet rays in the treatment of septic wounds and burns was abundantly proved during the War. There is evidence that actinotherapy is of value in disturbances of the parathyroid gland and deficient calcium metabolism; possibly the rôle of ultra-violet rays is the same in these conditions as in the case of rickets, since there appears to be an intimate association between vitamin D and the absorption of calcium from the alimentary tract. Certain conditions are also directly benefited by the local reaction of the exposed part, increasing the blood supply and facilitating the removal of toxic products of the morbid state; the successful treatment of chilblains and of varicose ulcers is probably to be explained on these lines.

The powerful bactericidal action of ultra-violet rays is well known, but this property is rarely made direct use of in practice, owing to the very slight penetration of the rays, and to the fact that many of the bacteria that normally infest the skin are effectively screened from the rays in the sweat-glands or hair-follicles.

These few points have been selected from a great many known facts in order to emphasise the importance of recognising that actinotherapy is based on established facts, and it is only on such lines that it should be used. There are, however, many who would spoil a good case by overstatement, or hide their ignorance of the facts, and a dislike for critical investigation, behind a mass of plausible speculation as to some mysterious property of this or that type of arc lamp, and hinting darkly that science cannot detect properties of the rays with which nevertheless they themselves are familiar.

As there are specific cures, so there are specific diseases due to light and ultra-violet rays, and, although these are fortunately rare, they should be considered by the advocates of wholesale light therapy. Xeroderma pigmentosum is the worst of all 'light' diseases and, in the unfortunate children affected, manifests itself as a malignant spread of pigmented spots under the influence of light, usually terminating fatally in early adolescence.

Equally rare are those cases of excessive sensitivity to light due to the presence of hæmatoporphyrin in the blood as a congenital abnormality, resulting in an eruption not unlike that of smallpox on the regions of the skin exposed to light.

Probably the greatest danger to the public from careless use of arc lamps is that of damage to the sight, a very real danger which, if not guarded against, may lead to many cases of permanent injury. Exposure of the unprotected eye to intense sources of light such as the tungsten or mercury vapour arc leads to acute conjunctivitis within a few hours, an experience that would probably induce greater caution on subsequent occasions, as few conditions are more painful. Deliberate staring at powerful sources of actinic light may lead to permanent blindness, or short of this to restriction of the visual field, the so-called 'ring scotoma.' There is a good deal of evidence that repeated exposure to unscreened arc lamps may lead to the development of cataract, and this is not surprising, since it is the lens of the eye that absorbs most of the ultra-violet rays.

If the dangers of this form of treatment have been rather stressed, it is only with the idea of emphasising that means of protection should never be neglected by anyone frequently exposed to the rays. As regards the skin, over-exposure is not as a rule followed by any permanent damage, though very painful burns and blisters are the penalty of careless handling of the lamps.

As there is no restriction of the supply of arc lamps or other apparatus for the production of ultra-violet rays to the public, the position is similar to that of patent medicines other than those scheduled under the Dangerous Drugs Acts. Inevitably, as in the case of proprietary drugs, a certain amount of amateur experimental medicine would follow the installation of arc lamps in private houses, and it cannot be too strongly pointed out that these rays are not to be regarded as practically foolproof, and should be treated with as much respect as a redhot poker or a loaded firearm.

Those who install lamps and wish to take regular doses of ultra-violet rays, would be well advised to begin by being medically examined and passed as fit for such treatment. Lamps should never be switched on until the eyes have been protected by goggles, which should be of glass tested and certified as cutting out the ultra-violet rays, and these should not be removed until the lamp has been turned off again. The technique of treatment does not come within the scope of this article, but it may be remarked that individual susceptibility varies greatly, and that this should be tested cautiously before starting general irradiation, otherwise extensive light-burns may result. The best thing would be for those who contemplate the installation of a source of ultra-violet rays to ascertain in the first instance whether they really benefit from such treatment, as by no means everyone is obviously improved by it.

One cannot help wondering whether the people who can afford to install arc lamps in their homes are those who would derive most benefit from the rays, since they are probably taking ample vitamins in their diet and live in relatively open and healthy neighbourhoods.

For the poor, whose diet is short of butter, eggs, milk, and fresh foods generally, there are already a number of clinics where they can be treated, with the best results, under proper medical supervision.

Extension of such clinics would appear to be the safest way of overcoming the defects of the rather sunless climate of Great Britain, though the intelligent use of artificial 'sunlight' in the home may be a means of improving the national health.

Lamps for Light-Baths.

By T. C. Angus.

ULTRA-VIOLET light between well-defined wave-lengths is one of the necessary accompaniments of primitive life in natural surroundings the tonic effects of which the human body is not only able to withstand, but without which it suffers a definite want. There can be no objection, therefore, to town-dwellers, during a European winter, who, while not being 'ill,' are still often in need of light and its good effects, making use of occasional light-baths from sources which emit ultra-violet light of moderate intensity. In fact, many such persons have followed this course for some time with considerable benefit, and there is little doubt that others will follow their lead.

A *practical biological measure of the strength of ultra-violet light* is the time for which it is necessary to expose the skin to these rays for an erythema (reddening) and its after-effects to be produced. This erythema does not begin to appear until some hours after the application, and reaches its full intensity about 12 hours after the exposure, being followed by a brownish pigmentation or 'sunburn.' A band of cardboard or thick paper can be put across the abdomen, and small windows cut in this, so that the skin is exposed to the source 2 ft. away for 5 or 10 minutes and the erythema observed in each area. The dose required is that giving a slight erythema.

Lamps of various kinds capable of producing these effects after exposures of as little as two to five minutes are now obtainable through the medical stores, and can be fitted up in doctors' houses and in hospitals. Such powerful sources of light should only be used after the test of dosage by skilled people, or severe burns will result. This is obvious when it is remembered that it usually requires exposures of an hour or more to the summer midday sun in England to produce a sunburn on the skin of the neck or arms, so that an arc or mercury vapour lamp capable of producing this effect in five minutes must emit much more potent rays.

LAMPS SUITABLE FOR DOMESTIC USE.

The Mercury Vapour Lamp.

In this well-known source of ultra-violet light the radiations are produced from an arc or stream of electrons carried by a column of mercury vapour, the whole enclosed in a quartz tube. The spectrum shows many characteristic lines of great intensity in both the near and far ultra-violet region, with much visible blue light and very little yellow and red.

A very small lamp of this kind would be suitable for the domestic use we are considering, and such a lamp would not take more than an ampere and a half after it had been alight for a few minutes.

The mercury vapour lamp is efficient and cheap in current consumption, whilst the cost of the quartz burner is lower than it was formerly, so that in price the mercury vapour lamp compares well with its rivals, and a very small lamp of this kind will be all that is desirable for domestic use. Elaborate stands and reflectors do not add to the efficiency of a lamp as they add to its cost. The quartz mercury vapour burner only requires a safe and simple support and a resistance and starting switch. The lamp is fairly cool, perfectly silent and easy to handle, though the burner is easily broken by shock or impact. The more powerful mercury vapour lamp commonly used for treatment might well be adapted for domestic use by interposing a thin filter or screen of vita-glass, which has the power of cutting off all the shorter ultra-violet rays and a proportion of those of medium length, whilst transmitting freely the near or longer rays: which last do not constitute a very powerful component of the mercury vapour lamp's output. The disadvantage of using such filters is that it is difficult to produce numbers of them with a consistent absorption, and that it would be more economical to use a much smaller and cheaper lamp to give much the same effect.

The running expenses of the mercury vapour lamp are due to current consumption, which is very small, and to deterioration of the burner, which usually has to be replaced or reconditioned after from 600 to 1000 hours' use. The atmospheric type of lamp lasts longer than the vacuum type.

Mercury vapour lamps can be made to work with direct or alternating current, lamps for the latter being rather more costly; or rectifiers can be obtained to make use of alternating current to work the direct current type of lamp.

The Arc Lamp.

This lamp has gained an unfair reputation for low output as a result of the perpetuation of obsolete designs by some manufacturers. As a result of recent improvements in lamp design and in the composition of the electrodes or carbons, therapeutic arc lamps are now obtainable that can give their effects as quickly, or more quickly, than the mercury vapour lamps commonly used.

Arc lamps using a current of three amperes, and therefore capable of being used on an ordinary lighting circuit, are now made, and these should be suitable for domestic use.

The quality and intensity of ultra-violet radiations from an arc can be varied over a wide range by the use of different electrodes—carbons cored with different metals and salts—so that the strength of the dose can be varied at will. The arc lamps used by Reyn of Copenhagen maintain a short arc between two plain carbons, the top one of which is the positive electrode. The distribution of light and ultra-violet light from such a lamp is greatest at an angle of 45° below the horizontal, and the relative strength of the biologically active rays is small compared with that of the visible light and the heat rays. Such lamps use very high currents, and the patients require exposures to them of an hour and more.

It was shown by Eidinow that the arc can be made a much more efficient source of ultra-violet light for treatment by lengthening the distance between the carbons, and by Angus by making the bottom carbon the positive instead of the top: the putting of the positive pole below ensures the diffusion up of the ionised gases and an effective flame from which most of the ultra-violet rays come. The distribution of light intensities from such an arc is nearly spherical, so that patients are best placed on the same level as the lamp. If a carbon cored with iron particles or a mixture of iron and cerium is used at the bottom, a much more powerful erythema-producing radiation is produced with which dosage time may be reduced to 2 to 5 minutes; it is then found that a plain and consequently cheaper carbon can be used in the top (negative) holder with practically no diminution of intensity of ultra-violet light from a direct current arc and a 20 per cent. diminution in an alternating current arc; this makes for a considerable saving in running costs, because the top carbon is always the more quickly consumed.

The advantages of the arc as a source of ultra-violet light may be given as:

1. Quality and intensity of output can be varied at will by changing the electrodes.
2. No deterioration or loss of power with age.
3. A large output of warm visible light as well as ultra-violet, making the treatment pleasant.
4. Not easily broken or put out of order.

The disadvantages:

1. Uses more current than an equivalent mercury vapour lamp.
2. Carbons have to be renewed when they burn away.
3. Lamp gets hotter than mercury vapour lamp.

PRECAUTIONS.

Overdosing should not be possible with lamps used for domestic self-treatment: lamps strong enough to produce overdoses should only be used under the control of a doctor.

Fire.—Lamps should be thoroughly stable and not so easily overturned that fires might be caused. All wiring and connexions should be of the best possible quality.

Electric Shocks.—Unlike the ordinary glass lamp in common use, ultra-violet lamps have one or two points where bare wires or points are exposed and may be touched when, by oversight, the current is switched on and the lamp is therefore 'alive,' although it may not be burning, and an unpleasant and even dangerous shock may thus be obtained. This may happen with the mercury vapour lamp when cleaning the burner with alcohol, as the makers recommend, and with the carbon arc when changing or renewing the electrodes; although, of course, both these operations should be carried out before the lamps are switched on at all. This being always a potential risk, it may be well to install lamps for home treatment in the *bedroom* rather than in the *bathroom*; this because the latter place is one in which possible shocks are far more likely to be serious on account of the large number of earthed metals and the state of moisture of floors, objects, and particularly of the body. Also, it may be well if buying an arc lamp to specify one where proper provision is made for changing electrodes without risk of shock should the switch be inadvertently left 'on.'

Care of the Eyes.—The cornea and conjunctiva are very sensitive to ultra-violet light and should always be protected by dark goggles during light treatment; these should have close-fitting side pieces.

The relative 'cost of lamps' is as follows:

	amperes. volts.
Short flame Finsen arc . .	70 × 110 = 7700 watts.
Long flame arc	25 × 110 = 2750 ,,
Tungsten arc . . .	5 × 110 = 550 ,,
Mercury vapour lamp . .	4 × 110 = 440 ,,

The carbon arcs require purchase of carbons. The tungsten arcs require expensive tungsten electrodes. The mercury vapour lamp usually wants renewing after about 600-1000 hours' run, but is the cheapest.

A self-regulating long flame arc costs about £20-£25. A mercury vapour lamp without stand or reflectors costs about £10. A hand-fed tungsten arc can be made for £1 or £2. Then there are the expenses of resistance coils, wiring keys, etc.

The price of lamps is put up by provision of plated reflectors and stands. A mercury vapour lamp with an iron retort stand and a tin or cardboard screen suffices. Domestic mercury vapour lamps are now sold complete for about £10 direct, or £18 alternating current. Hand-fed arc lamps with iron and cerium cored carbons can be had for about £5. These can be run off the house circuit.

Selection of Ultra-Violet Lamps for Home Use.

By B. D. H. WATTERS.

THE idea of employing ultra-violet radiation at home is a new one, and there is as yet no wide selection of lamps made for this purpose. Those at present on the market must be regarded as largely experimental attempts to meet the new demand. The majority of them are of the type used for general irradiation in hospital practice, but reduced in size, and it is not generally realised that an exposed and live electrode which is safe enough in the laboratory or clinic in the hands of trained workers, may be quite definitely dangerous in the home.

The first of these lamps which were put on the market were all carbon or carbon-cored arcs, but recently the quartz mercury lamp has been produced commercially in a small size. The carbon lamps burn either plain carbon electrodes or carbon cored, with some metallic mixture which volatilises and adds the characteristic spectrum of that metal to that of the carbon arc. The metals or mixtures of metals selected are such as to enrich the arc with radiation of the shorter wave-lengths. From a therapeutic point of view, there seems little to choose between the different corings.

CARBON ARCS.

Ajax, Ltd.—The lamp is known as the 'Uviray,' and is a magnetically controlled tungsten-cored arc. It is remarkably steady in running owing to the automatic control. The arc is housed in a deep hood supported on a stand which contains the series resistance. A small knife switch is fitted to break the circuit, which serves the purpose admirably, but the fact that the contacts are so much exposed is a weak point in an otherwise good design. The current consumed is 4-5 amp. Price £5 10*s*.

Apex Sun Ray, Ltd.—The No. 1 model made by this firm is a small arc made between two thin pencils of carbon which are mounted almost parallel in a deep metal hood. Very little adjustment is required. The series resistance is mounted on the large base of the instrument. The beam is somewhat concentrated by the narrow hood. Price £6 6*s*.

Arnold and Son (*John Bell and Croydon*).—The 'Arnold' artificial alpine sun lamp is a large and expensive instrument on a heavy stand which carries two carbon arcs in series. It is made in two sizes for 5 and 10 amp. respectively. Such a lamp is more suitable for use in a hospital than in an ordinary house. Not only is the heavy current of the larger model more than the fuses and wiring of an ordinary installation can handle, but the output of radiation is more intense than is necessary for the simple tonic treatment required. Price £20-£25.

Bower Electric, Ltd.—The 'Uvral' lamp is an interesting form of double arc. The whole instrument is housed in a teak outer case, a window being raised to expose the beam. On the side of the case is a special timing switch termed an 'expometer.' This is set for some predetermined period and the lamp switched on. At the end of the period the lamp is automatically switched off, thus reducing greatly the danger of too long exposure. The general design shows that much care has been taken to avoid accidental shock. The degree of safety has to be paid for as the price is relatively high. Current 4-5 amp. Price 24 guineas.

The 'Junior' U-V ray apparatus, by the same firm, is a much smaller apparatus. Two parallel carbon pencils are mounted in the usual hood. The series resistance takes the form of spiral coils mounted round the inside of the hood. These reach a dull-red temperature when the arc is running and radiate a certain amount of heat. The lamp requires more care and attention to use than the more expensive models. Current 4·5–5 amp. Price £5 15*s*. 6*d*.

Brodie, Oakley and Co.—'Artsun' lamp—a hand-controlled carbon arc mounted in a reflector hood. The electrodes are narrow pencils and stick out at top and bottom of the instrument quite unprotected. Price £4 17*s*. 6*d*.

Quain Ray Lamp Co.—This is also a hand-controlled carbon or cored carbon arc, but of an unusual type. The carbons are mounted horizontally in the centre of a shallow dish-shaped reflector which is covered with a grid of stout wire. The mesh is open and does not cut down the total radiation appreciably. The series resistances are radiator heating units which are also mounted in front of the reflector, so that a certain amount of heat is radiated as well as ultra-violet radiation. A switch on the back of stand serves to short-circuit the arc, when the lamp functions as a heating radiator of the usual type.

The carbons used are of medium size and burn fairly slowly, but the method of replacing them is clumsy and is likely to result in burnt fingers. There is also no main switch on the lamp itself for breaking the circuit. As the carbons burn away they have to be readjusted after a run of about ten minutes. This is claimed by the makers as an advantage, as it reduces the chance of an overdose owing to the patient going to sleep. At the same time, the output of radiation varies considerably during the ten minutes.

Rouse and Sons.—Rouse No. 1 Junior U.V. lamp. This is a simple carbon arc, the carbon pencils being mounted almost parallel in a metal hood supported on a light tripod. The series resistance is a separate unit. Tungsten electrodes can be obtained as well as plain carbon.

MERCURY LAMPS.

Medical Supply Association, Cox Cavendish Ltd., and other firms.—The 'Homesun' lamp is made with two types of burner for D.C. and A.C. In either form, the lamp is more constant than any of the carbon arcs, and the current consumption is only 2·0–2·5 amp. The radiation is also richer in the shorter wave-lengths of the ultra-violet, but whether that is an advantage or not is a question. The D.C. burner operates better when the current is flowing in a certain direction, but, unlike the big mercury arcs, it is not injured by being used with the polarity reversed. The mounting of the lamp is in a hood on a stand containing the series resistance. The heavy starting current which is characteristic of mercury lamps necessitates the use of fuses which will stand 6 amp. Price, D.C. £10; A.C. £18.

Medical Supply Association.—The 'Medisun' lamp is a similar instrument to the above, but requiring even less current (on D.C. 1·0–1·2 amp.). An indicating 'on and off' switch is fitted. So far as running costs only are concerned, this must be the most economical source of ultra-violet radiation available at the moment. Price, D.C. £10; A.C. £18.

Stanley Cox, Ltd.—The simple type 'Actinosun' No. 2 is a mercury lamp similar to the others described, and though not made specially for use at home, would be quite suitable for that purpose. Half-power burners can be supplied. The lamp is obtainable in two models for D.C. and A.C. respectively. Price, D.C. £9 15*s*.; A.C. £12 10*s*.

FILAMENT LAMPS WITH VITA-GLASS.

The use of ordinary incandescent filament lamps with a vita-glass bulb for home irradiation has been somewhat superseded by these newer and more powerful lamps. The Emesay warming screen sold by the Medical Supply Association is a light radiator using ordinary bulbs, but, if the bulbs mentioned above are substituted, the screen acts as a source of weak ultra-violet of the longer wave-lengths. Such an apparatus would be free from any of the risks attendant on the ignorant or incautious use of any of the lamps described above.

SELECTING A HOME-RADIATION OUTFIT.

For the purchaser and the designer of ultra-violet lamps for the home, the following points should be noted:

1. The live leads, etc., should be protected by a

deep hood or wire grid and should be as few as possible.

2. The lamp should be fitted with a good switch, in which the moving parts separate far enough to preclude all chance of arcing. A double pole type would be of advantage to ensure *both* electrodes being dead before they can be touched in the replacement of carbons, etc.

3. A well-fitting pair of goggles should always be worn. The use of goggles is so essential, especially with the small mercury arcs, that it would be an excellent thing if manufacturers agreed to mark all lamps intended for home use with the inscription, "Goggles must be worn when using this lamp." At present it is to be regretted that in a number of catalogues, etc., the artist has tried to express the pleasures of basking in artificial sunlight, but has omitted in his pictures the disfiguring goggles. The necessity of using goggles is mentioned in the catalogues, but a good illustration is often remembered when the written instructions have been mislaid. There are many satisfactory makes to be obtained, but, if there is any question, the only certain test is by spectrometer. A good pair of goggles should not transmit any ultra-violet radiation at all, not even of the longer wave-lengths.

The danger of falling asleep during the exposure is a perfectly definite one, as ultra-violet radiation often has that effect. In such a case it is possible for the patient to experience a severe blistering of the skin due to over-exposure, as this skin-burning does not appear until some time has elapsed. The simplest manner of guarding against this danger is to make it a rule always to stand up for an ultra-violet bath, and never to sit or lie down.

The most suitable place for the installation of these lamps is a matter for careful consideration. The bathroom, as has been pointed out elsewhere, is not the safest place, because of the danger of a bad shock due to the moisture present. On the other hand, it should be remembered that this radiation is a very powerful bleaching agent, and that the colours of fabrics, etc., will fade, and often the materials themselves perish, if exposed constantly to the rays.

The lamps reviewed here have been considered from the point of view of the man who wishes to have ultra-violet radiation available in his house as a tonic during the dark winter months. To use it for the treatment of any definite disease without the direction of a qualified physician is highly dangerous, for it must be realised that the irradiation used in medicine is often only a part of curative treatment. Further, there are conditions and diseases which can be made worse by ultra-violet radiation, and in spite of the enthusiastic pamphlets and catalogues which record its application in every human ill, it cannot be too strongly insisted that ultra-violet radiation is not a universal panacea.

The Ultra-Violet Transmission of Transparent Materials.

By Dr. L. C. Martin.

We may be forgiven for a little scepticism regarding the highly coloured reports which have been current during the last few years concerning the possibilities and effects of ultra-violet radiation. It must be admitted, however, that there appears to be a considerable measure of truth in such accounts; the physicist must assist in disentangling the errors and in weighing the evidence.

The shortest wave-length for which light is visible to the eye is roughly $0 \cdot 39\mu$, but the spectrum of sunlight extends, although faintly in the end, to a wave-length of about $0 \cdot 295\mu$ at sea-level; the cornea, the outer transparent coat of the eye, transmits down to about the sunlight limit. The 'lens' of the eye is more opaque; it will not transmit beyond $0 \cdot 376\mu$, and can be made to fluoresce by radiation of about this wave-length reaching it through the cornea. Severe inflammation of the conjunctiva can be caused by exposure to intense radiation of wave-lengths shorter than about $0 \cdot 305\mu$. Physiological and germicidal actions occur with radiation of still shorter wave-lengths down to about $0 \cdot 21\mu$, but beyond this point we soon reach the region $0 \cdot 193\mu$ to $0 \cdot 185\mu$, where air becomes practically opaque. The region of interest in ultra-violet transmission measurements for present purposes extends, then, roughly from $0 \cdot 4\mu$ to $0 \cdot 2\mu$.

In connexion with the various sources for the production of ultra-violet radiation for clinical purposes, the transmission of the globes, screens, or containing vessels has to be studied; the transmission of window glass is also a special case. It may be added that the photometric study of the *emission* of the source is of no less importance. Naturally, the ultra-violet emission of many sources such as tungsten filament lamps, for which the familiar 'black-body' radiation laws are a sufficient guide, is extremely low in proportion to the total radiation. Much more energy, relatively speaking, is derived from arcs and sparks which give bright line spectra. The region $0 \cdot 4\mu$ to $0 \cdot 2\mu$ can be studied with the aid of fluorescence or photography. In some cases the absorption of media grows very rapidly with changing wave-length in a certain region; thus the simplest kind of information useful in some cases is the short wave-length limit of the transmission.

Quartz in the crystalline state is fairly transparent down to $0 \cdot 18\mu$ in pieces 2 cm. in thickness; the quartz spectrograph as made by the firms of Hilger and Bellingham and Stanley, in which the whole optical system is made in quartz, projects the entire visible and ultra-violet spectrum down to about $0 \cdot 185\mu$ on a photographic plate; the substitution of a screen of uranium glass for the plate converts the instrument into an ultra-violet spectroscope in which the lines of the spectrum are seen by fluorescence. Wave-lengths can be given by a scale marked in the glass. An iron arc or tungsten arc gives a wealth of lines in the ultra-violet spectrum, so that if a piece of the substance under test has sufficiently good surfaces it may be held in the path of the light reaching the slit, when its 'limit of transmission' may become manifest by the darkening of the spectrum beyond a certain point. Such tests are useful for protective glasses or goggles. A compact ultra-violet spectroscope for hand use is made by Messrs. R. and J. Beck, Ltd.

Fluorite is one of the most transparent media for the ultra-violet (when pure it transmits down to 0·125μ), but it is difficult to obtain good specimens of any size, so that even its optical use is rather restricted; but this crystal, together with rocksalt and certain other crystals and gems, has important possibilities for scientific purposes.

Fused quartz is not doubly refracting, and is little less transparent than crystalline quartz; it has great resistance to heat, and its extremely high melting point makes it specially suitable for containing the mercury arc, one of the most useful sources of ultra-violet radiation. In spite of a great deal of research carried out for long periods, it has not yet been found possible to produce the material in a truly homogeneous state; there is always a residual structure showing small local variations of refractive index. Even though microscope lenses are made from it, they could be improved if the homogeneity were perfected.

The cost of using fused quartz for windows would be prohibitive, but since the range of transmission of glass can be made to include the whole sunlight range, it is unnecessary. Common soda glass is practically opaque beyond 0·33μ, but in Hovestadt's "Jena Glass" the increased ultra-violet transparency due to the use of barium is pointed out. Generally speaking, the transparency diminishes with increasing proportions of lead in the flint glasses. Researches in the effect of the composition of glass on the ultra-violet transparency have been made by Zschimmer, who found that boric oxide was very transparent. The use of sodium oxide in a glass decreased the transparency more than potassium oxide. Useful figures and curves are given by Schulz ("Das Glas," Munich; 1923. Kösel and Pustet) from the results of H. A. Kruss. Particulars are also given of the 'Uviol' Jena glass which has been most useful for spectroscopes and other purposes, since it transmits down to 0·280μ. Fritsch has published particulars of a glass made from calcium fluoride and boric oxide which is said to be transparent down to 0·185μ.

Comparatively recently, Messrs. Chance Bros. of Birmingham have brought out their 'Vita-glass' made to the specification of Lamplough. In a plate 2 mm. thick this will still transmit 10 per cent. at 0·272μ. Also, the Corning Glass Works have announced a special ultra-violet transmitting glass (not yet available in large pieces) for which an even greater transparency is claimed.

The measurement of the transmission is usually made with the aid of the spectrograph. Half the slit is illuminated by light transmitted by the specimen, the other half by an exactly similar beam, the intensity of which can be diminished (in effect at least) in definite ratios by a special device. The spectrum is thus split into two; we find the wave-lengths at which the intensity has been diminished by the specimen to those ratios used for the above device, by comparing the densities of the two parts of each spectrum photograph. The action in the variable beam can be controlled by a polarisation device or by a rotating sector; in the latter case it seems to be sufficiently accurate to assume that the reciprocity relation is valid for the plate. The optical arrangements for carrying out these tests have been so far standardised that they can be used without difficulty to obtain trustworthy results.

Special apparatus for ultra-violet spectrophotometry, for which greater speed and ease of working is claimed, has also been developed by S. Judd Lewis. Mention must also be made of the photographic methods in which special non-selective 'wedges' are employed; such methods have been worked out (chiefly for the visible region) by Mees, Dobson, and others; in some cases they can be applied to the ultra-violet.

The durability of the new glasses referred to above can only be tested properly by experience. One important matter is their stability under the continuous action of ultra-violet radiation. Some glasses containing small amounts of manganese are well known to develop a pink tinge when used in globes round arc lamps; such action under exposure to intense radiation is likely seriously to prejudice the ultra-violet transmission, and effects of a similar kind should be looked for even in the absence of manganese. Naturally, the relation between the conditions of normal use and the conditions of the test would have to be carefully considered.

Important questions are likely to arise in connexion with the screening off of undesirable components of the radiation; it is possible that liquid 'filters' may become useful in such cases. Much information on recent work on the transmission of liquids is given in Luckiesh's useful book on "Ultra-violet Radiation," and recent work on the transmission of solutions has also been carried out by Dahm.

In conclusion, it may be said that photometric methods are so far developed that it should not be difficult to measure and to control the characteristics and intensity of any ultra-violet radiation used for medical purposes. In the somewhat arbitrary and experimental condition of present practice, it is not possible to be too precise and definite in the specification of physical conditions.

Printed in Great Britain by R. & R. Clark, Limited, *Edinburgh.*

News and Views.

In an address on "Science and the Civil Service," given in November last to the Professional Institute of the Civil Service in Canada, Prof. J. C. McLennan reminded his audience, which included members of the Canadian Cabinet, of the benefits which scientific workers employed by the State have conferred on the populations in the Dominion. So far from scientific men being mere 'high-brows,' unpractical dreamers, and visionaries whose services are worth a mere pittance, they are more practical than the arm-chair politicians who despise science. It was a member of the Geological Survey of Canada, Dr. Dawson, who discovered the famous gold-bearing belt in the Yukon territory. It was largely owing to Prof. Miller and his colleague, Mr. Thomas Gibson, that a mining policy for the development of the silver, nickel, copper, gold, and other metallic mineral fields in Ontario was inaugurated. Canada's remarkable success in agriculture was based on the work of two public servants, Dr. William Saunders, who created the Experimental Farm System, and his son Dr. Charles Saunders, who discovered the Marquis variety of wheat. To another, Dr. Gordon Hewitt, who developed the Dominion Entomological Service and devised means for the control of grasshopper pests, must be given the credit of saving Canadian farmers millions of dollars yearly. The list of services rendered to the material prosperity of Canada by scientific workers in the public services could be extended indefinitely. For the most part they have worked for wretched salaries and, in some cases, with but the most meagre recognition of their great works. It is time the statesmen of the Dominion realised the immense potentialities of properly endowed scientific services.

Prof. McLennan did well to point out to the statesmen and other public men present that if the scientific services are starved in Canada, the best brains of the community will continue to migrate to its great neighbour, where they can expect greater encouragement and more freedom to apply their discoveries. The tendency on the part of the wealthy and financial houses to send money to the neighbouring State for investment is a direct consequence of the apathetic attitude of the Dominion Government towards scientific research. Money now goes for investment and people of ability for employment to places where science is appreciated, where invention and discovery find application in industry. Scientific workers, by the discoveries and advances they are making continually, not only stabilise industries, but also point the way for still greater developments. The best protection for Canada is the adoption of a policy "Science in the Civil Service and Science in Industry." Canada badly needs a National Research Institute in which those scientifically inclined, or those in control of industries, can have their problems investigated. With this view the Hon. Charles Stewart, Minister of the Interior, entirely agreed, and made the useful suggestion that the scientific workers of Canada, led by Prof. McLennan, should go out into the highways and byways and convert the laymen of Canada, who wield the 'big stick' to urge on or frighten members of Parliament, to the need for and value of scientific research.

At the risk of appearing tedious, anthropologists continue, and wisely, to urge the importance of their studies for purposes of administration among backward races. The latest pronouncement is by Mr. J. H. Hutton, of Assam, who is well qualified to speak both as an anthropologist and an official. In his presidential address to the Anthropological Section at the Calcutta meeting of the Indian Science Congress last January, he argues ably for the utility, and indeed the essential need, of a knowledge of the principles of the science in dealing with such a people as that with which he is most familiar, namely, the Nagas. He points his argument with many an apt illustration in which knowledge of sentiment and custom, especially in the judicial field, has been an essential condition to secure the right handling of incidents such as crop up daily in the path of the administrator. He deals with the difficult question of missionary activity temperately, even though he is compelled to conclude that their influence is in practice harmful, as it breaks bonds which form part of the tribal complex, but for which Christianity affords no substitute to help the native. Supporters of the missionary, it may be noted in passing, who think that Christianity should be able to afford the necessary influence to replace tribal custom, in arguing from the analogy of a Christian society, overlook the fact that ethics are fundamentally cultural even when they have a theological sanction, and to a great extent cannot be transposed from one sytem to another. Mr. Hutton's careful analysis of the results which arise from culture contact between east and west to the detriment of the health and numbers of the native population constitutes a warning against the too hasty introduction of civilising influences, which deserves careful pondering by those who are interested in the advance of backward peoples.

A paper was read on Mar. 30 by Mr. D. Brownlie, before the Diesel Engine Users' Association, on the subject of liquid fuel from coal. He pointed out how necessary a supply of liquid fuel produced in Great Britain will be if the Diesel engine is to attain an importance commensurate with its thermal efficiency. This supply may be derived from coal by carbonisation at high or low temperatures, by hydrogenation, or by synthetic processes based on carbon monoxide. The author dealt with these methods *seriatim*—in particular with the carbonisation of coal at low temperatures, on which he listed seventy-five different processes, describing thirty of major importance which have been in more or less continuous operation in large-scale plant. Hydrogenation and synthetic fuel production were described in outline. The author deplored the slow advance of the production of liquid fuel from British coal, and indulged in a jeremiad on the absence of scientific development of our home resources. It is easy to exaggerate here, for there has been no lack of ingenuity applied to the carbonisation of coal by British workers. About a third of the processes scheduled by the author are of British origin or development; undeniably capitalists have not withheld ample financial support, as many of them would ruefully agree. The author himself throws light on the slow progress when he enlarges on the development of mineral oil production. Oil *can* be produced from coal, but *must* be sold in competition with natural petroleum, and present-day economic conditions do not lighten the task of those who seek to manufacture liquid fuel from coal.

"The Agricultural Depression, its Causes and Possible Cures," was the subject of an address by Mr. W. C. D. Dampier-Whetham at the ordinary general meeting of the Surveyors' Institution, held on April 2. A comparison of the present situation with previous depressions shows that all have occurred during times of falling prices in both agriculture and industry and are ultimately due to monetary instability. After discussing the theory of prices, Mr. Dampier-Whetham showed that the general changes in price level from 1843 to 1914 are explained by the varying relations between the world's supply of and demand for gold Whereas plentiful gold invariably results in an increase of prices and prosperity for the farmer, depressions arise from a falling average level of prices, whether this be due to shortage of gold as in 1873, or to deliberate deflation as in 1920, when efforts were made to restore the gold standard. Protection or free trade has less effect on prices than changes in the value of money. As regards possible remedies for the existing depression, much may depend on the policy of the Federal Reserve Board and possibly on some future international agreement as to the control of the world's gold supply. A system, other than the gold standard, may ultimately be devised for the management of currency and credit, which will tend to keep the index number of wholesale prices constant, and counteract the effects of a probable world shortage of gold. Although such fundamental changes may be premature, some measure of relief will be obtained if efforts are made by the farmers themselves to reduce costs and charges in every possible way, particularly in the sheltered industries, and the questions of marketing, import control, and agricultural credit are still further explored by the Government. The only radical cure, however, is stabilisation of the general price-level, that is, of the value of money.

The contrast between the Building Exhibition of to-day and those that were held in former years at the Agricultural Hall is very marked. Those at Islington were well attended, it is true; for architects, builders, and others of such groups went there in order to gain up-to-date knowledge of marketed goods and processes; but it was purely as a duty that the journey was undertaken. Since Mr. Greville Montgomery has organised the show at Olympia, the duty of attendance has become a real pleasure. Environment and district have not a little influence in the change of sentiment; Kensington against Islington, for north is north, and west is west, "and never the twain shall meet." But the character of the display is a more powerful influence still. One outstanding feature is, that all the exhibitors may be regarded as having some association with building; and, again, there are no extraneous attractions, with the exception of good music. The Government shows its sense of the value of the exhibition by having representative departments there; there is the Empire Marketing Board, the name being self-explanatory; and at this stall are to be seen several interesting tests results upon timber beams carried out by the Forest Products Research Laboratory The Department of Scientific and Industrial Research supplies information as to the work carried on at the Building Research Station near Watford, to which reference was made lately in our columns. As the majority of people are interested in building in one form or another, the attendances at Olympia are naturally large; the goods are attractively displayed, and inquiries are dealt with intelligently. The work of various arts and crafts training institutes forms a feature, and there is also an admirable loan collection of antique and modern furniture, the latter from the designs of well-known architects and others. Altogether, there are close upon four hundred exhibitors.

The trans-Atlantic flight from east to west by a heavier-than-air machine has at last been accomplished. Capt. Hermann Kohl, Commandant James Fitzmaurice, and Baron von Hunefeld started from Baldonnel aerodrome, near Dublin, in the *Bremen*, early in the morning of April 12, and landed at Greenly Island in the Strait of Belle Isle on the following day. Capt. Kohl, manager of the night-flying department of the Deutsche Lufthansa, and Baron von Hünefeld, with a mechanic, flew from Berlin to Dublin on Mar. 26, where they had to await favourable weather conditions for their Atlantic flight. The mechanic was replaced by Commandant Fitzmaurice, acting officer in command of the Irish Free State Air Service, who acted as second pilot when the flight began on April 12. The *Bremen* is a Junker metal monoplane fitted with a 200 k.w. Junker engine. A rough analysis gives aeroplane weight as 1·2 tonnes; crew, etc., 0·2 tonne; fuel and oil 1 6 tonnes, giving 40 hours' flight at cruising speed 150 km./hr., that is, a range of 6000 km. in calm air. The actual geographical distance covered was about 3500 k.m., so that changes in course and head winds reduced the effective speed to about 90 k.m./hr. Herein lies the patent secret of previous failures. A small circle of about 3500 km. with Dublin as centre grazes the North American coast at Greenly Island, the landing point, from which we may infer that another disaster was averted by a sound decision, good navigation, and the last litre of fuel. Capt. Kohl and Baron von Hünefeld attempted a trans-Atlantic flight from east to west last August, but, after making their way from Dessau across England and Ireland, they were forced to turn back by bad weather and lack of fuel.

A PRELIMINARY notice of the International Meeting of Geologists to be held in Copenhagen on June 25–28, on the occasion of the fortieth anniversary of the Geological Survey of Denmark, has already appeared (NATURE, Dec. 17, 1927, p. 890). The provisional programme of excursions has now been revised. Excursions before the meeting are as follows: June 17–20, to Bornholm; June 21–24, to South Sjælland and the Island of Moen. After the meeting a longer excursion, June 29–July 9, is being organised to north-west Sjælland, Fyn and the Island of Langeland, and Jutland. Geologists who are returning to England or France from Esbjerg will have an opportunity of seeing the Yoldia clay of the Mindel-Riss interglacial episode. The number of participants in each excursion is to be limited, and notice of intention to attend should be sent as soon as possible, and in any case before May 1. Full details of cost, itineraries, and accommodation will be found in the second invitation circular, which can be obtained from the Secretary, International Geological Meeting, Danmarks Geologiske Undersøgelse, Gammelmont 14, Copenhagen K, to whom all other relevant inquiries should be addressed.

MARSTON TAYLOR BOGERT, senior professor of organic chemistry at the Columbia University, New York, who celebrated his sixtieth birthday on April 18, spent the past winter in Prague as the first visiting professor for international relations to Czechoslovakia sent by the Carnegie Endowment for International Peace. As the guest of the Charles' University he delivered five highly interesting lectures on his original researches on thiazoles and selenazoles; odour and chemical constitution; science and industry; science, the individual, and the State; science in the interest of peace. He also gave similar lectures at the Universities in Brno, Moravia, and Bratislava, Slovakia. The Charles' University Medal has been awarded to Prof. Bogert for his work for the advancement of science, and the honorary degree of Doctor Rerum Naturalium of the Charles' University has been conferred upon him for his discoveries and researches in organic and applied chemistry.

PROF. YUKICHI OSAKA has recently retired from the chair of physical chemistry which he has held for twenty-three years at the Kyoto Imperial University. An account of his career by S. Horiba, with a photograph, is given in the *Bulletin of the Chemical Society of Japan* for January. Prof. Osaka came to Europe in 1899, having already had some experience of teaching chemistry, and studied under Ostwald and Nernst. Four years later he was appointed to the chair of applied electrochemistry at Kyoto, but very soon became professor of physical chemistry. He is best known for his work upon heterogeneous equilibria, although he has also conducted researches upon the catalytic effect of the hydroxyl ion and upon overvoltage. Prof. Osaka is sixty years of age, and his latest paper also appears in the above journal.

DR. ROY CHAPMAN ANDREWS, after maintaining the headquarters of the Expedition of the American Museum of Natural History to Central Mongolia immobile at Peking for a period of two years owing to political troubles in China, has now left Kalgan to resume work in the desert. According to the Peking correspondent of the *Times* in a dispatch in the issue of April 17, he hopes to ensure the safety of the expedition by a capital payment to the Chief Officer of the brigands of the area, a monthly subsidy, and a sum equal to the first capital payment if the expedition returns safely. The expedition consists of ten Americans, experts in palæontology, geology, archæology, and topography, and a surgeon, a photographer, and two motor experts, with twenty-six Mongols and Chinese. The expedition will continue its search for traces of earliest man, and in addition of the five-toed horse, believed to be the progenitor of the four-toed fossil horse of Europe and America.

As promised, the results of Prof. Trombetti's researches in the Etruscan language, following his investigation of the "Liber Linteus," the linen book, in which the mummy of an Etruscan lady, discovered in Egypt and now at Agram, had been wrapped, were duly laid before the first International Congress of Linguists which opened at The Hague on April 10. Prof. Trombetti gave it as his opinion that Etruscan could not be regarded as an isolated language, but showed close relation to the Indo-European and belonged to the group in which the pre-Hellenic languages of Asia Minor were to be found. Of the twelve chapters of the "Liber Linteus," one was said to bear every indication of being an account of the ***lectisternium***, *i.e.* the meal provided for the images of various gods, while others contained a litany, an enumeration of the *Cepen* or magistrates, and a calendar giving the dates of various festivals.

WE learn from a *Daily Science News Bulletin*, issued by Science Service of Washington, that F. W. Peek has been able to store in a suitable condenser and discharge electricity at a pressure of three million six hundred thousand volts. The experiments were carried out at the Pittsfield laboratory of the General Electric Company. The object of the research was to imitate as closely as possible the phenomena that happen during a lightning discharge from a cloud, so as to help in designing effective lightning conductors and safety devices. Although the spark lasted less than a millionth of a second, yet its growth and decay were accurately measured by a cathode ray oscillograph, which uses a beam of electrons for a pointer. In some cases the flash lasted only the ten-millionth of a second. Remembering that light travels with a velocity of 3×10^{10} cm. per second, the flash will be over by the time the light has travelled a hundred feet from the spark.

THE following appointments have been made by the Secretary of State for the Colonies: Mr. S. Gillett to be assistant agricultural officer, Kenya; Mr. W. H. W. Baird, to be entomologist, Veterinary Department, Tanganyika Territory; Dr. R. R. Le Geyt Worsley, formerly sub-director of the Chemical Section, Egypt, to be chemist, East African Agricultural Research Institute, Tanganyika Territory;

Mr. J. G. Brash and Mr. J. C. Bytheway, to be produce inspectors, Nigeria. Recent transfers and promotions made by the Secretary of State include: Mr. R. A. Altson, formerly assistant botanist and mycologist, British Guiana, to be assistant mycologist, Department of Agriculture, Federated Malay States and Straits Settlements; Mr. J. T. Templer, formerly administrative cadet, Tanganyika Territory, to be assistant conservator of Forests, Uganda. Mr. Baird's appointment is of interest in that it appears to be the first appointment, on a permanent basis, of an entomologist to a veterinary department in the Colonial Services.

Farmers' and farm workers' associations and clubs, chambers of agriculture and horticulture, students' societies, and other bodies interested in agriculture or market gardening are again being invited to inspect the Rothamsted and Woburn Experimental Plots during the coming summer. Mr. H. V. Garner and Capt. E. H. Gregory will be available to demonstrate the plots at any time. At Rothamsted the soil is heavy. The experiments deal with the manuring of arable crops, especially sugar beet, potatoes, mangolds, barley, oats, wheat; manuring of meadow hay; effect of modern slags and mineral phosphates on grazing land and hay land; inoculation of lucerne; crop diseases and pests; new experiments are in progress on the laying down of land to grass; demonstrations of modern implements, tractors, and good types of tillages. At Woburn the soil is light. The experiments there are concerned more particularly with the manuring of potatoes, sugar beet, wheat, malting barley, and the use of green manures. All communications and requests to visit the Stations should be addressed to the Secretary, Rothamsted Experimental Station, Harpenden.

The Faraday Medal of the Institution of Electrical Engineers will be presented to Prof. J. A. Fleming at the ordinary meeting of the Institution to be held on Thursday, April 19, at 6 P.M. The presentation will precede the nineteenth Kelvin Lecture, by Sir Oliver Lodge, on "The Revolution in Physics."

A violent earthquake was recorded at Kew Observatory on April 16 at 9 h. 4 min. 32 sec. G.M.T. The epicentre is estimated to be 1430 miles away, probably near the western coast of the Black Sea. The disturbance at Kew was of about the same intensity as that produced by the destructive earthquake which occurred near Smyrna on Mar. 31.

The Council of the Institution of Automobile Engineers has awarded the Institution Medal to Major G. S. Wilkinson for the prominent part taken by him in the design of the Napier Lion 875 h.p. engine fitted to the Supermarine-Napier S5 with which Flight-Lieutenant S. N. Webster won the Schneider Trophy Race in September last.

It will be remembered that at an extraordinary meeting of the general committee of the British Association held on Dec. 2, it was resolved to apply for a Royal Charter for the Association. Mr. A. A. Campbell Swinton very generously offered to bear the cost of obtaining the Charter. It is now announced that His Majesty the King in Council has been pleased to grant the petition of the British Association.

The recently issued catalogue of Judex Analytical Reagents and Laboratory Chemicals, issued by the General Chemical and Pharmaceutical Co., Ltd., Willesden, includes a wide range of inorganic and organic chemicals. Among them are analytical reagents of guaranteed purity, standard solutions for volumetric analysis, special reagents for use in the analysis of water, gas, milk, sugar, urine, iron and steel, volumetric solutions of the "British Pharmacopœia," indicators, chemicals for electroplating, accumulator acid, etc. Besides supplying rare chemicals for research and analysis, the firm undertakes the manufacture of large or small amounts of unusual substances required for special purposes.

The "Statistical Report of the Health of the Navy for the Year 1925" and the "Report on the Health of the Army for the Year 1926" have recently been issued by the Admiralty and the War Office respectively (London: H.M. Stationery Office). As regards the Navy, the returns for the total force for the year show a decrease in the incidence of disease as compared with the previous four years' average and with 1924. In the Army, the incidence of sickness was a trifle higher than in 1925. The incidence of tonsillitis again increased, and as a cause of admission to hospital took second place; all attempts to elucidate the cause of this high incidence have so far failed. Middle ear disease, as in the previous year, heads the list of causes of invaliding.

Historical details given in a catalogue issued by Messrs. W. Ottway and Co., Ltd., manufacturers of optical and scientific instruments, Orion Works, Ealing, W.5, show that the foundations of the business were laid about three hundred years ago. In 1640, the shop at the Royal Exchange occupied by Thomas Francis Ottway, a maker of instruments of a scientific nature, was destroyed by the fire which devastated central London. The business was afterwards carried on at various addresses until 1900, when the present works at Ealing were opened. The firm is still owned and managed by descendants of the original founder, and their works are now so well equipped as to enable the company to manufacture all the various parts required for the instruments produced by them. These include equatorial mountings for reflecting and for refracting telescopes; astronomical transits; astronomical clocks and chronographs; cœlostats with driving clocks and with mirrors up to 18 inches in diameter; control instruments for controlling electrically the driving clocks of astronomical instruments; and a wide range of astronomical telescopes with object glasses up to 5 inches aperture. The instruments mentioned are fully described and illustrated in the catalogue, which contains also a list of various types of naval, military, and sporting telescopes. Achromatic object glasses up to 6 inches clear aperture and 90 inches focal length, heliographs, prismatic compasses, and prismatic binoculars are also included.

The 1928 edition of "British Spas and Climatic Health Resorts" has recently been published (London: J. and A. Churchill. 1*s*.). It gives much information concerning the choice of waters and climates and on British and Irish marine and inland health resorts. Lists of the residential accommodation available in the principal resorts are furnished.

In connexion with the tercentenary of the publication of Harvey's "De Motu Cordis," the Cambridge University Press will issue a limited edition of "A Bibliography of the Works of William Harvey," compiled by Mr. Geoffrey Keynes. The work will be illustrated by a number of collotypes and facsimiles in line. The same house also announces "The Theory of Probability," which Prof. W. Burnside had almost completed at the time of his death. The volume has been seen through the press by Dr. A. R. Forsyth, and includes the memoir of the author which Dr. Forsyth wrote for the Royal Society.

Applications are invited for the following appointments, on or before the dates mentioned:—An assistant part-time lecturer in the biology department of the Plymouth and Devonport Technical College —The Secretary for Education, Education Office, Cobourg Street, Plymouth (April 28). A district agricultural organiser under the Essex Agricultural Committee (on the Staff of the East Anglian Institute of Agriculture)—The Clerk of the Essex County Council, Shire Hall, Chelmsford (April 30). Professorships of geography, medieval history, Egyptian and Oriental history prior to Græco-Roman times, classics and Græco-Roman history, in the Egyptian University, Cairo—The Director, Egyptian Educational Office, 39 Victoria Street, S.W.1 (April 30). A professor of botany in the Egyptian University, Cairo—The Dean of the Faculty of Science, Egyptian University, Cairo (April 30). A junior assistant (engineer) at the Building Research Station, Watford—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (April 30). A government analyst and bacteriologist for Cyprus—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (May 7). A lecturer in physics in the University of Western Australia—The Agent-General for Western Australia, Savoy House, 115 Strand, W.C.2 (May 9). Head of the architectural, building and surveying department of the Northern Polytechnic—The Clerk to the Governors, Northern Polytechnic, Holloway, N.7 (May 11). A temporary agricultural entomologist in Fiji and, possibly, afterwards in the British Solomon Islands Protectorate—The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1 (May 21). An assistant professor in the department of mathematics of the Imperial College of Science and Technology—The Secretary, Imperial College of Science and Technology, South Kensington, S.W.7 (May 25). A curator of the Gloucester Museum—Mr. St. Clair Baddeley, Castle Hale, Painswick, Gloucestershire.

Our Astronomical Column.

Nova Pictoris.—Another telegram from Mr. Wood at Johannesburg was distributed from the I.A.U. Bureau, Copenhagen, on April 14. It states that the Nova is now surrounded by a ring 3 minutes of arc in diameter, with two smaller rings inside it. These rings are clearly much too large to be produced by the outward motion of matter from the Nova since the outburst in 1925. We may assume that they are similar to the nebulosity photographed round Nova Persei in the autumn of 1901, which was explained by the hypothesis that the nebulosity was previously there in a dark state, and became visible by reflecting the light of the outburst.

Pop. Astron. for April states that the magnitude of the Nova in mid-December last was 6·77. As it is falling at the rate of a magnitude per annum, it is probably a little fainter than mag. 7 at present. Several of the daily papers erroneously gave its present magnitude as about 11.

Comets.—M. Mineur obtained an observation at Paris on Mar. 28 of the comet detected on Mar. 17 by M. Giacobini; the following are the two positions:

	R.A.	N. Decl.	Mag.
Mar. 17. 9264 .	$5^{h}\ 50^{m}\ 0^{s}$	14° 35′ ″	11
28. 9585 .	6 12 26·5	14 57 39	10¼

The daily motion on Mar. 28 was given as $+3\frac{1}{4}^{\mathrm{mm}}$ in R.A., 0′ in decl. The position on April 21 may be about 8^{h} in R.A., 14° in decl.

Dr. C. P. Olivier states in *Pop. Ast.* for April that the comet Pons Winnecke yielded a rich shower of meteors on June 23 last. Meteors were fairly numerous on June 26-29.

April Shower of Meteors.—These meteors may be expected on April 21, and should attain a maximum either in the morning or evening of that date. Moonlight will not interfere with the display should it actively return this year. The shower is no doubt a periodical one, but the exact period, or that of the supposed associated comet 1861 I, is not known. Apparently the earliest exhibition of the meteors occurred in 687 B.C., and later returns possibly occurred in 15 B.C. and A.D. 582, but identity may not be absolutely certain though the dates conform within small limits.

April is one of the spring months when meteors are generally rare, so that, should the Lyrids fail to present themselves, meteoric apparitions are somewhat scarce, and long vigils are not suitably rewarded. But the special Lyrid shower may develop unusual strength at any time and amply repay observation. The sky should be attentively watched every year at the end of the third week in April, for evidence as to the character of the shower's return cannot fail to add to our knowledge.

On April 21, before daylight, the radiant will be very high and favourably placed for the visibility of its meteors, but the evening hours between 10 and 12 are indicated as the most probable time for the earth's passage through the denser part of the stream. At the latter time the radiant is in the north-east and not very high. Observations of the paths of any bright meteors that may appear will be valuable, whether they belong to the system of Lyrids or to one of the minor displays of this epoch.

Research Items.

Lubaantun.—In vol. 57 (1927), Pt. 2, of the *Journal of the Royal Anthropological Institute*, Mr. T. A. Joyce, with the assistance of notes contributed by Mr. Cooper Clark and Mr. J. E. Thompson, reports on the excavations which he conducted on behalf of the British Museum on the Lubaantun site in British Honduras in 1927. The excavation of the megalithic hill-terraces, discovered in the previous year, was continued. It is now confirmed that these terraces were constructed before the two large pyramids, and probably constitute the earliest phase of architecture on the site. Excavations to the north of Mound *S*, as it is now known, in search of a continuation of the megalithic hill-terraces, while unsuccessful in finding them, produced clear indication of five architectural periods. The earliest phase of building laid bare at this point consisted of a stairway which ran under the mound. It was approached by an inclined stucco flooring. Behind the stairway was a wall built against the hill-side, which may be earlier than the steps, or may have been built as a containing wall to enable them to be constructed. Examination of the exposed surface of the whole pyramid suggested to Mr. Thompson that the remarkable in-and-out style of architecture may have been the result of disintegration rather than an artificial and conscious product; but Mr. Joyce is not inclined to agree, especially as this style occurs only in the Lubaantun area and not elsewhere as might be expected if it were the result of disintegration. Mounds *D*, *F*, and *G* were also excavated and produced a considerable number of relics. A platform in mound *G* would appear to have carried a wooden structure which was destroyed by fire. The floor was covered with three feet of burnt clay mixed with wood ash. Old Empire pottery of excellent style precluded any possibility that the structure dated from a re-occupation of the site.

Vitamin Concentrates for Margarine.—It is generally conceded that the average consumption of fat in Great Britain is below the optimum, and also that a proportion, sometimes the major part, of that consumed is in the form of vegetable fat (or margarine). Now, although an animal fat can be replaced in the diet by isodynamic amounts of carbohydrate, protein or vegetable fat, so far as the supply of energy to the body is concerned, yet none of these other foodstuffs can supply the fat soluble vitamins A and D, which are present in varying degree in the different animal fats. The importance of these vitamins for the maintenance of general health and wellbeing and the prevention of certain diseases need scarcely be emphasised at the present time. The drawback to an increased consumption of animal fat is the cost of such products, hence a more practicable alternative would seem to be the enrichment of vegetable margarines with a source of the fat soluble vitamins. Messrs. Planters Foods Ltd., Brombro Port, Cheshire, have recently put on the market several brands of vitamin margarine: each contains a sufficiency of their vitamin concentrate 'Essogen' to bring the potency of the margarine up to that of the best summer butter. The potency of the products is controlled by experimental feeding tests. The addition of the concentrate has no deleterious effect upon the taste or palatability of the margarines.

Body Defence against Pathogenic Organisms.—Di Cristina's views on the processes by means of which the animal organism defends itself against infection is the subject of a communication by Caronia in the *Atti della Pontificia Accademia delle Scienze* for 1927. The results of more than ten years' work in the vaccine therapy of infectious diseases have led di Cristina to the conclusion that Ehrlich's original conception of immunity, according to which the defensive mechanism of the organism is based on the struggle between antigens and anti-body, neither corresponds with the facts nor explains the processes of cure. The infected organism is highly sensitive to the protein homologous to the pathogenic germ and remains so until the infection becomes extinguished naturally. Thus a direct relationship exists between the condition of hypersensitisation and the disease, and this stands out the more clearly as the special property acquired by the organism to withstand the action of the bacterial protein is the more marked. Cure occurs gradually as the organism becomes desensitised. The desensitisation, which takes place naturally in the case of spontaneous cure, is best effected artificially by the intravenous or subcutaneous administration of small doses of protein derived from the corresponding pathogenic agent. The antigen thus introduced leads, by true anaphylactic reactions, to complete desensitisation in a period varying with the method employed. The actual mechanism of this process is still obscure, but probably depends on phenomena originating at the expense of the equilibrium of the colloids of the tissues, new conditions, which prevent further development of the pathogenic action of the germs, being thus determined.

Microbiological Observations at Novaya Zemlya.—A. F. Kazansky, who is microbiologist of the Russian Academy of Science, according to the *Information Bulletin* of the Academy, has recently returned from an expedition to Novaya Zemlya, where he studied the microflora during the winter and summer of 1927. Microflora of the air proved to be remarkably poor, especially in winter, when Petri dishes with media remained sterile after long exposures; only in a few cases were micro-organisms found when the dishes were exposed near to habitations. In summer some micro-organisms were observed more regularly, up to 13 in one dish, but on the average only 1-3, while many dishes remained sterile even after exposures for an hour. Sterilised meat exposed for eight months, from February to September, remained fresh, though microscopic analysis revealed the presence of some micro-organisms. Analysis of snow gave in most cases negative results, but during summer the number of bacteria in snow was greater than in the air. Study of the soil microflora revealed the presence of atmospheric nitrogen fixing bacteria, nitrifying and de-nitrifying bacteria, and bacteria causing aerobic decomposition of cellulose. More detailed studies of the organisms found will be continued in the Academy laboratories in Leningrad.

Mouth-Parts of a Blood-sucking Midge.—In the *Bulletin of Entomological Research*, vol. 18, Feb. 1928, Mr. B. Jobling provides an illustrated account of the structure of the head and mouth-parts of the common blood-sucking midge *Culicoides pulicaris* L. Among various features described in this detailed study it is noteworthy that, unlike many blood-sucking flies, mandibles are present in both sexes, although weakly developed in the males. The labrum-epipharynx, hypopharynx, and mandibles form together a piercing organ which is driven into the skin of the person or animal attacked. The galeæ of the maxillæ are blade-like, with numerous fine teeth distally, but being only partially chitinised they evidently perform merely an accessory function in piercing. The labium plays no part in the process, but serves to maintain the other organs in position. The author follows Frey, Crampton, and others in regarding the labella as the modified labial palps. The intense irritation caused by the punctures of these minute flies is alleviated if the lesion be moistened and rubbed with a crystal of sodium carbonate. The author states that with this application it ceases in a few seconds and does not recur.

Lake Michigan Plankton.—Mr. Samuel Eddy ("The Plankton of Lake Michigan," State of Illinois Department of Registration and Education. Division of the Natural History Survey. Bulletin, vol. 17, art. 4, 1927) bases his account of the plankton from the inshore waters of Lake Michigan on two collections taken respectively in 1887–88 from November to October, and in 1926–27 in October, May, and July. These were worked out qualitatively, and in the later collection also quantitatively, the chief purposes being to present a general picture of the plankton of Lake Michigan, to determine the relative abundance of the constituent organisms and to incorporate and summarise the facts now known relating to the plankton of the Great Lakes. The physical conditions in Lake Michigan vary little from year to year, and variation among the plankton organisms is slight. A comparison of the two collections shows little change in the plankton over the period of forty years, the only notable exception being the copepod *Epischura lacustris* Forbes, which was abundant in the early collection but absent altogether later. This may be due to larger nets being used, as more of the larger and less of the smaller plankton animals were present in the earlier collection generally. The seasonal changes are slight, but in 1887–88 the animal plankton decreased in the cold weather and was almost entirely absent from December to March. The plankton is characteristic of a large and deep lake. The chief constituents are diatoms; especially Asterionella, Striatella, and Fragilaria. There are a few Cyanophyceæ and Chlorophyceæ, only two peridinians, and the metazoa are represented by Hydra, nematodes, rotifers, Cladocera, and copepods.

Survey in the Gold Coast Colony and Protectorate.—The *Report* of the Survey Department for 1926–27 records that nearly two-thirds of the total area, including the mandated territories on the east, have now been surveyed. The parts that remain to be surveyed are mainly in the north-east of Ashanti, the west of the Northern Territories, and the mandated territories which were formerly part of Togoland. The total number of one-inch sheets printed is eighty-two, and of half-inch sheets twenty. In recent years the department has had not only its own school of instruction for native surveyors but also its own printing establishment. It is of interest to note that during the season when the harmattan blows, which is chiefly in January, all colour printing has to cease. This dry wind following rapidly on humid conditions causes a change in the area of the paper of as much as a quarter of an inch in a sheet two feet square, making it impossible to secure registration. The department has also produced a wall map of the Colony for the use of schools. The *Report* contains indices of the published sheets.

The Lancashire Coalfield.—Another addition has been made to the valuable series which is being gradually issued by the Fuel Research Division of the Department of Scientific and Industrial Research (*Physical and Chemical Survey of the National Coal Resources*, No. 10, The Lancashire Coalfield, The Wigan Four-Feet Seam. London: H.M. Stationery Office). It contains a complete description of the character and composition of the important seam known as the Wigan Four-Feet Seam, as well as by a number of other names which appear to be variations of the words 'Ell Hole.' It occurs throughout the South Lancashire Coalfield, its thickness increasing with considerable regularity from about 2 ft. in the eastern portion of the Coalfield to a maximum of 6 ft. 3 in. at Garswood, and getting slightly thinner from this point towards the St. Helen's district. Analyses and laboratory tests show that the coal is of good quality with an ash which is generally low, averaging between 3 and 4 per cent., though occasionally going up to nearly 10 per cent.; volatile matter averages about 40 per cent., and the coal is accordingly used chiefly as a house coal or a gas coal, though its high coking qualities fit it for the manufacture of coke. The report records a complete series of laboratory tests including full analyses, carbonisation assays, investigation of the melting point of the ash, of the caking index, and washing tests, the latter showing that the coal is quite suitable for further cleaning. The report gives evidence of much careful and painstaking work, and there are numerous illustrations; it may be doubted whether the plates showing the cokes produced in the assays are worth the cost involved in their reproduction, and it is also to be regretted that more distinctive colours have not been employed in the map of the Coalfield affixed to the report.

Artificial Disintegration of Elements.—In the issue of *Die Naturwissenschaften* of Mar. 23, W. Bothe and H. Franz have given a short report of some experiments made by them at Berlin, by which they have attempted to decide whether or not the claims of the Viennese school to have effected an extensive disintegration of atomic nuclei by bombardment with α-particles can be substantiated. The source of α-particles employed was a strong preparation of polonium, and since this emits scarcely any β-rays or γ-rays a Geiger electrical counter could be used as a recording instrument in place of a zinc sulphide screen. On the whole, the results obtained confirm the work of Sir Ernest Rutherford and Dr. J. Chadwick. Less than ten per cent. of the retrograde particles from beryllium, carbon, aluminium, and iron recorded at Vienna could be detected, whilst in the forward direction about one H-particle of range greater than 10 cm. in air was found with aluminium and iron, and about ten from paracyanogen and boron, in each case per million α-particles. Boron seems to give two sets of protons, which it is suggested may come from its two isotopic components. It is pointed out that it has not yet been shown that flashes due to β-particles are not detectable with the powerful microscopes now used for viewing scintillations, and that if these are present they will be confused with flashes due to protons, which will thus appear to be present in unduly large numbers.

X-ray Kinematography.—The *Chemiker-Zeitung* for Mar. 24 contains a brief description of a new process evolved by Dr. Gottheiner, the Rontgen-ray expert of Berlin, by means of which kinematograph films can be made of objects illuminated by Rontgen-rays. The extreme shortness of the wave-lengths of these rays has hitherto been an insuperable barrier, since they do not converge when passed through lenses of glass or quartz. Thus it has been impossible to obtain reduced images except by re-photographing life-sized negatives. But by means of suitable screens it is possible to convert these non-converging rays into simple light rays, which can be photographed in the ordinary way on kinematograph films. Dr. Gottheiner has devised screens which give sufficient intensity for the purpose. The process should be extremely valuable in the diagnosis of diseases.

Long-Distance Telephony in Europe.—At the 'Volta' conference of telegraphists and telephonists, held at Como last September, P. E. Erikson read an interesting paper on long-distance telephony in Europe. In a few years the principal countries in Europe have developed rapidly and methodically methods of communication through underground cables. These now form the main highways of speech. The various countries have all made provision for international circuits. In many cases special mains have been included in the international circuits for the relaying of broadcasting programmes. These additional mains can advantageously be used during the hours when the ordinary traffic is light. They also enable small broadcasting centres to obtain excellent programmes of high artistic merit at a small cost. The cable between Plymouth and Glasgow, a distance of 554 miles, in the longest in Great Britain. There is now a regular service between England, Berlin, and Stockholm. The Paris to Strasbourg cable is destined to play a very important rôle in the future, as it will connect France with central and southern Europe. Paris and Berlin are linked by a cable about 770 miles long, which employs no less than fourteen repeaters. The Berlin-London cable, which was opened in 1926, is the longest through cable (858 miles) in Europe. It is interesting to learn that the London to Glasgow circuit contains some specially loaded cables which are part of the London to New York trans-Atlantic telephone circuit. The thermionic valve repeater has enabled small gauge conductors to be used for long-distance use. Thus many of these circuits are carried within the cable sheath. In addition, the number of communication circuits is appreciably increased by utilising certain of the circuits so as to form 'phantom' circuits. These circuits were first used in the London to Liverpool cable in 1913. To illustrate how rapidly long-distance telephony has advanced, it has been calculated that the total length of 'cable-pairs' in Europe alone would circle the globe sixty-eight times.

Variations of Radio Broadcast Signals.—Broadcast listeners who are situated between 100 and 150 miles from an emitting station notice that nocturnal variations of signal intensity frequently occur. If a galvanometer instead of a telephone be used, small variations in signal intensity at much shorter distances can be detected. In a paper on signal fading, read to the Institution of Electrical Engineers on April 4 by E. V. Appleton, it is shown by analysing the results obtained at the Peterborough radio research station that the phenomenon of fading is in accordance with the Kennelly-Heaviside layer theory. There are two sets of waves falling on the receiver. One of these is the ground wave and the other is reflected from the ionised layer. During a normal night the height of this layer may vary from 56 to 81 miles. On some nights in winter, however, heights varying from 155 to 217 miles were observed during the three hours before dawn. The author also gives an account of observations taken during the solar eclipse in June 1927. The results prove that the eclipse had a very definite effect on the properties of the ionised layer, which deflected the waves back to the ground. A very striking effect was the large increase in the intensity of the downcoming ray. This effect is ascribed to the increase in height of the deflecting layer and partly also to the rapid removal of the ionisation in the lower layers of the atmosphere consequent on the removal of the solar ionising agents. Another striking feature of the observations was the short time the eclipse effect lasted. The period varied between 20 and 50 minutes at the different stations, while the total time taken for the moon's shadow to pass across the earth was nearly two hours. This means that quite an appreciable fraction of the sun's radiation may be cut off before the effect can be detected by radio methods. The morning after the eclipse happened to be quite exceptional, as night-time conditions persisted for a long time after sunrise. The formulæ given in the paper will be a help to radio engineers.

A New Antiseptic Solution.—A new antiseptic solution has been introduced by Messrs. The British Drug Houses Ltd., London, in the form of "Caprokol, antiseptic solution, S.T.37." It is stated that 'Caprokol' lowers the surface tension of liquids in which it is dissolved: this results in increased penetration into the fissures of a surface, especially when the latter is greasy, increased adsorption on to the surface of suspended insoluble material, for example micro-organisms, and an increased rate of diffusion. Hence the antiseptic becomes concentrated round the cell wall of the organism and then penetrates with ease into the cell. 'Caprokol' solution is a solution of 'caprokol' in glycerin and water: its surface tension is 37 dynes per square centimetre, as compared with 77 dynes for water. The carbolic acid coefficient of 'caprokol' is 72: in spite of its strong disinfectant power it is nontoxic. The solution is also non-irritating, odourless, colourless, stainless, and non-corrosive: it is recommended for the disinfection of wounds or tissue surfaces, and for use in the mouth, nose, or throat, or for urethral and pelvic lavage. It is supplied in 3-oz. and 12-oz. bottles.

The Photochemical Decomposition of Nitrous and Nitric Oxides.—The *Journal of the Chemical Society* for January contains a paper by J. Y. Macdonald describing the results of an investigation of the decomposition of nitrous and nitric oxides by light of wave-length 1860-1990 A. The source of radiation was a condensed spark between aluminium electrodes, and a parallel beam was obtained by using a fluorite lens. Nitrous oxide was found to decompose according to the equation $4N_2O = 2NO + O_2 + 3N_2$, nitrogen peroxide being formed afterwards by the interaction of the nitric oxide and oxygen. The quantum efficiency, that is, the number of molecules decomposed per quantum of radiation absorbed, is 3·9, and appears to be independent of temperature, although the amount of light absorbed, and hence the rate of reaction, varies with temperature. The following mechanism for the reaction is suggested and discussed (N_2O' is an activated molecule):

$$\begin{gathered} N_2O + h\nu = N_2O' \\ N_2O' + N_2O = O_2 + N_2 + 2N \\ 2(N + N_2O = NO + N_2). \end{gathered}$$

In the case of nitric oxide, the quantum efficiency is much lower, about 0·75, and the absorption coefficient is less than that of nitrous oxide. The decomposition appears to take place in two ways according to the equations:

$$\begin{gathered} 2NO = N_2 + O_2 \\ 3NO = N_2O + NO_2, \end{gathered}$$

about 90 per cent. of the nitric oxide being decomposed in the first way. Beer's law for the absorption of light holds for both the oxides.

Commercial Shark Fishing.

An interesting article on a commercial net-fishery for sharks at Port Stephens appears in the *Australian Museum Magazine* (vol. 3, No. 5, Jan.-March 1928). The nets used, each twenty feet in depth, are constructed of forty-two or sixty thread cotton, and are of twelve, sixteen, and twenty inch mesh (six, eight, and ten inch squares). The 'headline' of the net is buoyed with glass floats, five inches in diameter, every eight feet. The 'ground-rope' is weighted with four-ounce leads every three feet. The nets are set loosely between pairs of buoys and lie vertically on the bottom. They are hauled daily at dawn. Entangled sharks are despatched by heavy blows on the back of the head, or by a revolver bullet through the brain after being initially secured by a large hook thrust through the jaws.

The commercially valuable sharks in their order of prevalence are the whaler (*Carcharhinus macrurus*), grey nurse (*Carcharias arenarius*), tiger shark (*Galeocerdo arcticus*), and white shark (*Carcharodon carcharias*). The largest specimens of these species so far captured vary from 8 ft. to 13 ft. in length and from 370 lb. to 1000 lb. in weight. Species of smaller sharks are actually the more prevalent but are at present discarded.

The daily catches are conveyed to the depot at Pindimar, where cutting up at once begins. First, the fins are removed; these are cut off close to the body and then dried in the sun or in patent hydrators. They are exported to the East for conversion into soup or gelatine. Next the skin in stripped from the carcase. The detached hide is placed on a beaming board, a curved upright iron stand, and the adhering flesh trimmed off with a sharp knife. After trimming is complete, the hide is thoroughly washed with salt water and placed in brine for from twenty-four hours to a week, after which it is stored ready for shipment to the tanners. If the leather is required for other than ornamental purposes, the shagreen must be removed before or during tanning. This is usually accomplished by treatment with hydrochloric acid and salt. Shark leather is very durable and makes an excellent shoe leather. Shark skins with the shagreen left *in situ* are being preserved for ornamental purposes, such as coverings for caskets, trinket boxes, and toilet sets. They may be dyed very beautiful colours. The flesh of the shark is cut into strips a foot long; these are soaked in brine and then hung in dehydrators. When dried it is ready for shipment to the Malay States or Africa, where there is a considerable demand for dried shark flesh for food.

When the hide is being stripped, the abdominal contents are exposed, the most conspicuous feature being the liver. Shark livers are rich in oil, which is extracted in a steam-jacketed kettle of fifty gallons capacity. The best oil producer so far treated is the tiger shark. A thirteen-foot tiger shark yielded eighteen gallons of oil, or at the rate of forty gallons to the ton of shark. Shark liver oil is used for the currying of leather, the tempering of steel, and in soap-making. If extracted from perfectly fresh livers it will probably be used for medical purposes, for it is rich in vitamins A and D.

The brief experience of the Port Stephens Company appears to indicate that catches of sharks are likely to be irregular, at least during some periods of the year. Careful consideration must therefore be given, before embarking on such an industry, to the question whether the profits which accrue from an intensive fishery will compensate for intervening slack periods. Solution of some of the difficulties may be found in the establishment of a depot vessel capable of treating the sharks on board, the catches being supplied by small shark boats fishing in the vicinity. Then, should the shark give out temporarily in one district, the vessel could proceed to other grounds and, if the catches proved to be good, remain there until the depletion of the supply necessitated a further change of ground.

Malay Resins and the Trade.

An interesting paper, and one of some value on Malayan varnish resins, was recently read before the Royal Society of Arts by Mr. Hedley Barry (*Jour. Roy. Soc. Arts*, Dec. 16), who has carried out considerable investigations into Empire resins. During the past three years the author has been more intimately concerned with the group of Malayan resins. The paper deals with the Malayan varnish resins, with special reference to the work of the Forestry Department of the Federated Malay States and Straits Settlements in the development of the damar industry in the Malay Peninsula.

The Forestry Department, said Mr. Barry, has indeed undertaken a task which all those who have to deal with resins will agree is of the utmost importance. It is endeavouring to supply definite standard grades of the resins found in the forests, the botanical origin of which shall be known, and their freedom from adulteration guaranteed by the Department. This is indeed an ambitious scheme and one of which chemists in particular will cordially approve. The author alludes to some of the difficulties which the Forestry Department—and the remarks are applicable to other Forestry Departments of the British Empire—has to face in carrying out the aims and objects its work entails. In Malaya the rapid development of the tin and rubber industries has been achieved at the expense of an enormous destruction of timber, which is estimated to be of the order of 75,000,000 tons in the last twenty years. At the present time Malaya uses about 5,500,000 tons of timber, of which it produces only about 5,250,000 tons. To produce this amount it is necessary, according to the author, to maintain about 25 per cent. of the country under forest. At present the Forestry Department controls about 19 per cent. of the area, but much of this is not productive land. Its policy is to balance the conflicting demands of the users of forest products and those who require land for rubber planting, tin mining, and similar activities which are making such headway in the Colony. In addition, the maintenance of forests on high land for the protection of cultivated tracts below from the dangers following excessive erosion and the protection of catchment areas requires the careful attention of the forest officer.

In view of these demands on its activities, it is not surprising that it is only within the last few years that the forestry officials have been able to turn their attention to improving the market position of the several valuable resins which the forests produce. The main difficulty which faces the forest officer on such occasions is to get into touch with the trade itself. The forests are situated in far-off tracts of the Empire—almost unknown to the actual users of the raw product—and without some intelligent connecting link little advance can be made, or so the past has shown on innumerable occasions, in placing a new and perhaps valuable product on the market. As this paper indicates, it is not the forest officer who is often to blame, but the merchant himself at the other end.

It is not possible here to follow the author through his interesting description of the resins and the methods of tapping the trees and so forth dealt with in his paper. The inadequate labour supply forms one of the main difficulties to an increase in output of the resins. At present about 26,000 trees are tapped, but of this number 16,000 are as yet only giving a partial yield, being only tapped up to eight feet instead of the whole height of the stem.

That Mr. Barry's treatment of the subject was that of the expert who is at the same time capable of making his meaning and the interpretation of his work clear to his audience is apparent from the very interesting discussion which followed the paper. An important representative of the trade said that they had learnt a great deal from the lecture. From the trade point of view the Malayan damars are the newest. Of the two Malayan damars the 'cat's eye' (derived from various species of Hopea), from the trade point of view, has the greater value and is pushing the Singapore almost out of use. It is far above the Batavian in value, and is certainly very favourably received by the trade. With regard to black damars, the first sample of black damar received in London came with the useful information that the natives use it to caulk their boats. That is the purpose for which it is usually used in Great Britain, and a huge business has been done in it. The genuine black damar has certainly made its mark. The chairman, Mr. Suter, a leading gum merchant, in winding up the discussion, pointed out the value of the paper with the remark that in the trade they often say, "What can the Government do for us? They simply hinder us: they ask questions and want to know things." Lecturers like Mr. Barry bring it home to the trade that they are mistaken. If they were allied more closely to those in authority, and if they looked to the authorities for more help, they would probably get on quicker than they do.

University and Educational Intelligence.

Aberdeen.—The King has appointed Prof. J. J. R. MacLeod to be regius professor of physiology in the University in succession to Prof. J. A. MacWilliam, resigned. Prof. MacLeod is at present professor of physiology and director of the Physiological Laboratory of the University of Toronto, and is well known for his work on insulin, for the discovery of which he was awarded, with Dr. F. G. Banting, the Nobel prize for physiology and medicine in 1923.

London.—The following courses of free public lectures are announced: "The Electrical Theory of Molecular Constitution," by Prof. P. Debye, at Birkbeck College, at 5.30, on April 26, 27, and 30; "The Pharmacological Evidence for Current Methods of Treatment," by Dr. J. H. Burn, at University College, at 5, on May 1, 2, and 3; "Anatomy and the Problem of Behaviour," by Dr. G. E. Coghill, at University College, at 5, on May 7, 8, and 10; and "Animal Psychology for Biologists," by Dr. J. A. Bierens de Haan, at King's College, at 5.30, on May 4, 9, and 11.

Oxford.—Three public lectures of general interest will be delivered during the ensuing term. These are: (1) At 5 P.M. on May 4, "Palæontology and the Origin of Man," by Prof. D. M. S. Watson (Romanes Lecture). (2) At 5.30 P.M. on May 18, "Professions: their Organisation and Place in Society," by Prof. A. M. Carr-Saunders (Herbert Spencer Lecture). (3) At 5 P.M. on June 18, "The Extent and Structure of the Milky Way," by Dr. Harlow Shapley, Director of the Harvard College Observatory (Halley Lecture).

On May 8, alternative schemes for the extension of the Bodleian Library will be considered by congregation.

Notice is given that applications for grants from the Dixon Fund for assisting scientific investigations, accompanied by the names and addresses of two references, must be made to the Academic Registrar, University of London, South Kensington, S.W.7, before May 15 next.

Applications are invited by the London County Council for two Robert Blair fellowships in applied science and technology, each of the value of £450 and tenable for one year. The fellowships are for advanced study or research in applied science and technology, and will be tenable in the Dominions, the United States, or other foreign countries. Application forms (T.2.a./300) may be obtained from the Education Officer (T.2.a.), The County Hall, S.E.1, to whom the form must be returned by June 18.

Applications are invited by the Ministry of Agriculture and Fisheries for research scholarships in agricultural and veterinary science, not exceeding seven in number, each tenable for three years and of the yearly value of £200. Applications must be received (upon form 900/T.G.) by June 15 by the Secretary of the Ministry. The Ministry also invites applications from students who propose to take up posts as agricultural organisers, teachers, or lecturers in agriculture, for not more than five agricultural scholarships tenable for two years and each not exceeding £200 in value per year. The latest date for the return of applications (on form A.189/T.E.) is June 15.

The Educational Settlements Association's report for 1926–27, published in a recent issue of *The Common Room*, shows that from the income of the year, consisting chiefly of grants from the Joseph Rowntree Charitable Trust (£5350) and the Thomas Wall Trust (£850), grants amounting to £3741 were paid to settlements and colleges. In addition, grants amounting to £735 from the Board of Education were distributed to settlements through the Association. Among the affiliated institutions, now numbering seventeen, are three settlements in London, a college at Surbiton for working women, a college near Evesham for rural workers, two colleges at Birmingham, Coleg Harlech in North Wales, and settlements at Plymouth, Bristol, Letchworth Garden City, Rugby, Leeds, York, Birkenhead, Gateshead, and Lemington-on-the-Tyne. The warden of Coleg Harlech, opened last September as a residential college for adults, contributes an article in which he calls it "a symptom of a universal tendency which owes its origin primarily to Denmark." Its teaching is to be characterised by attention to the needs of students individually; formal lectures are dispensed with, and, as in the Danish Folk High Schools, no encouragement is given to students to leave their former occupations. Intercourse with foreign countries is a noticeable feature of the work of several of the settlements. Thus, Avoncroft reports that Scotland, Holland, Denmark, and Germany are represented among its students; the Gateshead settlement entertained visitors from Germany and Czechoslovakia; Bristol Folk-house organised a Rhine tour, and Letchworth an Italian tour.

Calendar of Customs and Festivals.

April 23.

St. George, Patron Saint of England. Martyr under Diocletian, A.D. 285. Notwithstanding his wide-spread fame, nothing authentic is known of his life. According to the generally accepted version he was born in Cappadocia, son of a martyred father, served with distinction in the army, and, inheriting a great fortune on the death of his mother, declared himself a Christian before the Emperor, and was martyred with many miraculous incidents. According to Ammianus Marcellinus, however, he was born in Cilicia, and it is said that he acquired a fortune at Constantinople as a purveyor of bacon to the army by anything but honest means. On being found out, he fled to Cappadocia, where he professed Arianism and was promoted to the throne of St. Athanasius. As primate of Egypt he behaved with pride and insolence, while plundering the rich temples of the pagans. This led to his martyrdom at the hands of the heathen, but the date, A.D. 361, points to a confusion of two different personalities.

A mass of legend was incorporated in the lives of St. George, and he became one of the Seven Champions of Christendom. The story most familiar is that of the slaying of the dragon and the rescue of the princess, an incident which is said to have taken place at Silene in Libya. This story was accepted without question in orthodox belief of the Middle Ages; but was excised by Clement VII. It belongs to a group of legends of which the story of Perseus, the Minotaur, Fafnir, and the various 'worms' of English ballad are typical examples. This attained a great vogue in the medieval church from the identification of the dragon or snake with the devil.

St. George is a prominent figure among the saints of most, if not all, European countries. He became the patron saint of England under the early Norman kings, and was made the Saint of the Order of the Garter when it was founded by Edward III. It is, however, in the Mediterranean and in Russia and eastern Europe under the Greek Church that St. George is especially prominent. Among the peasantry of Greece and the Balkans, April is known as the month of St. George. He is the object of a cult of the gypsies of the East as their patron saint. They also, it may be noted, are specially connected with the snake, of which they are reputed to be skilled charmers.

Throughout the Mediterranean the feast of St. George has taken the place of a pastoral festival known to us principally through the *Parilia* of Rome, which took place on April 21, the traditional date of the birth of Numa. On that day the flocks and herds were purified, preparatory to driving them out to their summer pasturage. Fires were lit, the flocks were fumigated, or driven through the fires, over which the shepherds jumped, and offerings of milk and millet were made to Pales. This pastoral ceremony corresponded to the *Fordicidia* of April 15, an agricultural ceremony in which a pregnant cow was sacrificed to the earth goddess Tellus, and the ashes of her unborn calf, mixed with the blood of a horse and bean stalks, were preserved to be used by the senior Vestal Virgin to purify the people six days later at the shepherds' festival of *Parilia*.

April 24.

Hoke or Hock Day. Hock Tide.—An English popular festival of which the name appears in writers so early as the thirteenth century. At one time it was generally observed, but after the Reformation it gradually died out. The principal day of Hock Tide was the Tuesday after the second Sunday following Easter, when the women hocked the men, the men hocking the women on the preceding day, though in some localities the procedure was reversed. An alternative name, Binding Tuesday, indicates the nature of the custom. Women stopped the way with ropes and, pulling passers-by to them, released them only on payment of a fine. The proceeds, which were usually more considerable on the women's day, were devoted to the renovation of the parish church. The performance was accompanied by a good deal of merrymaking, and, according to one account, beating of brass instruments and singing old rhymes. Traditionally the festival was connected with a defeat of the Danes—according to one version, on St. Brice's day (Nov. 13) 1002. A Hock Tuesday play, acted before Queen Elizabeth at Kenilworth in 1575, represented this action, in which the Danes were shown to be finally defeated by the help of the Saxon women—clearly a popular explanation of the peculiar position accorded to the women by the custom.

Rents were sometimes payable on Hoke day, and at Hungerford, Hock Tide customs were observed in connexion with the tenure of rights over lands bequeathed to the town by John of Gaunt. These facts, like hirings and leasings at other times, point to it being a traditional termination of an annual period. This view is further supported by the resemblance of hocking to the Easter inter-sexual customs such as 'lifting,' buckle stealing, and the observance by which the men beat their wives on the Tuesday in Easter week, but the women beat the men on the following day.

April 25.

St. Mark's Day.—On the eve of St. Mark's day, ashes were riddled on the hearth. If any in the house were predestined to die within the year, a shoe would appear impressed in the ashes. A similar forecast was obtained in Yorkshire by watching in the church porch from eleven until one o'clock. When this has been done three years in succession, the ghosts of all who would die within the next year passed into the church, infants and young children rolling along the pavement. In Northumberland a practice similar to those of St. Agnes' eve was observed. Parties of girls, never more than three, baked a 'dumb cake,' made in silence and eaten at twelve o'clock, when the members of the party each retired to bed backwards. Those who are to be married see their sweethearts hurrying after them; or they may hear a knocking at the door or a rustling. Another ceremony with the same object is to eat the yolk of an egg in silence, filling its place with salt.

April 27.

From April 27 until May 3 (O.S.) is known in Morocco as *n-nisân*—a propitious period when everyone is happy. The rain is considered highly beneficial, alike to men, animals, and crops. Owing to its powers it is collected and used for a variety of magical purposes. It will prevent snakes and scorpions from biting if kept in the house, will cure headache, and will increase the butter-yielding qualities of milk. But it must not touch the earth, be exposed to the sun, or be breathed upon. It is used as a fertility charm by women, and it protects grain from the evil eye. Similar beliefs relating to this period are recorded from Palestine. In the Highlands of Scotland the period of fourteen days before May Day is known as the 'balk or ridge of Beltane.'

Societies and Academies.

LONDON.

Mineralogical Society, Mar. 20.—**A. F. Hallimond**: On the atomic volume relations in certain isomorphous series (2). The volume relations of compounds of calcium, strontium, barium, with oxygen, sulphur, selenium, and tellurium correspond in every way with those previously indicated for potassium, rubidium, cæsium, sodium, lithium, and the halogens. The difference in the volume produced by the interchange of eutropic elements exhibits a constant ratio in each series. The partial volumes calculated for the radicles from the volumes of the free metals agree with those already obtained for the alkali compounds, and the values for oxygen and fluorine agree with those calculated by Wasastjerna from the refractive indices. The volume effect of substitution in the sodium chloride lattice varies somewhat with the size of the cell, but the variation never attains the extent required for a law of constant radii. Other isomorphous series agree with the Law of Retgers, and the present results are therefore expressed in terms of a law of additive volumes rather than additive radii.—**A. Holmes** and **H. F. Harwood**: On the age and composition of the Whin Sill and the related dikes of the north of England. The rocks of the Whin Sill and its associated dikes are quartz-dolerites of substantially identical composition. Dikes of this series run north of east. They are quite distinct from the system of tholeiite dikes to which the Bingfield dike, the 'Brunton type' of Teall, belongs. A pebble of quartz-dolerite in the Upper Brockram of George Gill, Brackenber Moor, near Appleby, has been proved by chemical analysis to be definitely of the Whin Sill type. This, with other evidence, indicates that the age of Whin Sill and its associated dikes is post-Westphalian and pre-Upper Brockram.—**A. W. Groves**: The identification of dumortierite in grains: dumortierite in Cornish granite. Dumortierite may be confused with a number of more common minerals. It is recorded in several sediments in southern England and in the Land's End granite.—**T. V. M. Rao**: On 'bauxite' from Kashmir, India. The so-called bauxite of Kashmir consists mainly of diaspore and an opaque mineral corresponding in composition to a monohydrate of alumina. The deposit was derived from beds of clay, having been first altered into the dihydrate (bauxite) and afterwards to its present condition through dehydration and thermodynamic metamorphism.

Linnean Society, Mar. 29.—**Malcolm Wilson** and **Miss M. J. F. Wilson**: The Dutch elm disease and its occurrence in England. The Dutch elm disease was discovered in Holland in 1919, and during the same year in the north of France. The following year it was reported from all parts of Holland, and in 1921 was stated to be present throughout Belgium. In the same year it was recorded from western Germany, and since that date has spread over the greater part of that country. An outbreak of the disease was discovered near London last July. Three explanations have been offered as the cause of the epidemic: (1) The fungus *Graphium Ulmi* Schwarz; (2) *Micrococcus Ulmi* Brussoff; (3) unfavourable climatic conditions, *i.e.* drought and frost. The first explanation is generally accepted by the Dutch investigators. The disease may be readily recognised by the yellow discoloration of the leaves in the crown of the tree or at the tips of the side branches. This condition usually spreads rapidly over the tree, and is followed by leaf-fall and by the death of the tree. Defoliation may be complete within a week, but sometimes extends over a much longer period. Infected branches, when cut across, show one or more rings of small brown spots in the most recently formed wood. These internal symptoms sometimes, but not invariably, can be found in the roots. The disease is present in epidemic form throughout most of western Europe, and shows no sign of becoming less virulent. No species of Ulmus grown in Holland appears to be immune, and no adequate method of control has yet been discovered.—**R. W. Butcher** and **F. T. K. Pentelow**: The effect of pollution on the ecology of a small stream. An ecological study has been made during the past two years of the River Lark in West Suffolk. From September to February a beet-sugar factory empties into the river about four million gallons of waste waters a day. This water contains much organic matter and so deoxygenates the river-water; *e.g.* at one station the oxygen fell from 110 per cent. to 19 per cent. saturation. There is also an increase in the ammoniacal nitrogen. The effect on the flora is to increase the number of bacteria and cause very large growths of 'sewage fungus,' of which *Sphærotilus natans* is the commonest. The fauna of the river may be divided into three definite ecological associations dependent on the oxygen present—the Gammarus type occurring everywhere among the weeds and among stones and gravel on the bottom, the Sialis-Sphærium type occurring on the bottom in muddy stretches, and the Chironomid-Tubificid type which occurs in very foul mud. The effect of pollution is due to the reduction of oxygen, and results in the encouragement of Sialis-Sphærium and Chironomid-Tubificid associations at the expense of the Gammarus type.

Society of Public Analysts, April 4.—**John Evans** and **T. E. Wallis**: Coffee parchment as an adulterant of bran and sharps. The 'parchment' consists of the thin and tough endocarp of the coffee fruit, and may be recognised by its distinctive cellular structure. When added to sharps it is usually finely comminuted, and in testing a sample a few of the suspicious pieces should be boiled with chloral hydrate solution until transparent, and a fragment mounted in chloral hydrate for microscopical examination.—**W. B. Adam**: Determination of the colour-producing constituents of the cacao bean. The two principal colour-producing constituents are cacao catechin and cacao tannin. The former has been extracted with ether and determined colorimetrically by means of Mitchell's ferrous tartrate reagent, whilst the latter is extracted with hot water and determined by precipitation as cinchonine tannate. The catechin is destroyed during fermentation, and the tannin is reduced to about 2 per cent.—**A. T. Etheridge**: Determination of vanadium in steel. The method consists in removing iron (as chloride by extraction with ether) and other interfering metals, by electrolysis over a mercury cathode, leaving a solution in which the vanadium can be determined by titration with permanganate. The process is accurate for all kinds of steels. In the case of molybdenum steels the molybdenum is removed together with the ferric chloride on extraction with ether. Manganese, like aluminium, has no influence on the final permanganate titration.—**S. G. Clarke**: Colorimetric determination of small quantities of antimony and their separation from tin. The antimony is deposited on metallic copper as in the Reinsch method, the deposited film stripped off by means of sodium peroxide, and the antimony determined colorimetrically. The method is applicable to antimony in either state of oxidation, and in the presence of tin or arsenic, but bismuth and several of the other heavy metals give precipitates, usually coloured, with the reagents.—**A. Riad**: Determination of carbon dioxide in soils. Hepburn's modification of the Van Slyke method of determining carbon dioxide in carbonates (in which the evolved gas is absorbed in standard baryta solution, the excess of which is titrated with oxalic acid) has been adapted to the determination of carbon dioxide in soils. The method is suitable for general soil analysis.

PARIS.

Academy of Sciences, Mar. 12.—The president announced the death of M. Guignard.—**E. Gourat**: Some singular lines of surfaces admitting a given linear element.—**E. Mathias**: Magnetic measurements in the Haute-Marne, Côte-d'Or, and Aube. An account of work done in 1924 at forty-two stations, twenty-three of which are new.—**Georges de Rham**: Duality in *analysis situs*.—**Paul Montel**: Continued functions of a real variable, which admit a theorem of algebraic addition.—**Paul Lévy**: An asymptotic point of view in the study of ensembles of points on a right line.—**N. Saltykow**: The integration of partial differential equations by separation of the variables.—**Alfred Rosenblatt**: Certain stationary movements of incompressible viscous liquids.—**S. de Glasenapp**: Personal equations in the micrometric measurement of double stars. The method suggested is the comparison of the results of observation with the values, assumed to be known exactly, of the angles of position θ_0 and distances ρ_0 for a certain number of comparison stars, such that the relative displacement of the components is negligible. To facilitate the application of the method a list of comparison stars is given, uniformly distributed over the sky, with varied angles of position and distances ρ less than 3″.—**Mme. E. Chandon**: The tides of the Red Sea. Correction of an error in the calculations of A. Blondel. The differences between the observed and calculated values do not exceed 2 cm., and it is concluded that friction does not have any appreciable effect on tides in the Red Sea.—**A. Lambert**: The velocity of propagation of radiotelegraphic waves. The velocity as determined by recent experiments would appear to be appreciably lower than 300,000 km. per second, the mean result being 247,000 km./sec. ± 9000.—**Canaud**: The electrolysis of water by an alternating current. If the water is allowed to reach its boiling-point some hydrogen is evolved at a regular rate, in amount corresponding to about $\frac{1}{15}$ of that which would have been produced by the corresponding continuous current. Iron electrodes were employed.—**Svend Aage Schou**: The absorption spectrum of formaldehyde in solution. Previous work has proved that aqueous solutions of formaldehyde contain only the polymerised form. The monomolecular aldehyde in hexane at − 70° C. gives a spectrum with at least 17 bands between 3542 and 2750 A., the positions of which are given.—**A. Boutaric** and **Mlle. G. Perreau**: The determination of dilute saline solutions by the opacity of fine suspensions obtained starting with these solutions. An account of attempts to stabilise precipitates, such as silver chloride, by the addition of various colloids.—**J. Huggett** and **G. Chaudron**: The thermomagnetic study of some iron minerals.—**P. Nicolau**: Annealing anomaly of copper and brasses after hammer hardening.—**L. Bert**: A new general synthetic method for preparing arylaliphatic aldehydes. In a previous communication the author has given a method for preparing the chlorides $RC_6H_4(CH_2)_n\,Cl$. The magnesium compounds prepared from these condensed with methyl orthoformate give good yields of the acetals of the aldehydes $RC_6H_4(CH_2)_n\,CHO$, from which the corresponding aldehydes are readily obtained by hydrolysis with hydrochloric acid. Details of new aldehydes prepared by this method are given.—**Albert Kirrmann**: The action of amines on bromo-œnanthol.—**Vavon** and **V. M. Mitchovitch**: The *o*-cyclohexylcyclohexanols.—**R. Locquin** and **R. Heilmann**: The separation of the stereoisomeric unsaturated ketones.—**L. Neltner**: The geology of the Goundafi country (Morocco Haut Atlas).—**J. Repelin**: The Aquitaine basin at the Helvetian epoch: the marine gulf.—**G. Mangenot**: The cytological localisation of the peroxydases and the oxydases.—**Tsen-Cheng**: The phenomena of necrosis in potato disease. The necrosis of the diseased potato is in most cases only an exaggeration of the normal destruction of the sieve tubes accompanied by defensive reactions on the part of the neighbouring cells.—**Auguste Lumière** and **Mme. R. H. Grange**: The comparative toxicities of sera arising from venous blood and blood from the umbilical cord.—**Henri Pottevin** and **Robert Faillie**: The variation of the visual psychomotor reaction as a function of the lighting.—**Jean Verge** and **Edmond Grasset**: Researches on the microbial flora of frozen eggs. Amongst the organisms found in Chinese eggs were some belonging to the paratyphic and coli groups, which might possibly give rise to toxic infections. The eggs should be sterilised by heat during preparation as food.

GENEVA.

Society of Physics and Natural History, Feb. 16.—**F. Chodat**: The specificity of Stichococcus, more particularly from the soil of the [Swiss] National Park. The author communicates the results of his tests for Algæ in the soils of the National Park and presents a first series of pure cultures belonging to the genus Stichococcus.—**Amé Pictet** and **H. Vogel**: The synthesis of cane sugar. When fructose is treated with acetic anhydride, it forms a normal tetracetate and an isomer. An equimolecular mixture of these two substances, suitably treated, leads to the synthesis of cane sugar.—**O. Jaag**: New researches on the gonidia of lichens. These researches lead to the proof, for the two varieties of the lichen studied (*Parmelia caperata*), of the formation of gametes, a new fact for algæ of lichen symbiosis, and also to the existence of zoospores different from those already described.—**F. Wyss-Chodat**: The transmissibility to the animal of the parasite of fungoid mycosis. The author has studied a fungus isolated from the skin and from the ganglion of a subject attacked with fungoid mycosis. From the observations it must be admitted that this is a parasitic disease. The inoculation of mice has given results confirming this hypothesis.—**R. Wavre**: Figures of equilibrium of a heterogenous fluid mass. The author brings forward some results new to the solution of this problem of rational mechanics. These results, which are unsuitable for abstraction, lead to important modifications of the laws of rotation of planets in the fluid state.—**M. Gysin**: The application of the methods of Fedorow to the identification of microcline without macles. The author's researches allow of the identification of the mineral in gneiss and prevent the confusion frequently made between microcline and orthose.

Mar. 1.—**G. Déjardin**: (1) Recent spectroscopic applications of the electrodeless discharge. Experiments made on different substances, phosphorus in particular, show that the spectra characteristic of different degrees of ionisation may be separated by utilising the electrodeless discharge to produce them. (2) The filtration of the solar radiation by ozone.

(Observations carried out at the Mont Blanc Observatory, from 1923 to 1926, in collaboration with Lambert and Chalonge.) These experiments show that for each zenithal distance of the sun the curve representing the variations in absorption as a function of the wave-length reproduces perfectly, in certain regions of the spectrum, all the known details of the absorption curve of ozone. From this it is deduced that the ozone should be found localised, for the greater part, in a zone situated about 45 kilometres above the earth.

Rome.

Royal National Academy of the Lincei, Jan. 8.—**F. Severi**: Simple and double algebraic integrals (1 and 2).—**G. Fubini**: A new generation of Darboux's quadratics.—**U. Cisotti**: An exception to Kutta-Joukowski's theorem.—**N. Parravano** and **G. Malquori**: Molybdenum sulphides. (1) Tensions of the sulphur of molybdenum trisulphide. The logarithm of the tension of the sulphur of molybdenum trisulphide is a linear function of the temperature, the emission of the sulphur vapour being irreversible.—**P. Vinassa de Regny**: The geochemical inertia of the triad elements. As a general rule, both simple and compound substances, whether natural or artificial, organic or inorganic, have even molecular numbers. Almost the whole of the earth's mass is composed of substances with atomic numbers below 28, that is, those of the first triad. The geochemical inertia of the elements of the triads may be related to the number and disposition of the electrons corresponding with a condition of equilibrium.—**S. Franchi**: The series of rocks from the Priabonian to the Noric in the neighbourhood of Albenga.—**L. A. Herrera**: Artificial albuminoid cells. Imitations of the natural cells of organisms may be made with the help of egg albumin.—**S. Minetti**: The necessary and sufficient conditions that an entire function may be of a certain genus and of a certain order.—**Rosalind Cecily Young**: The values of the integral $\int_a^b f(x)dg(x)$ of a function $f(x)$ with a non-integrable point, in relation to $g(x)$.—**V. Hlavatý**: Linear differential systems with an indefinite quadratic integral.—**E. Pistolesi**: A supposed exception to Kutta-Joukowski's theorem. Investigation of the problem of a plane strip in an indefinite current, with circulation different from zero, regarded by Cisotti as an exception to Kutta-Joukowski's theorem, shows that this is not the case, and places beyond doubt the quite general character of the theorem.—**M. Maggini**: The effective wave-length of [radiation from the] stars and a method of determining it by means of the interferometer.—**G. Andrissi**: The absorption of stellar light in the atmosphere of Rome.—**M. Bossolasco**: Plasticity in the phenomena of orogenesis.—**U. Panichi**: Diabases and melanocratic veinous rocks of Sardinia.—**G. Quagliariello**: Action of cold on the fats of milk. The lowering of the surface tension of milk cooled below 10° C. is dependent on the passage of triglycerides of the lower fatty acids from the globules into the interglobular liquid, in which they dissolve.—**G. Martino**: Different contents in 'phosphogen' of striated muscle under rapid and under torpid contraction.—**G. Brunelli**: Anatomico-physiological investigations on the significance of the intrahepatic pancreas in the Teleostei.—**G. Brunelli** and **G. Fasella**: A very rare cetacean on the coast at Nettuno. A cetacean, stranded near Foco Verde in Nettuno in November last, belongs to the genus Mesoplodon and is probably *M. bidens*.—**R. Savelli**: Giant seeds and a case of poly-endospermia due to extraneous pollination on *Nicotiana rustica*.—**E. Francini**: Phenomena of somatic asporia, gonial asporia, and adventitious embryony in *Ochna multiflora*.

Washington, D.C.

National Academy of Sciences (*Proc.*, Vol. 14, No. 1, January).—**Raymond Pearl**, **Agnes Allen Winsor**, and **John Rice Miner**: The growth of seedlings of the cantaloup, *Cucumis melo*, in the absence of exogenous food and light. The growth in length of cantaloup seedlings grown in the dark on a sterilised medium and supplied only with sterilised water, with or without fresh supplies of sterilised air, follows a logistic curve essentially the same as that for normal growth.—**David White**: Some factors in rock metamorphism. The progressive transformation of carbonaceous sediments can be used as a scale for the determination of the stages of incipient metamorphism. Carbonisation is the result mainly of horizontal thrust, temperature, and time, of which the former is of pre-eminent importance. Vertical pressure is relatively insignificant in effect; it assists the strata to resist buckling and helps to raise the temperature. The time factor only becomes important in the presence of advanced pressures and their consequent temperatures.—**D. F. Hewett**: Late Tertiary thrust faults in the Mojave Desert, California. The Spring Mountains and adjacent ranges contain at least six extensive overthrust faults and numerous minor thrusts as well as normal faults. They dip westward at angles of 5°-45°, and rocks ranging from pre-Cambrian granite gneiss to Pennsylvanian limestones are thrust generally eastward upon younger rocks ranging from lower Palæozoic to Jurassic. The thrust faults seem to have been formed in early Eocene times.—**Raymond T. Birge**: The quantum levels and resulting constants of the hydrogen molecule (*v.* Nature, Jan. 28, p. 134).—**Charles S. Barrett**: The scattering of X-rays from gases. Filters of strontium oxide and zirconium oxide, each adjusted to absorb 50 per cent. of molybdenum $K\beta$ radiation, are well matched at all wave-lengths except between their K absorption limits; the two thus give practically monochromatic radiation (Prof. P. A. Ross). Such a beam is passed through a gas chamber and into an ionisation chamber. It is concluded that interference occurs in X-rays scattered from a single molecule of carbon dioxide or oxygen, and is absent in rays scattered from a hydrogen molecule (between 30° and 90°).—**Louis S. Kassel**: The distribution of energy in molecules. In a group of oscillators in statistical equilibrium, some classical and some quantum, the latter all having the same frequency, the chance that a given classical oscillator shall have energy equal to or greater than m quanta is exactly the same as the chance that a given quantum oscillator shall have m or more quanta.—**I. S. Bowen**: The life of atomic states and the intensity of spectral lines. The origin of the strong nebular spectral lines in electron jumps from metastable states in oxygen and nitrogen is evidence that metastable states are states of long mean life and not absolutely metastable. If the ratio of the mean time between collisions of the second kind to the mean life of the state before spontaneous emission is small, the majority of the atoms are taken out of the excited state by collisions of the second kind and the line is weak; if the ratio is large (as it is under nebular conditions) the atoms can radiate spontaneously and the line appears strongly. This explanation is applicable to other anomalous line intensities and suggests a gradation of mean lives from 10^{-8} sec. (normal lines) to 1 sec. or more (nebular lines).—**R. J. Lang**: The spectra of singly and doubly ionised germanium (Ge II and III).—**Jared Kirtland Morse**: (1) The structure and dimensions of the ethane molecule. A scale model is built up, using the cubic lattice already employed in discussing the crystal lattices of diamond and graphite. (2) The lattice structure of ethane. The model constructed would cause diffraction effects agreeing well with Mark and Pohland's results for solid ethane, except in regard to the 004 plane.—**R. A. Millikan** and **C. C. Lauritsen**: Relations of field-currents to thermionic-currents. It has been shown by Millikan and Eyring that in the extraction of electrons from metals, the electrons constituting the field current are not identical with the thermions and, over a range of 700° C., are independent of temperature. The data used, and also new data, give curves for the relationship between log i (i = field current) and $1/F$ (F = applied field) which are straight lines. At sufficiently high temperatures the thermionic- and field-currents are not independent. A combined formula is obtained showing that the application of an external field is equivalent to increasing the temperature of the electrons within the metal.—**Gregory Paul Baxter** and **Howard Warner Starkweather**: (1) The density, compressibility, and atomic weight of neon. In purification, the gas was absorbed on chabazite cooled with liquid oxygen or nitrogen. The density and atomic weight found are 0·89990 and 20·182 respectively. (2) The density, compressibility, and atomic weight of argon. The normal density is 1·78364, the limiting density is 1·78204, and the atomic weight 39·943. These values assume that the conventional method of calculating the deviations from Boyle's law is correct; a more rigorous investigation, however, only makes a difference of so much as 0·00001 in a few of the results. —**A. M. Showalter**: The chromosomes of *Pellia Neesiana*. The male and female plants contain nine chromosomes. One of those of the female seems to be an X-chromosome; in the growing regions, it remains condensed throughout the interphases, recalling the behaviour of sex chromosomes from spermatogonia of animals.—**T. H. Goodspeed** and **A. R. Olson**: The production of variation in Nicotiana species by X-ray treatment of sex cells. Mature plants bearing flower buds were subjected to X-ray bombardment for 10 min. or 20 min. Their seed gave more than 20 per cent of morphologically abnormal plants, but only rarely were the variants completely sterile. Similar effects are obtained if only the male sex cells are irradiated. Cytological examination of the variants shows that, in some of them, one of the meiotic chromosomes has an appendage similar to that born by many somatic chromosomes.—**L. J. Stadler**: Genetic effects of X-rays in maize. Heavy treatment reduces considerably the yield and viability of pollen, but seems to have no effect on crossing-over in a particular region of the chromosome; it does increase, however, the percentage of seed with mosaic endosperm when crosses of an endosperm dominant with an endosperm recessive are used.—**Edward Kasner**: General theory of polygenic or non-monogenic functions. The derivative congruence of circles.—**G. A. Miller**: Number of systems of imprimitivity of transitive substitution groups.—**R. L. Moore**: Concerning triods in the plane and the junction points of plane continua.—**Cecilia H. Payne** and **Frank S. Hogg**: On methods and applications in spectrophotometry. The work being carried out at Harvard in this field is described and discussed. It should result in placing several qualitative astrophysical arguments on a quantitative basis.—**Willard Owen Thompson**, **Phebe K. Thompson**, and **Mary Elizabeth Dailey**: The effect of posture upon the composition and volume of the blood in man. In standing still, the blood suffers a net loss of about 11 per cent. of the total plasma volume of approximately protein-free fluid, due to increase in capillary pressure. The loss, which occurs in 20-30 min. and is recovered in a similar time on lying down, is greatest at the extremities.—**Alfred J. Lotka**: Sterility in American marriages. Using the data for 1920 of the United States Census Bureau, it is calculated that the effective sterility of American (white) wives is 17·1 per cent. Of this total, 1·2 per cent. is due to premature death of wives, 2·0 per cent. to premature death of husbands, and 0·8 to divorces. The net sterility of American (white) wives is thus 13·1 per cent.—**Louis Harris**: The photochemical union of hydrogen and chlorine. The apparatus was entirely of quartz and the reaction vessel was illuminated with light of wave-length greater than 4050 A. A thermopile behind the reaction tube measured the energy available. The final hydrogen pressure was measured after freezing out the hydrogen chloride formed and the unchanged chlorine. The minimum yield with excess of hydrogen was 6×10^4 molecules of hydrogen chloride per quantum of light.

Official Publications Received.

British.

Government of Bengal: Irrigation Department. Report on Rainfall and Floods in North Bengal, 1870-1922. By Prof. P. C. Mahalanobis. Pp. v+90+32 maps. (Calcutta: Bengal Secretariat Book Depot.) 20 rupees; 30s.

The National Benzole Association. Fifth Report of the Joint Benzole Research Committee of the National Benzole Association and the University of Leeds. (Presented March 21st, 1928.) Pp. iv+237. (London: National Benzole Association.)

Colony of the Gambia. The Annual Report of the Department of Agriculture for the Period January 1st, 1926, to March 31st, 1927. Pp. 58. (London: The Crown Agents for the Colonies.) 5s.

Imperial Department of Agriculture for the West Indies. Report on the Agricultural Department, Dominica, 1926-27. Pp. iv+41. (Trinidad, B.W.I.) 6d.

Diary of Societies.

SATURDAY, April 21.

North of England Institute of Mining and Mechanical Engineers (Newcastle-upon-Tyne), at 2.30.—Dr. W. Cullen: Some Notes on Quarrying by the Well Drill Method.—R. J. Weeks: A Few Notes on an Explosion of Gunpowder.—Discussions on Electric Mine Lamps and Better Lighting, W. Maurice; A New Gas Detecting Miners' Electric Lamp, Prof. W. M. Thornton; and Notes on High Candle-power Lamps, H. Staples.

Mining Institute of Scotland (Annual General Meeting) (at Royal Technical College, Glasgow), at 3.—J. A. B. Horsley: Design and Maintenance of Flame-Proof Enclosures, with Special Reference to Coal Face Machinery.—Discussions on Supporting Underground Roadways with Steel Arches, D. C. Gemmell; and Life Saving in Colliery Explosions and Fires, T. A. Southern.

MONDAY, April 23.

Institution of Mechanical Engineers (Graduates' Section, London), at 6.30.—H. Heywood: Pulverised Coal Systems.

Institution of Electrical Engineers (North-Eastern Centre) (at Armstrong College, Newcastle-upon-Tyne), at 7.—Annual General Meeting.

Royal Institute of British Architects, at 8.—H. S. G. Rendel: The Work of Temple Moore.

Royal Society of Arts, at 8.—A. G. Huntley: Applied Architectural Acoustics (Dr. Mann Lectures) (II.).

Royal Society of Medicine (Odontology Section), at 8.—Dr. A. Livingston: Further Experiments on the Permeability of Enamel.—W. Rushton: Injection of Alcohol for Neuralgia and its Sequel.—L. Payne: A Paste for Obtunding Hyper-sensitive Dentine.

Royal Geographical Society (at Æolian Hall), at 8.30.—F. Rodd: Journeys among the Southern Tuareg.

TUESDAY, April 24.

Royal Dublin Society (at Ball's Bridge, Dublin), at 4.15.—Dr. J. H. J. Poole: A Simple Form of Photo Electric Photometer using a Neon Lamp to Measure the Current.

Illuminating Engineering Society (at Home Office Industrial Museum, Horseferry Road, Westminster), at 6.—J. S. Dow and others: Discussion on Daylight, Artificial Light, Artificial Daylight: their Merits and Drawbacks.

Royal Photographic Society of Great Britain (Kinematograph Group), at 7.—G. Malin: A Motor Cycle World Tour.

Royal Anthropological Institute, at 8.30.—M. C. Burkitt: South Africa's Past in Stone and Paint.

WEDNESDAY, April 25.

Newcomen Society for the Study of the History of Engineering and Technology (in Prince Henry's Room, 17 Fleet Street), at 5.30.—L. F. Loree: Steamers of Lake Champlain, 1809 to Present Day.

Institution of Civil Engineers (Annual General Meeting of Association of London Students), at 6.30.

Institution of Electrical Engineers (South Midland Centre) (Annual General Meeting) (at University, Birmingham), at 7.—Sir Oliver Lodge: The Revolution in Physics (Kelvin Lecture).

Royal Society of Arts, at 8.—Dr. J. M. Ritchie: The Education and Training of the Blind.

Eugenics Society (at Royal Society), at 8.30.—Dr. Feldman: Eugenics in Ancient Hebrew Literature.

British Psychological Society (Medical Section) (at Royal Anthropological Institute), at 8.30.—Drs. E. A. Bennet, D. Bryan, and T. A. Ross: Symposium on Fugue States. Discussion opened by Dr. T. W. Mitchell.

British Astronomical Association (at Sion College, Victoria Embankment).

THURSDAY, April 26.

London Mathematical Society (at Royal Astronomical Society), at 5.—A. Besicovitch and H. Bohr: On Almost Periodic Properties of Translation Numbers.—W. L. Ferrar: Conditionally Convergent Double Series.—R. M. Gabriel: An Additional Proof of a Theorem upon Rearrangements.—Margaret E. Grimshaw: A Contribution to the Theory of Uniqueness of Representation by Trigonometrical Integrals.—Prof. A. E. H. Love: Biharmonic Analysis especially in a Rectangle and its Applications to the Theory of Elasticity.—S. W. P. Steen: On Fermat's Last Theorem.—C. T. Preece: Theorems stated by Ramanujan. (I.) Theorems on Integrals.—Prof. G. N. Watson: Theorems stated by Ramanujan. (II.) Theorems on Summation of Series.—Rosalind C. Young: On Riemann Integration with respect to an Additive Function of Sets.

Royal Aeronautical Society (at Royal Society of Arts), at 6.30.—C. Dornier: Flying Boats.

Institution of Civil Engineers (Yorkshire Association) (at Hotel Metropole, Leeds).—C. J. Chaplin: Railway Construction in the Pyrenees.

FRIDAY, April 27.

Royal Sanitary Institute (at Guildhall, Worcester), at 4.—C. C. Duncan and others: Discussion on River Pollution.—Dr. M. Read and others: Discussion on Infant Mortality in Worcester from 1895 to 1925.

Physical Society (at Imperial College of Science), at 5.—Prof. W. C. Baker: Experiments with Mercury Jets and the Phenomena exhibited at their Impact with Steel and Glass.—H. P. Perman and W. D. Urry: The Elastic Constants of Glass.—G. E. Bell: A Valve-maintained High-frequency Induction Furnace and some Notes on the Performance of Induction Furnaces.

Institution of Electrical Engineers (London Students' Section) (Annual General Meeting), at 6.15.—R. A. Brockbank: Super Tension Cables.

Institution of Mechanical Engineers (Informal Meeting), at 7.—J. C. Armstrong and others: Pulverised Fuel in Locomotive Furnaces.

Institution of Electrical Engineers (at Newcastle-on-Tyne), at 7.30.—E. T. Williams: The Electrical Equipment of the Singapore Floating Dock.

Junior Institution of Engineers (Informal Meeting), at 7.30.—C. H. Plant: The Manufacture of Structural Steel, etc.

Royal Society of Medicine (Electro-Therapeutics Section), at 8.30.—Dr. R. W. A. Salmond: Observations on the Movements of the Duodenal Contents, with Special Reference to Antiperistalsis and Pyloric Regurgitation.—Dr. Bathurst: Treatment of Incontinence in Women.

Royal Institution of Great Britain, at 9.—Prof. A. M. Tyndall: Carriers of Electricity in the Atmosphere.

Institution of Electrical Engineers (Scottish Centre) (at Forresters' Hall, Dundee).—Dr. S. Z. de Ferranti: Electricity in the Service of Man (Faraday Lecture).

SATURDAY, April 28.

Royal Sanitary Institute (at Guildhall, Worcester), at 10 A.M.—T. Caink and others: Discussion on The Worcester Activated Sludge Plant.

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (jointly with Students' Sections of North-East Coast Institution of Engineers and Shipbuilders, and Institution of Electrical Engineers) (at Neville Hall, Newcastle-upon-Tyne), at 3.—L. H. Forster: Notes on Main Pumping.

PUBLIC LECTURES.

THURSDAY, April 26.

Birkbeck College, at 5.30.—Prof. P. Debye: The Electrical Theory of Molecular Constitution. (Succeeding Lectures on April 27 and 30.)

King's College, at 5.30.—Dr. K. Bělăr: The Mechanism of Mitosis.

SATURDAY, APRIL 28, 1928.

The Charter of the British Association.

THE grant of a Royal Charter to the British Association is, at least indirectly, a testimony to the virility of a national institution nearly a century old. When the question of the application for a charter was brought forward last autumn, it appeared to surprise many people that the Association did not possess one. That in itself was a compliment; but when the subject had been considered on previous occasions the difficulty of meeting the necessary charges stood in the way. That difficulty was removed by the generosity of Mr. A. A. Campbell Swinton, who undertook to bear the costs; and the petition made by the president, Sir Arthur Keith, and the general officers on behalf of the Association, has now been granted by the King in Council. The recognition of the Association as a body corporate should further strengthen its position in the public view. 'Further,' because that position has been materially strengthened, at any rate since the period of the Association's jubilee in 1881, of which the 'Red Lions' of that time sang:

> "At York they thought she was sure to die,
> For she didn't seem to enjoy age,
> But at last the doctors bade her try
> The effects of an ocean voyage,"

which evidently was efficacious, for the song went on to celebrate the recovery which 'she,' the 'British Ass,' had accomplished by reason of 'her' first journey to a meeting overseas in 1884. Now, when it is commonly admitted that the public recognition of scientific advancement, restricted though it still be and not always well directed, is at any rate more widespread than it was when the Association was founded to assist in the spreading, it may reasonably be claimed that the recognition of the Association's work also has broadened and is broadening.

Internal signs of this increased public interest—such as the multiplication by four of the number of press cuttings received in the office in a single year—have not been wanting since, in 1919, the annual meetings were resumed after two years' enforced abstinence, not without some sense of apprehension as to the future. On the financial side the generous benefaction of Sir Charles Parsons and others, supplemented later by that of Sir Alfred Yarrow, went far to ensure the maintenance of the Association's activities under the changed conditions of present times; while as regards those activities themselves, the Association benefited by friendly criticism and suggestion in these columns.

There can be no doubt that the Association has in recent years adapted the proceedings of its annual meetings more closely to modern practice and expectation in the furtherance of its aim to obtain "more general attention for the objects of science." In former years the Association used to stage its big effects almost accidentally: there is no better example of this than the famous disputation between Wilberforce and Huxley and Hooker at Oxford in 1860. To some extent it does so yet: under the impenetrable calm of the inaugural meeting, the presidential address may still be received with nothing more than a decorous murmur of applause; yet the words then spoken may, and sometimes do, carry far farther, and arouse more attention and even heart-searching, than they used to do among the public at large—for an illustration we need go no farther back than last year's address. In these days the members and the public have at least some foreknowledge, through preliminary programmes of the meetings, of the leading topics to be brought forward, so that when, for example, the title of one of the evening discourses at the forthcoming meeting in Glasgow is announced as "The Mystery of Life," they will be enabled to indulge in pleasing speculation as to the next 'wonder' which science may have to reveal.

This sort of publicity used to be something to discredit, and certainly the Association would offer no commendation for the type of pseudo-scientific headline of which lurid examples were quoted in these pages not long ago. On the other hand, it is as true now as when Lyell wrote of the Association in 1838, that in Great Britain "no importance is attached to any body of men who do not make occasional demonstration of their strength in public meetings." There was an undercurrent of satire in those words; yet it cannot be accounted a serious national defect if a proportion of the public is willing to listen to the spoken word: many can do that more easily than they can read, and get some good of it. Moreover, the range of the spoken word broadens with the use of broadcasting—the microphone has already made its appearance at Association meetings—as the range of the printed word will likely narrow if books grow much more costly. So that the faculty of 'thinking on their legs' is one which scientific men and women cannot afford to neglect, but rather should cultivate; or, if that ability fail them, at least they should fall back upon practice in reading their own written words intelligibly and with life; for even that is no common art, as many who 'listen-in' can testify.

It is as a public body, and not only as a 'hotch-potch of philosophers,' that the Association will benefit most materially by the possession of the Royal Charter. More particularly so, in its relations with the many public authorities with which it is brought constantly into contact, both in the course of the organisation of its meetings and in advancing science by making recommendations and tendering advice to administrative bodies in the work of which science plays, or should play, a part. Occasions for such action arise out of the proceedings of every annual meeting. The dignity conferred by the grant of a charter is intangible and difficult to define, but the Royal warrant is the highest recognition of the joint efforts of those men of science who voluntarily undertake the maintenance of the Association's work. It constitutes them a body corporate; it recognises them as a legal entity. Finally, this last consideration makes it possible for the Association to undertake without difficulty the grateful charge laid upon it by Mr. George Buckston Browne, of holding as a national memorial the residence of Charles Darwin at Down. That house is at present in the very appropriate tenancy of a school; but whatever its future may be, Mr. Buckston Browne's generosity has given the Association a new duty consonant with the new status conferred by the grant of the Charter, and it is to be hoped that in its new century of existence the Association may find scope for additional and equally worthy extensions of its activities.

The Physiology of the Higher Functions of the Brain.

Conditioned Reflexes: an Investigation of the Physiological Activity of the Cerebral Cortex. By Prof. I. P. Pavlov. Translated and edited by Dr. G. V. Anrep. Pp. xv + 430. (London: Oxford University Press, 1927.) 28*s*. net.

FOR the first time a full account of the work which Prof. Pavlov and a devoted school of pupils and associates have been doing in Russia has appeared in English. The results of the work, though recognised to be of extreme importance by physiologists, have been known in England in only one or two of its aspects, as all the literature of the subject has been in Russian, except for some short accounts. Furthermore, although the apparatus required is apparently not very expensive, the necessity for well-constructed research rooms and space for keeping animals, together with the difficulty and the time required in getting experience, have resulted in the confinement of the use of the method to the school of its origin. It is with special interest, therefore, that one surveys this translation of a comprehensive account of the method and its results.

The general principle of the method of 'conditioning' reflexes has been long known from early accounts of the work. Briefly, the method depends upon the temporary association of a stimulus of no particular meaning with an inborn reflex. Reflexes such as the secretion of saliva in response to the presence of food in the mouth are inborn and fixed and are present in animals in which the cortex of the brain has been removed. Such a reflex, therefore, does not require the presence of the cerebral cortex for its function, and like all the reactions of such an animal, it shows no evidence of intelligence except the purpose in its design; an inborn reflex is automatic. Prof. Pavlov and his pupils early showed that any particular signal, such as a flash of light, a sound, or a tactile sensation, can, by repeated association with the presence of food in the mouth, acquire temporarily the subsequent property of itself causing salivation without the accompaniment of food. The signal stimulus thus becomes the 'conditioned,' and the response it evokes is the 'conditioned reflex.' This temporary association was early demonstrated to be a true function of the cerebral cortex, and later work described in this volume continues to confirm that fundamental fact

That the new response is a true reflex is maintained by Prof. Pavlov, but the reviewer is not at all convinced. A similar response from man would surely be inseparable from consciousness, and there is some evidence that this is indeed the case (Hamel). It is not proved in this book that the response in the dog is other than that of a mechanism in which a conscious factor is an essential part and in which the sole representative of the original reflex is its final common path. Protopopov has been reported to have conditioned the knee jerk, but there is no mention of this in the book under review. If a true knee jerk (latent period of 0·005–0·01 second and a single volley of efferent impulses) could be conditioned, then the conditioned response may be accepted as a true reflex.

Prof. Pavlov makes use of two inborn 'unconditioned' reflexes to serve as the basis of the study of conditioned reflexes. The first is the secretion of saliva caused by the presence of food in the mouth, and the second the secretion of saliva caused by the presence in the mouth of a substance which is automatically rejected. The wisdom in his choice is seen when it is realised that the whole investigation is quantitative, *i.e.*, under like external conditions the response is measurable and comparable. The animal is provided with a permanent fistula of one salivary duct, so that the whole secretion of saliva by one gland can be accurately measured during experiments without any discomfort to the animal, and experiments can be thus carried out, at intervals of a few days, for months at a time. It is not to be supposed that, because Prof. Pavlov uses these reflexes of salivation, his insight into the cerebral mechanism is confined to the nervous mechanism of alimentation or to the nervous mechanism of defence. The motor reactions of the animal are carefully observed at the same time, and the two basic reflexes are harmonised with the general behaviour.

Much information is given in this book on the varieties of stimulus used, and the methods are continually illustrated by examples. There are long periods of waiting in each day's observations, and the reader has much admiration for the patience of the investigator. As a result of such long experience and concentration, the method has so been perfected that none can cavil with its conduct, and fallacies in interpretation which have been detected are fully explained. It is much to be desired and hoped that the method will be introduced into Great Britain.

The investigation of the process of conditioning reflexes and the use of the conditioned reflexes for other investigations have developed side by side. A stimulus can be conditioned so as to inhibit an already established conditioned excitatory reflex. By means of differentiating closer and closer values from one another, one excitatory and one inhibitory, the power of sense discrimination in the dog was investigated to a degree never before possible. The demonstration of discrimination between tones 12 d.v. apart, the finding that the dog can appreciate tones which are inaudible to the human ear, and that it lacks colour vision, were all surprising, but the recent investigations of skin sensation and its differentiation from muscle sense and joint sensation open further great possibilities. Here is a purely objective method of investigating sensation.

In dealing with the central mechanism, Prof. Pavlov wisely refrained from identifying the loci of analysis of these sensations and of the establishment of the conditioned responses with the conception of 'centres' developed by earlier writers and their methods. He calls the central mechanism for each sensation an 'analyser,' and several lectures are devoted to the investigation of the process of establishment and disappearance of localised excitation and inhibition. The 'investigatory reflex' which is discussed in several aspects is surely related to the property of 'attention' which is so conspicuous in animal behaviour.

Sleep, the mechanism of which has always seemed such a complete mystery, is identified as a variety of the process which Prof. Pavlov calls 'internal inhibition.' The investigations not only fully support this identity, but he also brings by them a great deal of light on intermediate states such as hypnotism. Prof. Pavlov brings forward evidence to show that the processes of inhibition and excitation as exhibited by conditioned responses are essentially the same nature as those processes as they are known in spinal reflexes. Inhibition is clearly not synonymous with exhaustion. The identity with spinal processes is only to be expected, but as inhibition in the spinal reflexes shows so much evidence of being an *active* process, the reviewer finds it difficult to reconcile sleep with a process implying cortical activity. But now that the process has been so brilliantly demonstrated, sleep and the intermediate states will surely become increasingly investigated by this method; we look forward to much further information of the mechanism of internal inhibition, especially as to the means of its localisation.

Subsequent lectures lead the reader to the investigation of pathological states. Here the work becomes of extraordinary interest to the neurologist and psycho-pathologist. With its facilities for comparable quantitative measurement, the method has a unique scientific value in investigating the temperament of an animal; the degree of 'stability' of behaviour becomes something definite and the physiological bugbear of 'nerve energy' appears in a new light. The interpretation is rightly most guarded, and few will deny the soundness of all the deductions. The results of experiments on functional interference with the cortex, indeed, bode serious rivalry to current psychological methods of attack on the problems of neuroses and psychoses. In analysis of the results of surgical interference with the cortex, the method also entirely replaces the old crude methods of appreciating defects in intelligence in animal conduct. One is surprised that some of the smaller operations should produce such large degrees of change attributable to scar tissue, and would like more detailed histological investigation of all the operated cases. Prof. Pavlov, however, realises this lack, and it is hoped that future work will fully remedy it.

The refutation of the doctrine of specific association centres is timely and well founded. The widespread representation of the visual and acoustic analysers will be a revelation to most of those interested in visuo-psychic disturbances, aphasia, and the psychic aspects of other special sense disturbances. The establishment of visual responses to luminosity and shape after extirpations of the occipital areas is not only a great advance in knowledge but also reflects the extraordinary sensitivity of the method. Prof. Pavlov points out the richness of speech in factors of intensity, time intervals, sound discrimination and discrimination of order in serial succession, each provocative of conditioned reflexes. A method for the physiological approach to the problems of aphasia at last seems indicated. Another striking result of the flexibility of the method is the proof that both hemispheres are necessary for the appreciation of direction of origin of sound, and the description of the extraordinary case of the dog showing symptoms of visual illusion following the appearance of strange objects in one field of vision and not when they appeared in the other.

The storing of past associations which forms the essential part of the process of conditioning would seem to form the greater part of the gulf between reflex action and conditioned response. The reviewer would like to have seen this discussed. The appreciation of relative time impresses the reviewer as being one of the fundamental properties of the cerebral cortex, and he considers it as another manifestation of the storage capacity of the nervous tissue of the cerebral cortex. The development of this storage factor is the fundamental process in the evolution of consciousness and memory.

The degree of precision in stimulus evaluation and measurement of effect, and the recognised high degree of intelligence of the dog in the study of conditioned reflexes, make maze learning and problem-box experiments with rats, as an approach to the problems of mind, crude and undifferentiated in comparison.

It is of vital interest to all who study the mind and the brain to become intimate with the developments described in this book. The wisdom of the Royal Society in enabling a translation to be made, and in the choice of translator, is manifest, and Dr. Anrep, a former pupil and collaborator of Prof. Pavlov, is to be congratulated on his excellent rendering into English, especially of the large new terminology.

D. Denny-Brown.

Hypothetical Ethnology.

Peoples and Problems of the Pacific. By J. Macmillan Brown. In 2 vols. Vol. 1. Pp. xiv + 327 + 65 plates. Vol. 2. Pp. x + 297 + 32 plates. (London: T. Fisher Unwin, Ltd., 1927.) 50*s.* net.

IN these two closely packed, well-illustrated volumes, Dr. J. Macmillan Brown has collected a number of articles written during the last fifteen years for various magazines, newspapers, etc., and it must be admitted that the book rather suffers from its journalistic origins. It is the record of many wanderings throughout the Pacific, and contains a great number of original observations and suggestions on the past, present, and future of the Polynesians. In this, as in his previous books, Dr. Macmillan Brown lays great stress on movements of upheaval and depression in the area, and refers to accounts of islands which later have become submerged. He heard in the Cook Islands that the island of Tuanaki had disappeared about the middle of last century. If this be so, W. T. Brigham had not been informed, as he describes it as being an uninhabited atoll ("Index to the Islands of the Pacific Ocean," 1900). An interesting reference is made (vol. 1, p. 188) to Malden Island; it is reported to contain ruined pyramid-temples and paved roads, and thus deserves careful investigation. Malden is quite incapable of supporting human life, and "the people who built the temples could not have lived on the island as it is. Probably they lived on fertile archipelagoes within canoe-distance of its shores," as uncharted shoals exist in its neighbourhood.

Dr. Macmillan Brown also is of opinion that the great ruins of Ponape in the Carolines "cannot be explained without assuming a submerged empire with millions of inhabitants." He argues that the culture of Ponape was due to a Polynesian migration bringing with it kava, father-right, and megalithism. It is true that kava drinking, which also occurs in Micronesia only in Kusaie and Ponape, is a characteristic Polynesian custom. Christian and Rivers have suggested that probably it was not an independent invention, but merely a retention of one element of betel chewing, which was developed in Oceania into a ceremonial rite. Kava drinking was unknown in Torres Straits (vol. 1, p. 104). Dr. Macmillan Brown adds, "Hereditary chieftainship could have come from Polynesia alone, the realm of father-right; but Williamson states that in most of the Polynesian islands women were qualified to succeed, and that the line of succession could pass through women" ("Social and Political Systems of Central Polynesia," 1924, vol. 3, p. 395), though, as a matter of fact, succession was practically invariably in the male line. Rivers says, "If the succession of women to the dignity of chief be put on one side as capable of special explanation, it becomes probable that such indications of matrilineal institutions as are found in Polynesia are to be connected with the earlier stratum of the population" ("History of Melanesian Society," 1914, vol. 2, p. 322). It therefore appears that the predominance of patriliny (father-right) in Polynesia is relatively recent. Hereditary chieftainship could as readily have come from the west, and W. J. Perry as easily disposes of hereditary chieftainship, megalithic remains, and many other matters as being brought into the Pacific from the west by the 'Children of the Sun'; but he has nothing to say about kava. The third argument is based on megalithic structures; such certainly occur in Polynesia, but they are also to be found in Melanesia, Indonesia, and Asia. However, our author goes on to say, "there are features in the architecture of this wonderful city [Metalanim] that never came from Polynesia"; these he traces to a later movement from Japan.

The author is a strong supporter of the thesis that there were great land masses in the central Pacific which have only recently disappeared. On these very hypothetical lands the Polynesians developed their civilisation, untouched by foreign cultures, and it was due to their submergence that the Polynesians migrated westwards. By a linguistic argument he comes to the conclusion that the Polynesian language was brought into the Pacific lands by the first migration in the "Old Stone Age . . . at least twelve thousand years ago" (vol. 2, pp. 175, 176), and with it came the race that contributed traces of blond hair that still persist in Polynesia; but apart from this "there is sufficient in the physique of the Polynesians to point to western Europe as their origin and home," and he suggests that "Polynesian physical characters point through Japan and Central Asia to Western Europe" (vol. 2, p. 153)! The facts upon which he bases many of his theories admit of other solutions, and in not a few instances the data themselves are open to question. The reader should be warned that specialists in the various subjects dealt with in this book do not regard Dr. Macmillan Brown as a safe guide to follow.

Many interesting and suggestive remarks are made by Dr. Macmillan Brown about the present and future economic and political problems of the Pacific. A historical sketch of ancient empires paves the way to a consideration of Japan and what may happen there. He regards British Columbia and New Zealand as "the sure naval shields of the English-speaking peoples in the Pacific"; indeed, he prophesies a great future for New Zealand, but is pessimistic about the United States of America. The strictures on the condominium in the New Hebrides are outspoken and timely—if they are not too late; the present writer has recently had information from Malekula which shows the unsatisfactory nature of this compromise—but indeed it is generally admitted.

The decay of the native population in Oceania is discussed in several places, and our author comes to the following conclusion, for which there is much to be said: "If our paternal governments and our missionaries mean to save our primitive peoples from themselves and death, they must recognise the law of struggle and work as the only panacea. They must study their manners and customs and see how far they can modify these so as to make them methods and stimuli to work."

A. C. Haddon.

Crystal Surfaces.

The Nature, Origin, and Interpretation of the Etch Figures on Crystals. By Prof. Arthur P. Honess. Pp. xiii + 171. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 17*s.* 6*d.* net.

It is probably evident to many others besides specialists how greatly the science of crystals has lately progressed by the introduction of the X-ray method. Brilliantly created some fifteen years ago by Laue, and simplified and developed by Sir William and W. L. Bragg, the method early led to convincing deductions of the atomic arrangements within certain crystals; and almost immediately was also applied by Moseley to the elucidation of the atom itself. After a marked pause due to the War, the method has been systematically developed in many directions, not least actively in its original rôle as a crystal probe. The purely crystal development has in fact been so rapid that a general halt is now recognisable, not in the number of workers or of their results, but in the kind of results. It is probably true to say that there has been no advance in principle for the last three years.

It therefore seems possible to make an estimate of the present position without incurring much danger of its being upset by immediate developments. Divested of all qualifications, it may be said that the X-ray method illuminates the interior of a crystal and casts shadows on its surface. Dürer's picture of "Melancholia beholding a Crystal" possibly acquires prophetic qualities!

The second half of the above conclusion doubtless needs support. From time immemorial have crystallographers been concerned with the problem of structure, although possibly only with limited curiosity: they would pry into the inside mainly in order to understand the outside. A partial understanding was first allowed to Haüy, according to whom the plane boundary faces correspond to the simpler planes, drawn through a close-packed stack of the presumed structural units. But subsequent accumulations of material gradually led to a knowledge of scores, if not hundreds, of substances the external planes of which bear no thoroughgoing, simple relation to any conceivable structure. Bravais in the middle of the last century and Fedorov at its close had to leave much unsimplified. In this they have been strongly supported by the X-ray method, which adds considerably to the sum total of perplexities. A single example will serve as an illustration.

Early in his career, Haüy felt quite sure about the shape of the barytes unit—an orthorhombic prism, walled-in by cleavage planes and of a modest altitude. Later workers equally confidently doubled the height, as giving a slightly simpler correlation between boundary planes and structure. Fedorov was not so certain. In his "Krystallreich" (a catalogue critically arranged according to classical conceptions of structure) he places barytes here; its isomorph potassium perchlorate there; and potassium beryllio-fluoride elsewhere (others would have placed all three together). The X-ray results show that Fedorov was right for barytes and wrong for the perchlorate (for the beryllio-fluoride there is still no evidence). It must here be interpolated that Fedorov's treatment of barytes seems to have been guided by instinct rather than a close adhesion to his own expressed principles. In any case, the X-ray results prove that the crystal distances along the front-to-back direction of barytes are twice those advocated by any crystallographer, simpler-minded than Fedorov. Inferentially, structurally simple planes are not always observed on a crystal, giving place to complex planes. Conversely, omnipresent cleavage planes may be structurally complex.

The present-day position is now perhaps realisable. The relation between form and structure, after being deemed simple and then less simple, must be recognised as being complex now that exact information concerning structure is available. It is of course not impossible that another Haüy may bring about a tolerable synthesis of cause and effect, but it seems more probable that another Laue must first appear—one who shall conceive of a method of examining surfaces as powerful as that which now penetrates into the interior.

In the meantime, crystallographers have obviously to carry on in their several spheres of work. Some, no doubt, will acquire the new X-ray technique in time to win results from simple compounds, while others, whose field of work lies in the investigation of complex molecules, may hesitate to ponder whether the results justify an expensive equipment. Perhaps the majority will remain on the surface; either investigating new substances in the classical way; or seeking to classify morphologically the existing crystal kingdom for purely utilitarian ends (the identification of substances by crystal measurement); or in the pursuit of truth by a more intensive examination of individual crystals—which brings us to the book under review.

It is now many years since students of crystal symmetry first recognised how important it is to supplement older observations on forms of growth by the more experimental method of a partial dissolution. The etch figures (plane or curved) thereby obtained frequently take up highly significant forms and orientations. The results are, however, only to be found in German monographs, so that any attempt to render them more generally available to English-speaking students is welcome, especially when it comes from one who has adopted this subject as his own province of work.

The work falls informally into two parts, general and special. In the former, divided into five chapters, the author presents a historical and well-documented discussion under the following main heads: introduction; methods; the process of growth of the etch figure and its interpretation; anomalous etchings; the etch figure and isomorphism. In the special section, occupying one long chapter of some eighty pages of text and illustrations (mainly photographs), are brought together the results of his own investigations on some ten mineral species, representing six classes of symmetry. A concise statement of conclusions brings the monograph to a close (except for a good index).

In offering any general criticism of the book, the reviewer is so conscious of its many good qualities that he would expressly ask a reader not to conclude from any indications of defects, that it is lacking in aim or achievement. Here and there one meets with doubtful expressions. The statement "theoretically, of course, a crystal cannot possess a curved face" leaves one guessing at the identity of the theory, which is sufficiently powerful to override a wealth of facts—if the author had extended his survey beyond the limits of the mineral kingdom, he would have been able to cite many cases of crystals making good their claim to develop curved surfaces under uniformly continuous conditions of growth. But quite apart from an occasional lapse, there seems to be more general grounds of dissatisfaction.

We are told in the preface that the book is a thesis offered by a candidate for the D.Sc. degree. Unfortunately, it has preserved not only the virtues but also the defects of its origin. It was no doubt originally advisable to bring together the author's own work and stress its importance by a wonderful series of photographs and diagrams, but now that the work is addressed to a wider audience, a less complete polarisation seems desirable. Many of the excellent photographs and diagrams of the special part seem badly needed in the first part, as well as others not included in the book. Anyone new to the subject might do worse than read the particular before the general.

Another element of weakness is possibly referable to the same antecedent. The author has elected to specialise in the older methods of investigation by microscope and camera, and there is no doubt still much to be done in this way. But much has also been done by the aid of the two-circle goniometer, the introduction of which first placed a three-dimensional measuring instrument in the hands of the crystallographer. A chapter on the results obtained by Goldschmidt, Wright, and others, would seem to be almost indispensable in any general account.

It is high time to turn, however, to the author's merits. Within his self-imposed limits he has covered much ground in an engaging way, the whole work being illumined by a simplicity of style which many will covet. He is ever cautious in drawing a conclusion, even if it be his own; and there is certainly no other such work in English (and probably not in German). The book can be confidently recommended to the attention of senior students, both on account of the importance of the subject and as a corrective to the text-book attitude that Nature is simple; and also to the researcher, as showing how one may hope to attain further information concerning surfaces by present-day methods. In any selection of material for such future work, a plea may perhaps be here offered for the six thousand or so non-minerals catalogued by crystallographers. Although the kings and queens of the crystallographic pack may be minerals, there are surely not a few useful cards among the laboratory products the constitutions of which are known—not to speak of the embarrassing number of aces in the four hundred orthorhombic, monoclinic, and anorthic crystals, the symmetry classes of which are *a priori* fixed by the Pasteur principle. The extensive application of the etch method to such first-rate material would seem to be bound up with any serious attempt to define its standards. T. V. B.

Kostychev's Plant Respiration. Authorised edition in English with editorial notes. By Dr. S. Kostychev. Translated and edited by Prof. Charles J. Lyon. Pp. xi+163. (Philadelphia: P. Blakiston's Son and Co.; London: Arthur F. Bird; American Book Supply Co., 1927.) 2.50 dollars.

This book seeks to do what has not previously been attempted, namely, to outline the main features of plant respiration. There is no student of this subject better qualified to write on it than Prof. Kostychev. Trained by Palladin, among others, and long an active worker on the chemical problems associated with fermentation and respiration, he is in a position to present a balanced and authoritative discussion of a subject in which Russian workers have long been leaders.

As might be expected from the author's researches, attention is focused principally upon the biochemistry of respiration, and particularly upon the establishment of the theory of the connexion between the intermediate products of alcoholic fermentation and 'normal' respiration in the presence of oxygen. While the author expressly states that this is only a working hypothesis, he marshals his facts ably and presents a most attractive case in its support. Kostychev undoubtedly lays very great stress upon his discoveries that partly fermented sugar solutions not only greatly increase the rate of respiration in oxygen, but will also liberate carbon dioxide in quantity when acted upon by an oxidase system. He clearly regards the former fact as good evidence for the view that oxygen respiration starts with the intermediate products of alcoholic fermentation, and the second fact accounts for his preference for the Bach-Engler theory of oxidation. He states very clearly alternative explanations and theories.

It is in this broad statement of Kostychev's point of view that the great interest of the book will be found. It should not be assumed, however, that other aspects of respiration are ignored. Adequate space is given to the relation between external conditions and respiration, including fermentation, and there are valuable outlines of methods used in measuring the products of these processes. The translator and editor has judiciously amplified these, and has added many references which serve to bring the extensive bibliography up-to-date. The author has also added an account of Warburg's theory of respiration which was absent from the original German edition. There is, finally, an interesting attempt to co-ordinate the various processes in the respiration of different types of plants, on the basis of the ratios of oxidising to fermenting enzymes which are present. W. H. P.

Air Ministry: Meteorological Office. The Observatories' Year Book, 1924: comprising the Meteorological and Geophysical Results obtained from Autographic Records and Eye Observations at the Observatories at Lerwick, Aberdeen, Eskdalemuir, Cahirciveen (Valencia Observatory), and Richmond (Kew Observatory), and the Results of Soundings of the Upper Atmosphere by Means of Registering Balloons. (M.O. 289.) Pp. 366. 57*s.* 6*d.* net. *Year Book, 1925.* (M.O. 229.) Pp. 372. 63*s.* net. Published by the Authority of the Meteorological Committee. (London: H.M. Stationery Office, 1927.)

The appearance during 1927 of two issues, for 1924 and 1925, of the "Observatories' Year Book" of the Meteorological Office indicates notable progress in overtaking arrears of printing due to post-War causes; it may be hoped and expected that a continuance of this acceleration of printing will soon lead to the attainment of the ideal practice of publishing each year's observations before the close of the following year. The volumes include an immense amount of standard observational data for meteorology, terrestrial magnetism, and seismology, made efficiently by good observers and published in concise, economical form. The period in question was marked by the retirement from Kew Observatory of Dr. C. Chree, who had been superintendent for thirty-two years; he was succeeded by Mr. F. J. W. Whipple. At the same time, 1925, the Kew magnetographs were discontinued, and their place was taken by Galitzin seismographs brought from Eskdalemuir; Kew thus succeeds Eskdalemuir as the official seismological station in the British Isles. The last-established observatory under the Meteorological Office is that at Lerwick, in the Shetlands; its work is almost wholly confined to atmospheric electricity, terrestrial magnetism, and auroræ; many experimental difficulties, not wholly overcome by the end of 1925, have been experienced with the instruments installed there.

Meteorology. By David Brunt. (The World's Manuals.) Pp. 112+8 plates. (London: Oxford University Press, 1928.) 2*s.* 6*d.* net.

The aim of this book is, in the author's words, to give "a brief sketch of the physical principles underlying the phenomena which constitute 'weather,' in so far as this is possible without mathematical analysis."

The absence of mathematical formulæ and the small size of the book, together with a certain simplicity of style, may combine to give the impression to a meteorologist who may casually glance at it, that he has before him one of those entertaining little handbooks in which the presence of numerous inaccuracies is regarded by the author, if he should happen to be aware of them, as a matter of small importance, seeing that few readers will be likely to detect them. A more careful perusal of the book will dispel this impression: not only will he find a high standard of accuracy, but he will see also that a serious effort has been made, and with a considerable degree of success, to give a picture of the development of meteorology as a branch of physics and some suggestion of the lines along which it may advance in the future.

There is no account of practical weather forecasting—a wise omission in view of the size of the book and the predominant part played by unsystematised experience in the 'science' of weather forecasting; on the other hand, a whole chapter is set apart for the important subject of the reception of solar radiation by the atmosphere. The general and local circulations of the atmosphere are admirably dealt with, having regard to limitations of space.

Some knowledge of physics is essential to anyone who wishes to appreciate fully the later chapters, but these chapters should nevertheless be very instructive to those whose only knowledge of physics is 'picked up' in the earlier chapters.

The printing and the illustrations of cloud forms and lightning are both exceptionally good, and the work can confidently be recommended for educational purposes.

A Handbook of the Birds of Iceland. By Masa U. Hachisuka. Pp. v + 128 + 7 plates. (London: Taylor and Francis, 1927.) 12*s.* 6*d.* net.

THE Honourable Masa U. Hachisuka is a very young ornithologist, but his work—his first, we understand, of any magnitude—shows that he is keen, industrious and methodical, and, though it is an ambitious attempt for a first work, there is little doubt it will prove most useful. We congratulate the author, not only on his pluck in undertaking it, but also on the result itself.

The author admits a total of 141 birds actually found, either as straggler, regular visitor, or resident in Iceland. A few of the birds mentioned he admits as 'non-proven,' and one new species, *Calidris maculata*, the American Pectoral Sandpiper, he adds as new to the Iceland list. The author's remarks on the various geese sum up our knowledge of these birds to date and are interesting. He considers it reasonable to believe that the pink-footed goose breeds in Iceland, and, though he admits the Bean goose on very slender evidence, probably indeed quite insufficient, he agrees that it never breeds there.

The photographs with which this little book is fully illustrated are quite good, though we fear that the plate giving the comparative size in diagram form of the eggs of ducks and geese will not be of very much use, as the overlapping of dimensions in big series of these eggs is very great. We shall look forward to further works on birds by Mr. Hachisuka, and recommend this, his first, to all those who intend to visit Iceland to study ornithology. It summarises in a compact form much scattered information and will save Icelandic visitors an immense amount of research and trouble.

The Crustaceans of South Australia. By Herbert M. Hale. (*Handbooks of the Flora and Fauna of South Australia*, issued by the British Science Guild (South Australian Branch), and published by favour of the Honourable the Premier.) Part 1. Pp. 201. (Adelaide: Harrison Weir, 1927.) 5*s.*

FULL descriptions and good illustrations of all the South Australian Malacostraca are given in this useful book. It is intentionally written in a popular way, and quite untrained naturalists should be able to identify any species, whilst the specialist is greatly helped in having this book for reference. The malacostracan fauna of South Australia is large and of great interest, and obviously many problems are only waiting for the worker to elucidate them. This seems specially the case with the life histories, so little being known about the larval forms and the few notes given suggesting so much. Some of the Reptantia hatch in a very late stage of development. It is well known that members of the family Potamonidæ hatch as forms very like the parent, the truly larval stages taking place within the egg. In South Australia we find other crabs with the same peculiarities. Thus some of the Dromiidæ are known to hatch as tiny crabs, having no free-swimming stage and sheltering under the body of the parent; other species with very large eggs are probably similar.

Notes on habits and biology make the book readable as well as valuable, and the low price places it within reach of anyone interested in the group.

Proceedings of the London Mathematical Society. Second Series. Vol. 26. Pp. ii + 558. (London: Francis Hodgson, 1927.) n.p.

THIS volume of *Proceedings* maintains the usual high standard of the London Mathematical Society's publications. Of the thirty-two papers it contains, twenty deal with various aspects of the modern theory of functions, four with geometry, and three with applied mathematics. This preponderance of function theory should be regarded more as an indication of the tendency of present-day mathematical research in Great Britain than as a sign of the relative importance of the subject. When Cayley and Sylvester, Clifford and Smith, dominated mathematical development, papers on geometry and invariants were paramount, while recent volumes of the *Transactions of the American Mathematical Society* contain a large proportion of papers on non-commutative algebra, a subject which has scarcely been touched by British mathematicians. Meanwhile, the higher function theory is enjoying a protracted run which is likely to continue until there arises an outstanding leader inspired to direct research activities into some other branch of pure mathematics. The Relations of Nile and Faiyum in Pliocene and Pleistocene Times.

During the past winter we have had an opportunity of investigating, under the auspices of the Oriental Institute of the University of Chicago, the Pliocene and Pleistocene geology of that part of the Nile Valley adjacent to the Faiyum depression; and it has occurred to us that some of the results may interest readers of Nature who followed some time ago a discussion of certain archæological problems of the Faiyum and its lakes.

It has long been known that the northern part of the Nile Valley was occupied by an arm of the sea in early Pliocene times and that a marine fauna was succeeded by an estuarine one, which lasted until the close of the Pliocene epoch. This indicates a Lower Nile Valley cut to much its present form in pre-Pliocene times.

Fossiliferous marine strata have now been found to a height of 100 metres above sea-level, resting on the old valley side, with a gulf stretching into the southern part of the Faiyum basin. They had been eroded before the deposition of the estuarine beds, which are found upon them and filling hollows in them. The deposits have now been connected with a remarkable system of lateral valleys, which drained a part of the Libyan plateau and in Upper Pliocene times became choked with boulders and gravel. The fossil valleys are in all stages of dissection, some standing out as the most prominent ranges of hills in a soft Eocene country, eroded below their base, others still retaining substantially their original form. Some of the valleys flowed across the region which is now the Faiyum, some draining directly into the Nile Valley and one or more into the southern Faiyum gulf already partially filled with marine and estuarine strata. Part of the northern side of the basin is now bounded by one of these dissected Pliocene valleys, cut along the boundary of the Eocene and Oligocene beds. While the Eocene marls on the southern side of this old valley have been entirely removed by erosion, the harder Oligocene rocks on the north still stand as a high escarpment above the Pliocene filling. The Faiyum basin, as such, did not exist in Pliocene times, and the southern gulf was probably but a flooded pre-Pliocene tributary of the Nile.

The Nile Valley returned to normal fluvial conditions in Plio-Pleistocene times, when a magnificent series of terraces was cut along its western side, the river at times meandering over the eastern part of the region now the Faiyum. The terraces with Nile gravel first appear at 470 feet above Nile, and below this three successive river channels may be identified to 150 feet, which stage seems immediately to have preceded Pleistocene times (assuming for convenience that the incoming of Lower Palæolithic man marks the beginning of that epoch in Egypt).

There follows the most extensive remaining channel, with a marginal level of about 60 feet. This contains Lower Palæolithic implements, while at a similar level a fragment of terrace or beach containing implements has been found inside the eastern boundary of the basin.

Prior to the Middle Palæolithic, the Faiyum seems to have been dissected by normal processes of stream and river erosion, in harmony with the rest of the Libyan plateau. But, owing to the extremely soft strata locally exposed, a broad plain had been formed at a low level, and the drainage of this could only escape into the Nile by cutting a narrow passage (the Hawara Channel) between two of the Pliocene valleys choked with virtually indestructible materials. In Middle Palæolithic times this plain first appears definitely as a lake, and for the first time we find a reversal of drainage. In the Nile Valley a Middle Palæolithic terrace has been found at about 25 feet, sweeping through the Hawara Channel and falling as it does so. On the inside it passes into shoals, a beach, and a storm-beach, which have been followed and mapped along the eastern side of the Faiyum. Implements and fossil Mollusca have been found *in situ* throughout this series.

At a slightly lower level, with an increased tilt towards the Faiyum, another similar series has been found, of Sebilian, probably Lower Sebilian, age. (Sebilian is the term applied by M. E. Vignard to a post-Mousterian industry of Capsian affinity in Upper Egypt, and we now find it *in situ* at this level in Lower Egypt.)

Succeeding stages in the Nile Valley and in the Hawara Channel are hidden below the level of recent alluvium, but it will be remembered that the extremely valuable work of Miss E. W. Gardner proved the existence of two lower lakes in the Faiyum. Miss Caton-Thompson showed the more recent to be Neolithic, but the age of the older remained in doubt. On the east side of the Faiyum, where its magnificent storm-beach first appears, such evidence as we have collected is suggestive of a probable Upper Sebilian age. Accurate levelling was carried to the point of meeting with Miss Gardner's lakes on the north and south sides of the basin.

There is no sign of desert conditions in Palæolithic times in the region with which we have dealt; on the contrary, the rainfall was heavy. Levels set certain bounds to the size of any lake, and in view of the climate and the essentially fresh-water fauna of the Palæolithic lakes, it would appear that the water flowing in from the Nile returned to it at times, with the local drainage water, by the Hawara Channel. No evidence has been found that there was ever any other inlet from the Nile. The presence of the fresh-water fauna at a sufficiently low level on the divide between the Faiyum and Wadi Rayan to the south-west leads us to suppose that the latter was flooded in Mousterian times.

The excavation of that part of the Faiyum basin below sea-level must, in view of the above, be relegated to late- or post-Sebilian times, when the Nile cut a deep channel, now choked with alluvium of unknown thickness. The rise in the bed of the Nile, with the deposition of this alluvium, seems to have synchronised with the inception of desert conditions. The cutting off of rainfall prevented local detrital material from silting up the Faiyum basin and it became a 'sump' of the rising Nile, with a bottom below the new sea-level. The evidence recently published by Miss Gardner that the old lake bed was drained and eroded before the advent of the Neolithic lake here acquires new significance.

We find it difficult to believe that the Faiyum was excavated by any other means than fluvial erosion, although the modifications to which it has been subjected since the incoming of desert conditions are obvious. In view of this, the conclusion seems to be inevitable that a gorge of about the same depth as the Nile Valley was cut beneath the

Hawara Channel and has since been filled with alluvium.

The work will be published in full by the Oriental Institute of the University of Chicago.

The Origin of the Spectrum of the Solar Corona.

THE arguments which have been brought forward to explain the origin of the spectra of nebulæ may be used with certain modifications to explain the spectrum of the solar corona; for it must be composed of such atoms thrown out by radiation pressure or other agencies from the general atmosphere of the sun. On account of the lower temperature of the sun, the atoms concerned should be non-ionised, or such as can be easily ionised. They should also be light. All these considerations narrow down the choice to a very few elements like Li^+, Be^+, B^+, C, N, O . . . Si, P, S, P^+, and S^+, etc. It is the object of this note to discuss how these elements can give rise to the coronal spectrum.

It is now generally recognised that matter above the solar photosphere is largely supported by radiation pressure acting in a selective way. Prof. Milne has shown from transition probabilities of the Ca^+-atom (or the average life), that Ca^+ emitting the *H*-*K* lines is subjected to such a large radiation pressure that it almost overcomes the force of gravity. If this argument be true, the logical consequence would be to extend it to other elements. We can leave out H and He because their resonance lines are in the extreme ultra-violet and their normal atoms would be subjected only to slight radiation pressure. But such is not the case with Li. The resonance line of Li is at 6708 A., the corresponding $E_\lambda = 0{\cdot}8\ E_m$, the maximum emission E_m of the sun regarded as a black body at 6500° K; hence the force of radiation would more than balance the force of gravity; it would be expelled entirely from the solar atmosphere. It can be retained only in the ionised form. The entire absence of Li-lines from the Fraunhofer spectrum seems to support this view. If Li^+ be present, it may or may not be detectable, as the fundamental lines are in the Schumann region, and the excitation required to bring out the next important lines will be too large. The only favourable line is λ5484·69, or λ5484·90 (Rowland's Scale—a very weak line is given at 5484·846 in Rowland's Table, but the identification is doubtful), which belongs to the singlet system of Li^+ ($2S - 3P$). Similar considerations would apply to Be^+ and B^+.

$\bar{P}_2$		2506·904 39877·83(9)	2516·123 39731·73(10)	2970·35 33656·27(1)	
$^1\bar{P}_1$	2438·782 40991·64(3)	2443·378 40914·54(3)	2452·136 40768·42(3)	2881·585 34692·97(10)	3905·515 25597·61(9)

In carbon we come across a new feature. This new feature is best explained by taking the case of Si, for which the full details of the spectrum are known. Si has five fundamental levels, $^3P_{012}$, $^1\bar{D}_2$, $^1\bar{S}_0$, all arising out of the combination *pp* (or M_2M_2). The next combination is $ps(M_2N_1)$, and it gives rise to $^3\bar{P}_{012}$, $^1\bar{P}_1$. The lines are shown in the accompanying table, the figures being taken from Fowler, *Phil. Trans.*, vol. 225, p. 45. The table shows that the ($^3P - {}^3\bar{P}$) lines are the most fundamental, but their wave-length is at λ2514 – 2528, while the less fundamental $^1S_0 - {}^1P_1$, $^1S_0 - {}^3P_1$ lines are at λ4103, λ3905. Si is in fact detected in the sun by those two lines, some other subordinate lines, and some lines of Si^+. The problem now arises that if we heat Si to incandescence, to say 4000° C., so that the corresponding wave-length of the maximum emission is towards the red, will the group at λ2514-2528 be more intense or the lines λ4102, λ3905? Laws of temperature radiation demand that λ4102, λ3905 will be more intense, while the theories of spectra require that λ2514-2528 will be more intense at all temperatures, as the $^3P_{012}$ states will be much more numerous than the $^1\bar{S}_0$-states $\left(n_{1_S}/n_{3_P} = e^{-\frac{22000}{T}}\right)$, and there is always a greater tendency on the part of the higher excited $^3\bar{P}_{012}$, $^1\bar{P}_1$ states to revert to the more fundamental state.

An experiment was performed at this laboratory by Messrs. Majumdar and Kichlu to decide this question. They did not work with silicon, but with the more easily manageable thallium. This has two fundamental states, $2p_1$, $2p_2$, separated by a large interval $\Delta\nu = 7793$, so that $n_{2p_2}/n_{2p_1} = \frac{1}{2}e^{-\frac{[illegible]11}{T}}$. They heated thallium in a vacuum graphite furnace to about 2500° A. and photographed the spectrum of thallium vapour. The $2p_1 - 3s$ line has the wave-length λ3775·72, the $2p_2 - 3s$ line has the wave-length λ5350·46. As the $2p_1$ state is about a hundred times more in abundance, we expected that the line λ3775·72 would be more intense; at any rate it would not have less than half the intensity of λ5350·46 (because the weights of $2p_1$ and $2p_2$ states are as 1 : 2). But λ5350·46 was at least ten times more intense than λ3775·72. This fact is therefore more in accordance with the view that thallium vapour is partly in equilibrium with temperature radiation from the walls. But still we have to find out why the larger proportion of the $2p_1$-atoms is maintained. This is met by assuming that the prohibited transition $2p_1 - 2p_2$ occurs in large proportion—in other words, under the influence of the existing field of radiation, most of the thallium atoms in the $3s$-state return first to the $2p_2$-state, and then from the $2p_2$-state they return by the prohibited transition to the $2p_1$-state, so that the equilibrium between the proportion of atoms between the $2p_1$- and $2p_2$-states is maintained by the prohibited transition, which marks the emission of the line $\nu = 2p_1 - 2p_2$.

Turning now to the case of silicon in the sun, we find that the same argument can be applied. The emissivity of the sun is almost a maximum at λ4102 and λ3905; at λ2500, the emissivity is about 0·57 of the maximum. When silicon atoms are traversed by a radiation field of this type, we shall find that transitions corresponding to the emission of $^1S_0 - {}^1P_1$, $^1S_0 - {}^3P_1$ of silicon will be very frequent, while the transitions $^3P_{012} - {}^3\bar{P}_{012}$ will be too small. The proportion between the fundamental ^3P and metastable $^1D_2$, $^1S_0$ levels will be maintained by the prohibited transitions $^3P_1 - {}^1S_0$, $^3P_{12} - {}^1\bar{D}_2$. Also it follows that if the transitions from the excited $^1\bar{P}_1$, $^3\bar{P}_1$-state to the $^1\bar{S}_0$-state are as numerous as in the case of calcium, then silicon, being much lighter than calcium, would be thrown out into the corona in the metastable state ${}^1\overline{S}_0$. Hence the coronal spectrum would show the prohibited transition.

If these hypotheses regarding the presence of silicon be correct, we should expect the following deductions to be verified:

(1) The Fraunhofer spectrum of the sun should show the line corresponding to ${}^3P_1 - {}^1\overline{S}_0$, $\lambda = 6527{\cdot}05$ (Rowland Scale). Rowland's table shows a line at λ6526·89, intensity zero. The agreement is not satisfactory.

(2) The coronal spectrum should also show this line. There is a line of approximately this wave-length in Father Cortie's table of coronal lines; the wave-length is given as λ6528·9.

(3) The silicon lines λ4103 and λ3905·67 should be high chromospheric lines. This is not quite confirmed; in Mitchell's tables they are stated to reach only heights of 500 km. and 800 km. This may be due to paucity of transitions from the ${}^1\overline{P}_1$-state to the ${}^1\overline{S}_0$-state.

Excited silicon atoms may or may not (in the ${}^1S_0$-state) form a constituent of the corona. But the above arguments will apply to other suitable elements. I have chosen silicon for illustration because we know all about its spectrum. The same cannot be said of carbon, nitrogen, and oxygen, to which similar arguments can be applied, because in these cases the differences in value between the metastable states are only roughly known. To take carbon; this has an ionisation potential of about 11·3 volts; the spectrum is in all respects similar to silicon. The fundamental ${}^3P - {}^3\overline{P}$ lines are at λ1656-1658, but the metastable ${}^1S_0 - {}^1P_1$-line is probably the line λ2478. Hence it can be stated that metastable carbon atoms, being very light, would be thrown into the corona, and there give rise to prohibited transitions ${}^3P_1 - {}^1\overline{S}_0$, ${}^3P_{1,2} - {}^1\overline{D}_2$. The electrical field in the corona would increase the number of transitions. The frequencies of such lines are of the same order as the frequencies of the more intense coronal lines, but whether they agree absolutely will depend upon the exact determination of the value of these terms.

Similarly, prohibited transitions between the fundamental levels of N and O, P and S, P^+ and S^+, may account for some of the coronal lines. The present spectroscopic knowledge of the metastable states of these elements is so meagre, and the wave-lengths of the coronium lines are so roughly known, that I have not yet tried to institute any search for their origin amongst these states.

Mammoths and Man in the Transvaal.

Prof. Dart's paper in the Supplement to Nature of Dec. 10, 1927, on "Mammoths and Man in the Transvaal," followed by Dr. R. Broom's letter in the issue of Mar. 3, 1928, under the same title, renders desirable the immediate description of two elephant teeth kindly sent to me by Curator Wilman, of the McGregor Museum at Kimberley, South Africa, in 1926 and 1927.

The first type (represented in Fig. 1) I name *Archidiskodon subplanifrons*; it is a low-crowned, broad-plated, heavily cemented tooth, apparently a third inferior molar of the right side (McGregor Mus., 3920). The specific name *subplanifrons* refers to the fact that the crown height—from 2 to 2¼ inches—is about equal to that of the low-crowned types of *Elephas planifrons* Falconer of the Siwalik Hills, India; in some of Falconer's Upper Siwalik specimens the crown rises from 3½ to 4¼ inches. The present specimen accordingly is believed to be of Upper Pliocene age.

In the second type (Fig. 2) the anterior half of a third superior molar, probably of Pleistocene age, we observe a far more progressive stage, with lofty ridge-plates, the sixth attaining a height of 5 inches, equal to that of certain specimens of *Archidiskodon meridionalis* in which the ridge-plates equal or exceed 5 inches. This relatively high-crowned type (McGregor Mus., 3682) I name *Archidiskodon broomi*, in honour of Dr. Robert Broom, who, after the specimen was named in MS. and figured by myself, requested that one of these molars should be named after Mr. W. Millett, who discovered the type of *A. subplanifrons* at a depth

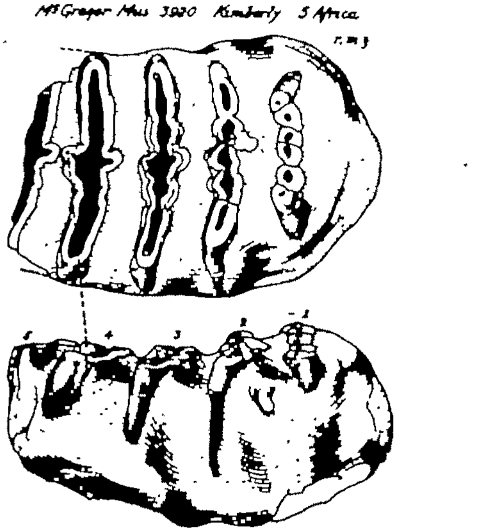

Fig. 1.—Type third inferior molar of *Archidiskodon subplanifrons* sp. nov., from the Upper (?) Pliocene, Sydney-on-Vaal, Vaal River diggings, South Africa, one-sixth natural size. McGregor Mus. 3920, Kimberley, South Africa; cast Amer. Mus. 21924.

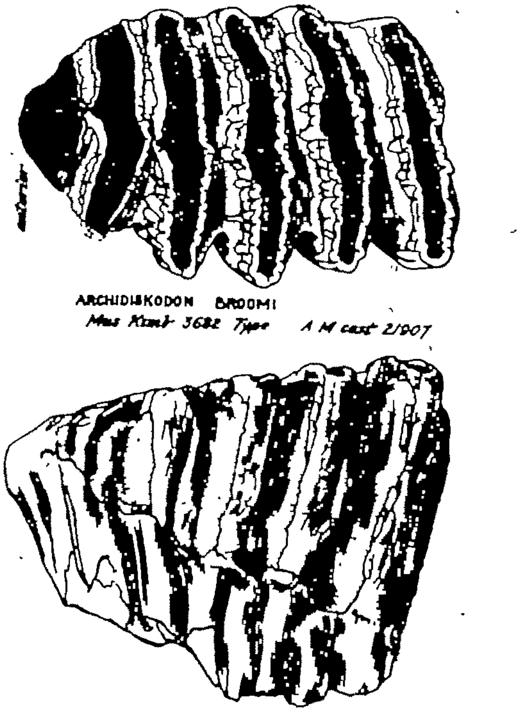

Fig. 2.—Type third superior molar of *Archidiskodon broomi* sp. nov. Original in the McGregor Museum, Kimberley, South Africa (No. 3682), cast Amer. Mus. 21907, one-sixth natural size. Seven ridge-plates partly preserved, broadest portion of the crown at fifth ridge-plate, indicating that three or four posterior ridge-plates are missing and that this may represent a ten- or twelve-plated molar.

of from 50 to 60 feet in the Vaal River diggings near Sydney-on-Vaal.

Neither of these new types is as progressive or as elevated in crown structure as the types of *Archidiskodon transvaalensis* Dart, 1927, or *A. sheppardi* Dart, 1927, in which the posterior portion of the crown of the third superior molar in *A. transvaalensis* attains a height of 247 mm., or 9¾ inches, far exceeding the height recorded even for the corresponding molar of *A. meridionalis*; it also exceeds the height of the American species *A. columbi* (7 inches), but is far below the height of the very tall ridge-plates of *A. imperator* (10¼ inches). Consequently we attribute a relatively recent Upper Pleistocene age to *A. transvaalensis*.

THE AFRICAN CENTRE.

Apart from this evidence of at least three progressive stages in the evolution of Archidiskodon, a genus hitherto known only in the northern hemisphere, is the increasing proof of the existence in southern and central Africa of many different kinds of proboscideans,[1] which will shortly be reviewed by Mr. Arthur T. Hopwood, of the British Museum (Natural History). Pending this thorough examination of past and original materials, I am inclined to summarise the previous discoveries, including the present descriptions, as follows:

ORIGINAL DESCRIPTION.	PRESENT REFERENCE.
Loxodonta griqua Haughton, 1922, type, Griqualand West, Transvaal .	= *Archidiskodon griqua.*
Elephas (*Loxodon*) *zulu* Scott, 1907, type, Zululand	= *Loxodonta* (*Pilgrimia*) *antiqua zulu.*
Elephas zulu, referred by Hopwood, 1926, Kaiso bone beds, near Lake Albert	= *Loxodonta* (*Pilgrimia*) *antiqua zulu.*
Elephas antiquus Recki Dietrich, 1916, type, Oldoway, British East Africa	= *Loxodonta* (*Pilgrimia*) *antiqua recki.*
Elephas aff. *meridionalis* Nesti, 1825, referred by Hopwood, 1926, from Kaiso bone beds, near Lake Albert	= *Archidiskodon meridionalis.*
Archidiskodon transvaalensis Dart, 1927, type, lower Vaal River gravel terrace	= *Archidiskodon transvaalensis.*
Archidiskodon sheppardi Dart, 1927, type, lower Vaal River gravel terrace	= *Archidiskodon sheppardi.*
Archidiskodon subplanifrons sp. nov., upper (?) Vaal River gravel terrace	= *Archidiskodon subplanifrons.*
Archidiskodon broomi sp. nov., lower (?) Vaal River gravel terrace . .	= *Archidiskodon broomi.*
Mastodon (*Bunolophodon*) sp. Felix, referred by Beck, 1906, Waldeck's Plant	= *Mastodon* (*Bunolophodon*) sp.

The absence up to the present time of the distinctive lozenge-shaped grinding tooth which distinguishes the existing African elephant as the genus Loxodonta, is a striking circumstance. All the above new types belong either to the broad-plated and broad-crowned Archidiskodon or to the narrow-crowned type of tooth with much more numerous ridge-plates for which I proposed (1924) the generic name Pilgrimia, typified by *Elephas falconeri* Busk from Malta, also by *E. antiquus Recki* Dietrich, from Oldoway, northern British East Africa; numerous species of small elephants with grinders of this type have been described, extending northwards throughout Africa into the islands of the Mediterranean, none of which presents the true Loxodonta molar.

Natural Reactivity and the Origin of Species.

DARWIN'S theory of the origin of species presupposes the occurrence of occasional variants from the parent stock, of which some are preserved and fostered by natural selection. The cause of this natural variation has been sought in various quarters; and indeed it is to be presumed that it is due not to one cause, but to many. It is our purpose in this note to direct attention to an agency which must play an important, and may prove to play the predominant, part in producing variations among plants and animals.

It has been demonstrated for two forms of animal and plant life the antecedents of which have been known for many generations, namely, the fruit fly (Muller, *Science*, 66, 84; 1927) and the tobacco plant (Goodspeed and Olson, *Proc. Nat. Acad. Sci.*, 14, 66; 1928), that treatment with X-rays produces new and permanent varieties which far exceed those which occur normally, both in number and in degree of departure from the parent. Thus, when a bud of the tobacco plant was X-rayed, eighty per cent. of the resulting seeds which germinated were decided variants, and the extent of variation in this one planting was greater than had been observed in a study of the normal plant lasting over a quarter of a century. Some of these variants were not fertile, but many were, and in particular one giant form seems more fertile and more vigorous than the normal plant. Equally striking results were obtained with the fruit fly.

In Nature, all living things are exposed throughout the whole of their existence to gamma rays of low intensity which are due to widely distributed radioactive substances. It therefore occurred to us at the time the experiments with the tobacco plant were begun, to inquire what part this feeble gamma radiation might play in causing naturally occurring variations. This question has also been asked by Muller, but his data did not suffice for an answer. The tobacco experiments, however, were so planned as to permit a direct comparison with natural radiation.

It is true that the relative effect of rays of different frequency upon the production of variants has not been experimentally ascertained. However, since the rays can only be effective when they are absorbed, and thus produce ionisation, it seems safe to assume that the various rays will produce biological effects in proportion to the ionisation which they cause.

In one cubic centimetre of air, natural radiation produces per second about six ionisations, while the X-rays used in the tobacco experiments produced $2 \cdot 8 \times 10^8$. This ratio of about 5×10^7 will not be materially changed when we consider the ionisation in living tissue. The exposure to X-rays lasted about ten minutes and resulted in eighty per cent. of variants. We may substitute these figures in an equation based simply upon the law of probabilities, namely, $\log(N/N_0) = kIt$. Here N_0 is the original number of germ cells exposed, N is the number remaining unaffected at the end of the time t, and I is the intensity of the radiation in terms of ionising power. We thus obtain k, the constant of the process. From this equation we calculate that the same plants exposed to natural radioactivity for one year would produce two variants per thousand.

In this calculation we have considered only the surviving plants, no account being taken of the occasional lethal effect of the rays. If the cells which have been killed are to be regarded merely as one type of variant, the calculation is unaffected. However, in the experiments with the intense X-rays a large fraction of the cells experienced several ionisations. This would be likely to increase relatively the number of cells destroyed, a view for which there seems to be some experimental evidence (for example, the work of Wood, quoted by Crowther, NATURE, 118, 86; 1926). Any allowance made for this effect would increase the calculated number of variants produced by natural radiation.

---

[1] A. T. Hopwood, "On some Mammalian Remains from Lake Nyasa," *Quart. Jour. Geol. Soc.*, London, vol. 83, pt. 3, pp. 442-441; 1927.

We may, therefore, conclude that the number of variants caused per year in the tobacco plant by natural radiation is greater than two per thousand. The number of variants in the normal plants actually found per year in a prolonged study of this plant is estimated as lying between two and four per thousand. It seems, therefore, not altogether extravagant to assume that such variations as actually occur in Nature are due largely to the radioactivity of the environment. It becomes an extremely interesting task to ascertain whether, in those places where an exceptional accumulation of radioactive material occurs, any unusual variability of fauna and flora is to be observed.

What becomes of Stellar Radiation?

ON the occasion of Dr. Jeans's magnificent lecture (NATURE, Mar. 24, pp. 463-470) Sir Oliver Lodge (*ibid.*, p. 462) asked: "What becomes of the radiation which the stars are continually pouring into space? . . . No one has yet been able to hazard even a plausible guess as to where it goes or is destined to go in a possible finite space." Formerly we should have been obliged to assume that it vanished into infinite space. Einstein's theory of relativity has, however, entirely changed this point of view, and to-day space must be regarded as finite. If a straight line starts from a star it does not go straight to infinity, but returns to the original source. I beg to conjecture or suggest that the radiation from a star may behave like the straight line and be brought back to its origin again, after having travelled around the universe.

According to Dr. Jeans, *light* would require for this return 100,000 million (10^{11}) years. As the stars are much older, some 10^{13} years (Jeans), a great part of their *radiation* might have been brought back to them, or to other stars in its way, which will again provide other stars with their energy, so that the energy which they have lost would be partly renewed in this way. The stars might be regarded as a kind of *perpetuum mobile*—to some degree, like a mill on the river. Thus the lives of the stars would be prolonged.

BOHUSLAV BRAUNER.

Bohemian Academy, Prague,
Mar. 27.

IT is, I think, generally recognised that light can travel round and round an Einstein universe in the way described by Prof. Braumer. Alternative universes have of course been imagined in which this cannot happen; that of de Sitter, for example, expands so rapidly that light can never get back to its starting point.

If light goes round and round, a certain fraction must inevitably re-enter the stars, but the faintness of the night sky seems to show that the fraction must be very small; if it were nearly unity we should see a star in every direction in space, and the sky would be a uniform blaze of light. The sun occupies about a hundred-thousandth part of the half-sky, so that if even one part in 100,000 of their light fell back into the stars, the night would be half as bright as the day. Or, if the radiation were transformed into heat on its journey, the heat received from the night sky would be equal to that received from the sun. The actual fraction, then, must be very minute.

Personally, I do not feel the difficulties of Sir Oliver Lodge and Prof. Braumer as to the ultimate fate of stellar radiation. Hubble estimates the average density of matter in space to be $1{\cdot}5 \times 10^{-31}$, so that the total annihilation of all the matter in the universe would produce an energy-density of $1{\cdot}35 \times 10^{-10}$ ergs per c.c., which would only raise the temperature of space from 0° abs. to 11·5° abs. The total annihilation of all matter outside the solar system would only raise the temperature of the earth's surface by 0·00018 of a degree centigrade, so that the radiation of ten thousand dead universes may be eternally wandering round space without our suspecting it. Space is so vast by comparison with the matter it contains, that discussing the ultimate fate of radiation seems rather like discussing the ultimate fate of a few lumps of sugar dropped into the Atlantic.

It is particularly hard to see how stray stellar radiation could create new matter. The creation of a single electron and proton, or of a hydrogen atom, requires a quantum of energy 0·0015 erg. Quanta of this energy do not begin to appear until a temperature of the order of 7,500,000,000,000 degrees is approached. Then, and not until then, there begins a free (reversible) transformation of energy between its two forms of matter and radiation. The statistics of such a process have been discussed by Stern (*Zeits. f. Elektrochem.*, 31, 448; 1925; and *Zeits. f. phys. Chem.*, 120, 60; 1926) and Jordan (*Zeits. f. Phys.*, 41, 711; 1927), but in view of the foregoing figures the interest would seem to be academic rather than astronomical. A simple calculation shows that if the present universe were left to itself long enough for its total energy to distribute itself in thermodynamical equilibrium between atoms and radiation, the expectation of the total number of non-permanent atoms in the final steady state would be of the order of $e^{-mc^2/RT}$, or $10^{-420,000,000,000}$. The reciprocal of this, raised to a power equal to the total number of non-permanent atoms in the present universe, may be interpreted as the odds (relative to our present knowledge) in favour of the universe being a special creation and not a mere fortuitous concourse of atoms and radiation.

Apart from all calculation, the widely desired cyclic universe in which just as much matter is created as destroyed, would seem to be a universe already dead. Its entropy must be a maximum, otherwise the system could and would increase its entropy by irreversibly disturbing the balance between creation and destruction of matter. With universes, as with humanity, the only possible life is progress to the grave.

J. H. JEANS.

The Branchial Gland of the Cephalopoda: a Possible Endocrine Organ.

UP to the present day, no definite endocrine organs have been discovered in any invertebrates, though some evidence of adrenalin production in annelids has been obtained by Gaskell,[1] [2] and of an internal secretion of the testis in turbellarians by Vandel,[3] [4] and in oligochæts by Harms.[5] The purpose of this letter is to direct attention to the probable endocrine significance of the branchial gland of the cephalopod molluscs.

[2] *J. Gen. Physiol.*, 2; 1919.

[3] *C. R. Acad. Sci.*, 170; 1920.

[4] *Bull. Biol. Fr. Belg.*, 55; 1921.

The branchial gland is found in all the dibranchiate Cephalopoda, lying beneath the gill on each side and clearly visible from the mantle cavity. It is stated by Huxley and Pelseneer[6] to be absent in Spirula, but in a specimen of that rare mollusc which I examined through the kindness of Mr. G. C. Robson at the British Museum, it appeared well developed. The 'gland' has a rich blood supply which has been studied in detail by Joubin.[7] A capillary network can be demonstrated by injection. No lumen or duct exists, the organ consisting of cells in a connective tissue meshwork and of syncitial tissue perhaps derived from the degeneration of such cells. The histology was chiefly investigated in Sepia, but is essentially similar in Octopus. Sections of material fixed in Bouin and stained by the methylene blue and eosin method advocated by Lim[8] show irregular polygonal cells with large vesicular nuclei. Most of the peripheral cytoplasm is filled with a fine basiphil suffusion or granulation. In some cells, frequently found in groups, one or more vacuoles containing highly eosinophil bodies are found; such bodies may also be found in the intercellular spaces, and it is hard to avoid the conclusion that they have been extruded from the cells.

The gland can be extirpated in *Octopus vulgaris* unilaterally, through a slit in the mantle. In one such individual which survived 62 days, very marked hypertrophy of the remaining gland was noticed. The hæmocyanin content of the blood of this specimen, determined by the refractometric method of Quagliariello,[9] was identical with that of its control.

The Cephalopoda are in many respects of the same grade of organisation as the lower vertebrates, and it is among them that we should most probably find endocrine organs if they exist in invertebrates. Such histological evidence as is presented above suggests that some substance is produced by the branchial gland and liberated into intercellular spaces where it might be taken up by the blood stream. The branchial heart appendix, another organ of unknown function in the Cephalopoda, may also be worthy of investigation along similar lines.

My investigations of the branchial gland were made at Naples, October 1925–May 1926, while holding an International Research Fellowship of the Rockefeller Foundation and occupying the Cambridge table at the Stazione Zoologica. My very best thanks are due to Prof. R. Dohrn and his staff for every help and encouragement during my stay in Italy; also to Prof. Quagliariello for demonstrating to me the use of the refractometer in the physiological laboratory of the University of Naples. If opportunity occurs of continuing the work, a detailed account will be published.

Investigation of a Mercury-Thallium Molecule.

EVIDENCE has been obtained which seems to prove the existence of mercury-thallium molecules when the vapours of the two substances are mixed. The evidence is the result of two quite different methods of attack.

In the first method, two evacuated pyrex U-tubes were prepared, one of which contained a small amount of thallium in one branch, and a small amount of mercury in the other. The second U-tube contained only a small amount of thallium in one branch, the other branch being empty. The tubes were placed together in a vertical furnace with their ends down, and were heated to 600° C. The amount of mercury was so small that it was entirely volatilised at this temperature, while only a small part of the thallium was vaporised. The ends which had not contained the thallium were then cooled simultaneously for thirty seconds by means of an air blast, and the tubes were removed from the furnace. The ends which had been cooled by the air blast were analysed for thallium. More thallium was found in the end which had contained mercury than in the end which had been empty. The experiment was repeated once, giving the same result. While it might be possible to explain this result on the grounds of lack of temperature equilibrium or of a mechanical entrainment of the thallium molecules in the mercury vapour, neither seems at all likely under the conditions of the experiment. The more probable explanation is that mercury-thallium molecules were formed, and that these molecules were more volatile than thallium.

A more convincing proof of the existence of such molecules resulted from the study of the absorption spectra of mixtures of thallium vapour and mercury vapour. The region investigated extended from about 2200 A. to about 7000 A. The vapours were studied at temperatures ranging from 300° C. to 1100° C. A number of bands have been photographed in the ultra-violet and one in the green. In no case has the resolving power been sufficient to show the fine structure. These bands have not been observed in the spectra of pure mercury or of pure thallium, hence it seems that their origin must be a mercury-thallium molecule. Most of the bands are sharp on the side of shorter wave-length and shaded toward the longer wave-lengths. With rising temperature most of the bands broaden more on the long wave-length side than on the short. The results confirm an early experiment on the ultra-violet absorption spectra of mixtures of mercury vapour and thallium vapour (Wood and Guthrie, *Astrophysical Journal*, 29, 211; 1909).

The problem was undertaken at the suggestion of Prof. R. W. Wood, and the work carried out under his direction and with his assistance.

Prof. A. Abetti and the 1874 Transit of Venus.

As a supplementary note to the obituary notice in NATURE of April 14 of my old friend, Prof. Antonio Abetti, of the Arcetri Observatory, Florence, may I direct attention to a remarkable observation of his made in India at the transit of Venus in 1874? This consisted in viewing the planet projected against the solar chromosphere on the *C*-line through the open slit of his spectroscope. The observation, which is figured in the *Mem. Soc. Spett. Ital.*, and which he described to me on one of my visits to Arcetri, was considered most remarkable at the time and, by some, was scarcely credited. Venus, however, remained visible through the slit for four minutes, while the chromosphere appeared with its usual brightness interrupted only by the dark body of the planet. A similar observation in the case of a transit of Mercury was suggested a few years ago by the late Mr. Thorp.

An Inexpensive Solar Telescope and Spectrohelioscope.

By Prof. George E. Hale, For. Mem. R.S., Mount Wilson Observatory, Pasadena, California.

In previous numbers of Nature I have described some of the new possibilities in solar research afforded by the spectrohelioscope.[1] Since their publication I have developed a cœlostat telescope and spectrohelioscope which can be built at such small cost that I trust it may come into general use. At least eight spectrohelioscopes will soon be systematically employed at solar observatories distributed around the world, thus permitting the sun's atmosphere to be observed frequently throughout the astronomical day. It is hoped that under this scrutiny few important eruptions will be missed, and that their connexion with auroræ, magnetic storms, and other terrestrial phenomena such as radio transmission can thus be more certainly determined.

In the well-known method of Lockyer and Janssen, the form as well as the spectrum of a prominence can be seen at the sun's limb. Suppose the narrow slit of a spectroscope to be tangent to an image of the sun, across the base of a prominence. The bright lines of hydrogen and helium will then be seen against the spectrum of the sky, which is due to scattered sunlight, weakened by the dispersion. Consider only the red hydrogen line Hα, which is nearly monochromatic if the prominence is free from irregular motions in the line of sight. The form of this line then corresponds to that of the straight narrow slit. When the slit is widened the brightness of the prominence remains unchanged, while that of the sky spectrum increases. If the prominence is of average brightness, and not too high, the slit can be opened sufficiently to show its entire form against the background of the sky spectrum. If, however, the sky were as bright as the sun's disc, the prominence, except in rare cases, would be rendered invisible by its overpowering brilliancy.

Prof. Charles A. Young, one of the ablest and most experienced of solar observers, stated the case as follows in his well-known book, "The Sun": "In a few instances the gaseous eruptions in the neighbourhood of a spot are so powerful and brilliant that with the spectroscope their forms can be made out on the background of the solar surface in the same way that the prominences are seen at the edge of the sun. In fact, there is probably no difference at all in the phenomena, except that only prominences of most unusual brightness can thus be detected on the solar surface." Secchi also remarked in "Le Soleil," after describing the use of the spectroscope for the observation of the *spectra* of objects on the sun's disc: "Ce qui serait à désirer maintenant pour faciliter encore davantage ces recherches, c'est la découverte d'un milieu parfaitement monochromatique pour les raies de l'hydrogène. On verrait alors l'image de ces flammes rouges comme on voit celles des taches." The spectrohelioscope has some important advantages over such a medium, even if it were attainable, because of the ease of changing the wave-length of the transmitted light, thus rendering visible rapidly moving flocculi, and at the same time indicating their velocity in the line of sight.

Prominences observed in projection against the sun's disc (flocculi) usually appear dark, because their comparatively cool gas absorbs the light of the hotter photosphere. Bright flocculi also occur, due to hotter hydrogen, usually found at lower levels. When these flocculi are intensely bright their forms can be made out roughly against the disc with a spectroscope by widening the slit, as noted by Lockyer, Secchi, and Young in 1869–70. Extremely dark flocculi may also be seen imperfectly in the same way; but these are exceptional cases. Most of the flocculi, bright or dark, disappear when the slit is widened sufficiently to include their forms. The weakening and disappearance of most of the lines of the solar spectrum, observed when the purity is decreased by widening the slit of a spectroscope, illustrates this effect. The spectrohelioscope retains the strong contrast given by a narrow slit, and thus renders visible the flocculi, both faint and intense, against the brilliant disc. It also shows the prominences at the limb with greater contrast than is obtainable with a wide slit. Moreover, as a narrow slit prevents the overlapping of images observed in white light with a wide slit, the spectrohelioscope renders visible the structure of sunspots, which can be sharply seen with light from any part of the solar spectrum away from the dark lines.

The spectrohelioscope consists of a spectroscope of considerable dispersion, provided with a slit in the focal plane of the spectrum, which permits only the light of the line in use to reach the observer's eye. If the first slit, on which the solar image is focused, is moved in the plane of dispersion, the spectrum will move a corresponding distance. To remain on the line, the second slit must be displaced accordingly. The first and second slits are therefore carried at the opposite ends of a very light metallic bar, mounted on a bearing half-way between them. This bar is oscillated rapidly by a small electric motor, through an amplitude (usually about a quarter of an inch) which is limited by the brightness of the spectrum. The observer, looking through the oscillating second slit, which remains exactly on the Hα line, sees by persistence of vision a hydrogen image of a portion of the sun. This may include a part of the limb, where a prominence appears bright against the sky, and at the same time a part of the disc, upon which a portion of the same prominence may extend as a dark flocculus.

High velocities in the line of sight produce distortions of the Hα line, towards the violet when the gas is approaching, toward the red when it is receding. To see a mass of hydrogen receding at a velocity of say sixty kilometres a second the second slit must be set, not on the normal position of the Hα line, but at a position completely outside of it toward the red. A simple 'line-shifter' is employed for this purpose. A graduated arc indicates the displacement of the line from the zero position, and thus gives the radial velocity of the portion of the flocculus under observation.

---

[1] "Some New Possibilities in Solar Research," Nature, July 3, 1926; "The Fields of Force in the Atmosphere of the Sun," Nature, May 14, 1927.

As in the case of the spectroheliograph, a monochromatic image can be produced either by motion of narrow slits with respect to the solar image, or by motion of the solar image with respect to the slits. The chief difference between the two instruments lies in the fact that the spectroheliograph builds up its image gradually, slit-width by slit-width, by a slow motion of the slits or of the solar image with respect to the photographic plate, while the spectrohelioscope must reveal a considerable area of the image at once to the eye, which obviously could not see the forms of the flocculi through slowly moving slits a few thousandths of an inch wide. Hence the rapid motion of the slits or of the solar image required for the spectrohelioscope.

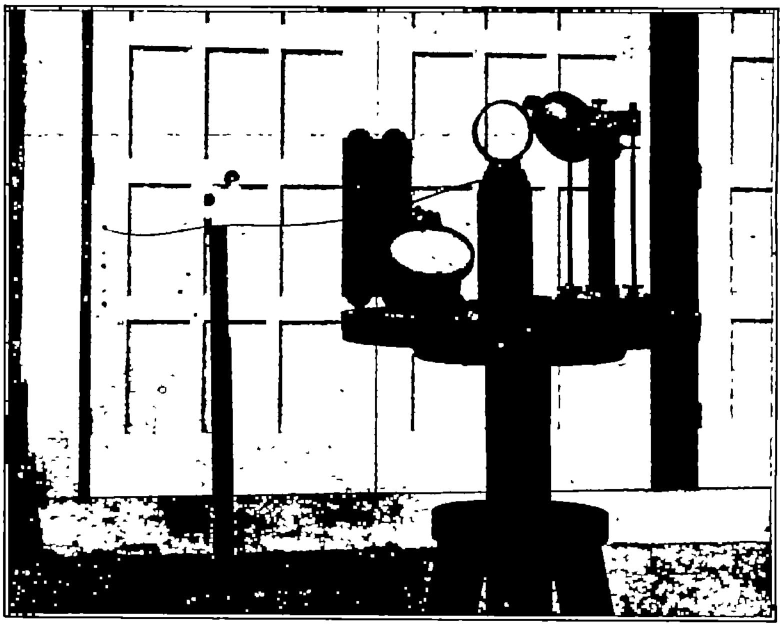

Fig. 1.—Solar telescope. The cœlostat mirror at the left, driven by clockwork, reflects the sunlight to the second mirror, which is provided with slow-motion screws for directing the solar image. This is formed by the simple lens (centre), adjustable by a screw for focusing the image on the slit of the spectrohelioscope 18 feet away, within the building.

I have tried successfully three systems of moving slits, as follows:

(1) An oscillating bar carrying single slits at each end.

(2) An oscillating bar carrying three or more slits at each end. By increasing the number of slits the rate of oscillation necessary to avoid flicker may be reduced, with corresponding reduction in any effects of vibration.

(3) A rotating disc carrying fifty radial slits.

Three means of producing rapid motion of the solar image with respect to fixed slits have also been devised:

(1) An oscillating plane mirror, so mounted in conjunction with a second plane mirror that the second slit can be viewed in another part of the same mirror system. This was suggested by Dr. Sinclair Smith.

(2) A square prism of glass, mounted before each of the slits, rotating uniformly about an axis parallel to them. The portion of the solar image under observation reaches the first slit through one prism, while the resulting fixed monochromatic image is seen in an eye-piece focused through the other prism on the second slit. This device is due to Dr. J. A. Anderson.

(3) An oscillating right-angle prism, mounted with its edge parallel to the slits and its hypothenuse surface normal to their plane. In this arrangement, previously used in somewhat different form on the spectroheliographs of our 60-foot and 100-foot tower telescopes, the solar image moves at twice the speed of the prism.

All three of these devices are here supposed to be used with a spectroscope in which the apparent motion of the solar image, as observed through the second slit, is opposite in direction to the actual motion of the solar image across the first slit. In this case, when looking at the second slit through an extension of the oscillating or rotating optical system which causes the motion of the solar image, the effect of this motion is exactly compensated and the monochromatic image appears at rest. The same devices can be adapted for use with spectroscopes of other types.

The Solar Telescope.

The small solar telescope, temporarily mounted in conjunction with a horizontal spectrohelioscope, is shown in Fig. 1. A wooden tripod serves for support, but in a permanent arrangement the cœlostat, second mirror, and lens should be mounted on a solid pier of brick or concrete.

The cœlostat, with plane mirror 5¼ inches in diameter, is driven by an ordinary two-dollar clock movement. With the low powers employed the intermittent motion is not perceptible. The second mirror, 4¼ inches in diameter, receives the parallel beam of sunlight from the cœlostat and reflects it due north to a 4-inch single lens, of 18 feet focal length. This forms a solar image 2 inches in diameter on the first slit of the spectrohelioscope. A crossed lens is here employed, but a plano-convex lens (or, with a modified arrangement, a concave mirror) would serve well. On account of the small angular aperture and the use of monochromatic light, an achromatic lens is unnecessary. By means of cords or rods leading to the position of the observer (not shown here in the case of the second mirror), any portion of the solar image can be brought upon the slit by tipping the second mirror, and focused by sliding the lens.

The 4-inch lens is sufficient for a 13-foot spectrohelioscope with a 4-inch grating (ruled surface about 2¼ inches × 3 inches). When a smaller grating or prisms are employed, a lens of 3 inches aperture and the same focal length (18 feet) will serve equally well.

THE SPECTROHELIOSCOPE

Last August I completed and tested a simple spectrohelioscope of 3 inches aperture and 13 feet focal length, designed for use with this solar telescope. A 4-inch grating was an essential part of its optical equipment, but unfortunately such gratings are not easily obtained, and all our efforts to secure satisfactory reflecting grating replicas have proved futile. Moreover, the length and mass of the oscillating slit-bar (7 inches between centres in the chosen design) rendered it difficult to push the vibration rate to a point sufficiently high to eliminate flicker without jarring the instrument. Excellent images of the flocculi were obtained with this spectrohelioscope, but the above considerations, and my desire to decrease the cost of construction, made further study of the problem advisable. A few weeks later Dr. Anderson and Dr. Sinclair Smith suggested the ingenious devices already mentioned, and I determined to make a comparative test of a variety of designs, in the hope of reaching a simple and inexpensive solution.

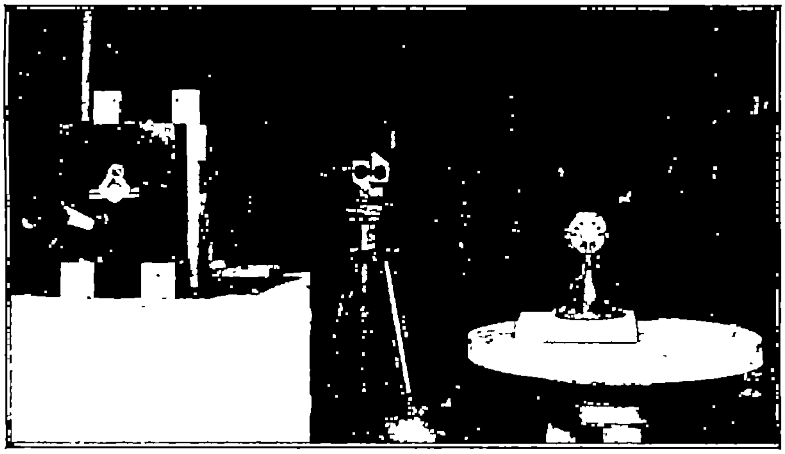

FIG. 2.—Spectrohelioscope of 13-feet focal length. Sunlight passing through the first slit (right) falls on the collimating mirror, which returns a parallel beam to the grating, mounted above the slits behind the casting. An image of the $H\alpha$ line of hydrogen in the first order spectrum is formed by the left concave mirror on the second slit. When the slits are rapidly oscillated by the motor, a portion of the solar atmosphere is seen in hydrogen light through the eyepiece on the left (here turned aside to show the second slit).

Several of these designs have proved satisfactory, including one in which the monochromatic image is produced with the aid of a revolving glass disc, cut in the milling machine, on a surface of silver or of "Duco" paint, with fifty radial slits; as well as one employing the revolving prism device of Anderson, which can be adapted to any suitable spectroscope of sufficient dispersion provided with fixed first and second slits. These instruments will be described in detail elsewhere; my object here is merely to mention briefly the simplest and least expensive spectrohelioscope that I have found to give excellent results.

The oscillating slits are shown in Fig. 2, a general view of the spectrohelioscope temporarily set up in a garage. As their centres are only 3¼ inches apart they are mounted horizontally, so as to permit direct observation through the second slit by the right eye without obstruction of the solar image on the first slit by the observer's head. The bar that carries them, like the slits themselves, is extremely light and stiff. An upward extension of this bar is pierced by a fibre-lined vertical groove, in which a steel pin, fixed eccentrically in the head of a horizontal shaft, serves as the driving device. A small electric motor, belted to a pulley on this shaft, causes the slits to make thirty or forty single oscillations per second. The amplitude is about a quarter of an inch or less, and the motion is smooth and quiet.

Light from any part of the 2-inch solar image given by the cœlostat telescope passes through the first (right hand) slit and diverges until it meets a 2-inch concave spherical collimating mirror of 13 feet focal length, which returns a parallel beam to the dispersing system (not visible), consisting either of a plane grating, ruled with about 15,000 lines to the inch, or a pair of 60° prisms of flint glass, through which the light passes twice. The plane of dispersion is vertical, and the grating (or the mirror behind the prisms) is set at such an angle that the $H\alpha$ region (of the brightest first order spectrum, if the grating is used) is returned to the centre of a second concave mirror. This is exactly like the collimating mirror, and is mounted with it on an adjustable support with screw for focusing. The centres of the mirrors are opposite the centres of the slits, and the second mirror is adjusted so as to cause the $H\alpha$ line to coincide with the second slit. This is viewed through a positive eyepiece magnifying from two to four diameters. The line-shifter, a strip of plane parallel glass, is mounted behind the second slit on a short shaft, provided with a large milled head for easy rotation by the observer and a divided arc showing the displacement in angstroms or the equivalent radial velocity. An important adjunct is a screen to prevent the diffuse light of the collimating mirror from reaching the eye of the observer.

I have found by experiment that with slits 0·004 inch wide, oscillating with an amplitude of $\frac{3}{16}$ inch, the bright and dark hydrogen flocculi can be well seen on the sun's disc when the grating aperture is reduced to $1\frac{3}{16} \times 2$ inches.[2] A larger grating naturally gives a brighter image, in which more detail can be seen, but the above will serve for most classes of work.

Suitable gratings, even of the smaller size just mentioned as a minimum, may not be obtainable. I have therefore tried a less expensive arrangement, which may be adopted by amateurs who wish to build their own instrument and are content (until a good grating or replica can be obtained) to see only the more conspicuous phenomena. This is a pair of 60° prisms,[3] which should be of very dense flint, and may be only just large enough to transmit a beam 1 inch in diameter, though a somewhat larger aperture is preferable. The dispersion of two ordinary flint prisms (here equivalent to four) is less than that of the first order of a (15,000) grating, and their performance is much inferior to that of a good grating; but with suitable slit-widths they will show the stronger bright and dark flocculi, as well as the prominences at the limb. If, as I greatly hope, a satisfactory method of producing cheap reflecting grating replicas of excellent definition can be found, these may ultimately become available in place of original gratings or prisms.[4]

The ingenious rotating prism device of Dr. Anderson, which is used with fixed slits, is shown in Fig. 3. This is more expensive than the oscillating slits, and seems to show no details of the flocculi not visible with them. However, the elegance of this method, and the complete freedom from vibration and flicker which it affords, make it an attractive alternative for oscillating slits. It can be readily attached to any Littrow spectroscope of suitable dispersion, but I have found this type of spectroscope much less satisfactory for the purposes of the spectrohelioscope than the two-mirror form illustrated, because of the impossibility of excluding from the eye the light due to the illumination of the collimating lens and grating by sunlight from the first slit. The reflected light can be excluded, by using a suitable lens for the collimator, but the remaining diffuse light, superposed upon the $H\alpha$ line, materially reduces the contrast of the flocculi, even when a red glass is placed over the eyepiece.

The spectrohelioscope shown in the illustrations was built from various parts that happened to be available, and does not represent the final design. Thus the casting that carries the slits, line-shifter, and eyepiece will be considerably reduced in size in the finished instrument. The working drawings now in preparation will also show a more compact support for the two concave mirrors, and various other improvements. These will soon be published in a series of articles, intended for those who wish to build and use their own instruments.

USE OF THE SPECTROHELIOSCOPE.

I have indicated in previous papers some of the many possible applications of the spectrohelioscope. Mr. Buss (NATURE, May 28, 1927) and M. Deslandres (NATURE, Oct. 8, 1927) apparently think that a solar spectroscope would serve equally well for such work, but as all the astronomers and physicists who have observed the sun with my instrument seem to agree with me as to its usefulness, I am quite willing to leave this question to the future. If one wishes to see the characteristic structure of most of the dark hydrogen flocculi, the slit-widths must be kept below one-hundredth of an inch, even when very high dispersion is employed. As already remarked, the prominences at the limb are also shown in greater contrast by the spectrohelioscope than by the spectroscope with wide slit. As for the line distortions caused by the radial velocities of the hydrogen flocculi, which have been known since

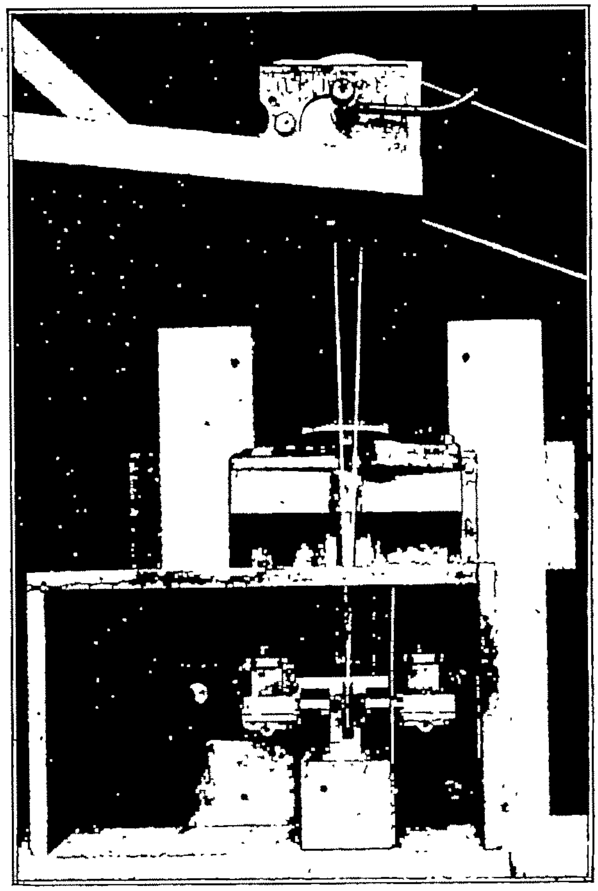

FIG 3.—Anderson's rotating prism device for use with fixed slits. A square prism of glass, rotating uniformly, causes a succession of images of a part of the sun to move across the first slit at the rate of four per revolution. When the second slit (set on $H\alpha$) is viewed through a similar prism, rotating at the same rate, a stationary image is seen in hydrogen light.

---

[2] This is nearly the size of Hilger's plane grating K14, ruled with about 14,400 lines per inch at the National Physical Laboratory on a surface 3·5 cm. × 5 cm.

[3] Loaned me by the Massachusetts Institute of Technology, through the kindness of Dean Goodwin.

[4] The most promising means of reproducing reflecting gratings appear to be either an electrolytic process or the method described by Merfield (*Proc. Roy. Soc. Victoria*, vol. 38, 1926). The latter can perhaps be used for copying speculum metal as well as glass gratings by adopting means of preventing firm adhesion of the cathode deposit.

the earliest days of solar spectroscopy, the advantages of the spectrohelioscope in quickly interpreting them must be seen to be appreciated. The line-shifter serves in somewhat the same way as the 'blink' device of a Zeiss stereocomparator, but instead of merely indicating, in a very striking way, any differences between two photographs, it shows at a glance the connexion of a series of related phenomena by linking them into a sequence. This is what I referred to in my last article when describing "a new effect of inflow," by which I meant the motion of the maximum of intensity along a flocculus due to progressive differences in radial velocity, at once interpreted by the line-shifter.

In M. Deslandres's remarkable theory of the sun, "tout se passe comme si le rayonnement corpusculaire de nos orages émane d'une couche solaire profonde qui tourne comme un corps solide ; et cette couche offre au moins 24 volcans permanents, répartis uniformément autour de l'axe de rotation, et d'activité variable, qui rejettent au dehors la matière ionisée ou radioactive des masses intérieures. Cette division régulière est celle des corps à symétrie circulaire qui se refroidissent." This theory involves so many considerations that it cannot be discussed in the space at my disposal. In any event, such a discussion would be premature, as the theory rests upon M. Deslandres's belief in a regular sequence of terrestrial magnetic disturbances which Messrs. Chree and Stagg, after an exhaustive study of the international magnetic data for twenty years, have been unable to confirm.[5]

The New Vision.[1]

By Prof. G. Elliot Smith, F.R.S.

THE recent researches of Minkowski, Brouwer, and Woollard have brought to light the remarkable fact that in man and his nearest allies such revolutionary changes have been effected in every part of the visual system as to justify the statement that a new visual instrument has been evolved. Considering these facts from the point of view of function, we may speak of the emergence of a new vision, which differs profoundly from that enjoyed by all other living creatures. It may be of interest to discuss the nature and meaning of these changes, which are intimately related to the evolution of intelligence and the attainment of what in colloquial language we know as insight, foresight, and the wider vision.

A quarter of a century ago the term neopallium was introduced to express a new conception of the nature of the essential evolutionary changes that transformed the brain of a primitive reptile into that of a mammal, and conferred upon the latter enormously enhanced powers of learning from experience and modifying behaviour. Incidentally, the development of the new cortical area provided a means whereby vision for the first time secured representation in the cerebral cortex, which created fuller opportunities for the confluence of visual with other kinds of perception. On the anatomical side it inaugurated a series of interesting structural arrangements which marked the transference to the neopallium of functions which in all other vertebrate animals are carried on in the mid-brain and other lower centres. The new light recently thrown on this interesting process of transformation reveals the fact that the transference of functions did not occur at one time, but in progressive stages. Magnus showed experimentally that the optic-righting reflexes in mammals were not acquired until binocular vision developed. Still later the development of the macula lutea in the retina (in monkeys and man) brought about the further changes in the brain which I am attempting to define.

In all vertebrates the nerve fibres proceeding from the retina cross (wholly or only in part in most mammals) to the other side of the brain, where they end in two masses of grey matter, the lateral geniculate body, which is part of the thalamus, and the superior quadrigeminal body, which is part of the mid-brain. The former connexion is concerned with the awareness to vision, the phenomena of consciousness, and the latter (mid-brain), with such unconscious functions as the reflex actions of the eye muscles and the general musculature of the whole body. Brouwer has shown that in a lowly mammal such as a rabbit the four quadrants of the retina have a topographical representation in the quadrigeminal body. Wilson (of Cairo) has recently demonstrated that the corresponding quadrants in a lizard's brain control definite movements or postures of the body—a kind of autonomous mechanism for the analysis and functional expression of optic influences analogous to the analytic functions of the semicircular canals in connexion with equilibration.

In mammals the lateral geniculate body, for the first time in the vertebrate series, emits a large strand of fibres (optic radiation) to provide a path for visual impulses to the cerebral cortex. But the neopallium also begins to assume some of the motor control, which hitherto has been a function of the quadrigeminal bodies. It is interesting to note that, according to Allen, this process is not completed in the rabbit. Its cerebral cortex, according to him, controls the movements of the head, fore-limbs, and body, but the control of the hind-limbs is still retained by the mid-brain. In most mammals, however, the transference of motor control to the cerebral cortex is complete.

With the acquisition of binocular vision (in mammals such as the cat or, better, monkeys) the fibres of the optic tracts become rearranged. The fibres from the lateral part of each retina no longer cross to the other side of the brain, but become connected with the same side, so as to bring into connexion the terminations of the fibres coming from the medial side of one retina and the lateral side of the other, which in binocular vision necessarily act together so as to merge in consciousness the two images of one object.

---

[1] From the Bowman Lecture delivered on April 20 to the Ophthalmological Society of the United Kingdom.

But this rearrangement of the optic tracts necessarily affects the endings of these tracts in the geniculate and quadrigeminal bodies. Instead of a modification of the retinal localisation in the quadrigeminal body to adapt it to the new conditions, the cerebral cortex seems more fully to usurp its motor-controlling functions. With the loss of such functions the quadrigeminal body also loses most of the direct connexions with the optic tracts, and the cerebral cortex acquires a correspondingly enhanced control of the quadrigeminal body.

In monkeys and man further profound changes occur in the whole of the visual system. A definite macula lutea develops in the retina, and each of the percipient cells in the area of acute vision transmits its impulse (indirectly) to a separate fibre of the optic nerve. In the rest of the retina and in the retinas of other mammals groups of sensory cells (rods) transmit their impulses into one granule and ganglion cell, so that there are far more percipient elements than nerve fibres in the optic nerve. Hence, when the macula develops in monkeys and man, this small area adds a contribution to the optic nerve and tract that is out of all proportion to its size. The macular fibres form more than a third of the optic nerve, and there is added to the geniculate body a new formation as a macular receptive mechanism.

With the atrophy of the quadrigeminal fibres of the optic tract and the sudden increase of the geniculate connexion in monkeys and man, practically the whole (more than ninety per cent.) of the optic fibres go to the lateral geniculate body. But with the enormous increase of the latter the body loses much of its autonomy. Its ventral nucleus, which in other vertebrates controlled the quadrigeminal body, atrophies in the Primates. In its place the cerebral connexion is still further strengthened. The geniculate body becomes more and more an intermediary between the retina and the neopallium, and almost the whole function of visual perception becomes concentrated in the cerebral cortex.

The development of macular vision confers upon man the ability to see the world and appreciate its meaning in a way that no other living creature is able to do. His new vision depends upon powers of visual perception as distinctive as the use of articulate speech to give expression to what he sees and thinks. The late Dr. Henry Watt, of the University of Glasgow, expressed the opinion that

> "Of the conditions which enrich the sensory basis of the human mind and so provide the greater wealth of material by which it attains levels beyond those of the animal mind, probably the most important are the functions of the fovea (macula lutea), of accommodation, and of static stereoscopy, and the development of a delicate skin and prehensile hands. All these make in some way for a differentiation that is the first form of abstraction. The fovea refines and distinguishes positions and forms, while accommodation sharpens the objects of attention and dissipates the rest; stereoscopy adds a new character to a group of forms that may persist for indefinite periods of observation; delicate skin gives greater sensitivity to variations of pressure, and the prehensile hand implies a very great refinement in the positions and forms of the derived articular sense. In the hand this becomes a fine mobile tridimensional sense that, like the stereoscopic eye, can go round and through things, so almost isolating them from their surroundings. At the same time the articular sense is the conscious correlate of action and of the individual's share in his experiences."

All these conditions that confer upon man the fuller vision to see and understand the world and interpret what is happening around him, can be shown to be the results directly or indirectly of those profound structural revolutions which have given man what is virtually a new instrument of sight and with it a new vision.

News and Views.

Mr. G. H. Wilkins, accompanied by Mr. C. B. Eielson, left Point Barrow, Alaska, on April 15, and flew across the Arctic Ocean to Spitsbergen, a distance of 2200 miles, in a little over twenty hours. The machine used was a Lockheed monoplane with a 220 h.p. Wright Whirlwind engine. The start was difficult and a long snow runway on the frozen surface of a lagoon had to be made. For the first five hundred miles the weather was clear; then a hundred miles of cloud were passed through before the visibility again became good. In lat. 84° N. long. 75° W., dark clouds were seen to the north, described as possibly land clouds, but as this was near one of Peary's tracks, on which he reported no land, Mr. Wilkins did not turn aside. Landing-places on the pack-ice which might have served in an emergency were seen, but no attempt was made to descend, since the ascent would have been a very difficult matter. A view of Grant Land (Ellesmere Island) was obtained, and then the course was set for Spitsbergen. This course, it will be noted, did not pass over the North Pole itself. Strong winds were experienced and there was much cloud to the south over Greenland, but one high peak of the land was seen. The temperature was then about −48° F.

Within 200 miles of Spitsbergen, flying conditions became more trying. The open water and high temperature to the south were associated with great cloud masses, and even at 8000 ft. they could not be avoided. The difficulty was to locate King's Bay, Spitsbergen, where it was hoped to land. The weather became worse and flying was difficult. Petrol was running short when a landing was made on fast ice near the shore at the northern entrance to Ice Fjord. The reports mention an island, but there is no island off the plains of Dödmandsoren. The arrival was followed by four days of bad weather, during which the airmen lived in the cabin of their machine. At length, on April 21, the fifth day after landing, the conditions improved sufficiently for the flight to be resumed. There were only 20 gallons of petrol left and the start proved difficult. At a height of 3000 ft. the mast of the wireless station at Green Harbour was seen and the station was reached shortly afterwards. Mr. Wilkins will leave for Europe as soon as a vessel is available. The shipping season in Spitsbergen opens shortly. The flight scores a new track over the unexplored Beaufort Sea to the east of Amundsen's track of 1926. No new land was seen, but it must be remembered that low islands, the only possible land in that sea, would be snow-covered and not easily distinguishable at this season, even if the weather were clear. Meteorological observations were taken throughout the flight. The pilot is to be congratulated on the accuracy of his navigation, especially in view of the bad weather between Greenland and Spitsbergen.

The following official records of earthquakes have been received from Kew Observatory: A violent earthquake was recorded at 19 hr. 27 min. 22 sec. G.M.T. on April 18. The epicentre is estimated to be 1360 miles away at a bearing of 115° from true north from Kew, which locates the disturbance in the Balkan States. The size of the disturbance recorded is quite as big as that of the destructive earthquake which occurred in the same region on Saturday, April 14. A further disturbance of very much milder character, and estimated to be at the same place, was recorded later at 23 hr. 19 min. 21 sec. G.M.T. Another earthquake was recorded on April 22 at 20 hr. 18 min. 41 sec. G.M.T. The epicentre is estimated to have been 1470 miles away and probably in Bulgaria. The intensity of the disturbance was about one quarter of that produced by the two destructive earthquakes which recently occurred in that region.

The earthquakes felt in southern Bulgaria during the latter half of April have been remarkable for their number as well as their intensity. The first occurred on April 14. Its epicentre was evidently close to Chirpan, which was almost entirely destroyed. The area of damage was of wide extent, for it includes Plovdiv (Philippopolis), nearly 30 miles to the west. Another violent earthquake occurred on the evening of April 18, the centre having shifted to the neighbourhood of Plovdiv, where more than five thousand houses were damaged and many persons lost their lives. Even at Sofia, more than 80 miles from Plovdiv, houses were injured. So far, the most interesting features of the earthquakes are the westerly migration of the focus along a line parallel to the Balkan ranges, and the great size of the areas over which damage occurred in the principal earthquakes, the latter feature pointing to a great depth of focus. The Athens correspondent of the *Times* reports that the earthquake of April 22 wrecked Corinth, and that Kalamaki and Loutraki, near Corinth, have also been much damaged. It is estimated that 15,000 people are homeless.

Although the Society of Chemical Industry is this year holding its annual general meeting in New York, and is combining that function with interesting visits in Canada and the United States, distance is not yet so completely annihilated as to render it possible for all to take part who have a mind to do so. Numbers of members will therefore welcome arrangements enabling them to meet in Great Britain and discuss matters of common concern. The Society, in co-operation with its London section, the Chemical Engineering Group, and the Institution of Chemical Engineers, has organised a conference to be held in London on May 11-15. On the first day the Chemical Engineering Group will hold a business meeting, followed by the annual dinner; Mr. F. H. Carr, president of the Society, will afterwards deliver an address entitled "Some Chemical Engineering Aspects of the Fine Chemical Industry." Rothamsted Experimental Station, Harpenden, is to be visited on the second day. On Monday morning Sir Arthur Duckham, the first president of the Institution of Chemical Engineers, will discuss "The Fuel Industries and the Work of the Chemical Engineer," and Prof. G. T. Morgan will deal with "The Chemical Study of Low-Temperature Tar," the chairman being Sir Hugo Hirst; in the afternoon Lord Desborough will preside, and Sir Alexander Houston will speak on "Water Purification," and Mr. J. H. Coste will give an account of "The Pollution of Tidal and Non-Tidal Streams." On the same evening there will be a dinner, preceded by a reception by Mr. and Mrs. F. H. Carr, and followed by dancing. The British Science Guild has been invited to participate in the final sessions of the Conference on May 15, when Sir Alfred Mond, the president of the Guild, will deliver an address entitled "Scientific Research as applied to Industry," and Sir John Russell will describe "The Part Played by British Workers in the Application of Fixed Nitrogen to the Soil." The afternoon session, over which Lord Bledisloe will preside, will be devoted to a consideration of "Developments in the Heavy Chemical Industry," by Lieut.-Colonel G. P. Pollitt.

Prof. J. H. Breasted has issued an account of the work accomplished by the Oriental Institute of the University of Chicago, of which he is director, during the eight years of its existence. A summary of the report appears in the issue of the *Times*, April 12. It records an activity in the archæological field, especially in the later years, which reflects great credit on the organisation of the Institute. During the past two years an expedition to Asia Minor has discovered fifty-five new and unmapped Hittite sites. By its excavations at Alishar Huyuk it has established clearly a pottery sequence and the criteria for dating levels on Hittite sites. Further evidence of Hittite influence in Palestine has been found at Megiddo. Human occupation there has been traced back to the Stone Age, and a monument has been found recording the victory of Sheshonk (Shishak) over the son of Solomon and the capture of Jerusalem. It is expected that the excavations of the present season will reach the Egyptian Imperial levels. Reference is made to the researches of Dr. Sandford and Mr. Arkell on the pliocene and pleistocene history of the Nile, and the finding for the first time of stratigraphically dated palæolithic implements on the borders of the Red Sea. Reference is also made to the alabaster vessel workshop discovered in the Fayum, originally over-hastily attributed to the palæolithic, which more careful examination has shown to be dynastic. The Institute is devoting itself to two valuable and extremely important pieces of work in recording the wall paintings and carvings of the Egyptian temples, beginning with Medinet Habu, and in the compilation at headquarters in America of a dictionary of cuneiform.

DURING the past winter, Miss G. Caton-Thompson has continued her work on the archæology of the Northern Fayum Desert under the auspices of the Royal Anthropological Institute, to which body a concession to excavate was granted by the Antiquities Department of the Egyptian Government. Miss Caton-Thompson was accompanied by Miss E. Gardner, who continued her researches in the geology of the area with special reference to the question of lake levels at different periods. The main object of the expedition was to search for cemeteries which might afford material for dating the 'Fayum industry.' Reports of the season's work received to date, of which a partial summary appears in a letter from Miss Caton-Thompson in the *Times* of April 17, indicate that, while the main objective has not yet been attained, results of no small importance have been achieved. Of these the most interesting is, perhaps, the discovery of an unsuspected irrigation system in the Fayum of Ptolemaic date, which has aroused considerable interest in Egypt, and has secured the practical co-operation of the Irrigation Department in the provision of workmen and monetary contributions through H. E. Osman Pasha Moharram, late Minister of Public Works, and Ahmed Bey Raghéb, of the Irrigation Department. The examination of neolithic mounds and granaries has carried the investigation of the Fayum flint industry a step further, and it is now divided on stratigraphical and typological grounds into two well-defined stages. A big gypsum quarry and alabaster vase factory of the early Old Kingdom have been discovered and explored, the site including a village of hut circles belonging to the workers. Investigation of the lake levels has fixed the Fourth Dynasty shore-line at about O.D. zero, or 145 feet above the present lake. The remaining weeks of the season are to be devoted to work on new ground. In order that these plans may be carried out, a further amount of £250 is required towards the cost of the expedition. The Royal Anthropological Institute has issued an appeal for subscriptions, which may be sent to the Honorary Treasurer, 52 Upper Bedford Place, W.C.1.

THE number of passengers arriving and departing from the Croydon Aerodrome, which is London's terminal port for the Anglo-Continental transport service, was last year more than 20,000, and the value of the goods exported and imported amounted to ten million pounds. As a modern air liner accommodates eighteen passengers besides a crew of three, it is necessary that all precautions be taken for their safety. A new radio telegraph and telephone equipment has just been installed at Croydon by the Marconi Co., Ltd. The control tower is 80 feet above the ground and gives a clear view of the aerodrome on all sides. The radio officer is in control of the receiver and direction finder. He also operates three of the four transmitters at the sending station at Mitcham, which is 2¼ miles from the aerodrome. One of the transmitters is for telegraphy, another for telephony, and the third is a spare one in case of need. Some distance from the control tower is the receiving station, which has a 200-foot long horizontal aerial. The receiving and transmitting officers work quite independently of each other. A radio goniometer is used to determine the bearings of aircraft. When the pilot of an aeroplane sends a request to Croydon for his position, Pulham and Lympne, at which stations constant watch is kept, simultaneously take his bearings and transmit them by radio to Croydon. At Croydon these bearings, together with the local bearings, are plotted on a large map, the point of intersection of the three bearings giving the position of the aeroplane. This reading is at once communicated to its pilot, the whole process taking less than one minute. The transmitters at Mitcham are brought into action from the control tower. An ingenious device makes it impossible to damage the transmitting valves by switching them on in the wrong order. The valves are kept constantly alight, as it is found that continual switching on and off shortens their lives more than when they are left to burn continuously.

THE first elaborate attempt to light a theatre by electricity was carried out at the Opera House, Vienna, in 1886 by Col. Crompton and other Englishmen. A few months afterwards the electric light was installed in the Theatre Royal, Drury Lane, and the Savoy Theatre. During the last few years theatre lighting has been revolutionised. We learn from a paper on the subject by H. D. Wilkinson, read to the Royal Society of Arts on April 6, that high candle-power gas-filled lamps (1000 c.p. and above) are now almost invariably used instead of arc lamps. The factor of safety has been very greatly increased. The long-standing problem of controlling the auditorium lighting from the stage has been solved. The fuses are grouped in readily accessible and fire-proof positions. In the early days they used to be scattered over the house in order to economise on the expense of wiring. The L.C.C. Regulations prescribe that the lighting of the auditorium and all parts of the house open to the public shall be from two independent sources of power supply. Half the total number of lights is supplied from each source, and so far as possible alternate lamps are supplied from a different supply. The stage lighting, both the overhead lights (battens) and the footlights (the float), must be from a third and independent source. Pleasing lighting effects are sometimes produced by ultra-violet rays falling on objects covered with fluorescent paint. It seems probable that a still higher degree of illumination on the stage will be used in the future. An ingenious mechanism for the production of moving clouds from photographs has recently been developed. It is called the cyclorama, and has been much used abroad. Apparatus of British manufacture for producing sky and horizon effects quite equal to the cyclorama is, however, now available.

In the April number of the *Electrical Age for Women*, Mrs. Lawson writes an interesting article on electricity at the London Zoo. In the new buildings great difficulty was experienced in regulating the heat so as to suit the individual requirements of each inmate. The average temperature maintained is 80° F. The temperature of each cage and department is separately controlled, electrically. Should the temperature rise or fall 5°, this is at once detected by a coloured lamp lighting on a board, the number beside the lamp indicating the cage. A red light indicates that the temperature is too high, and a green light that it is too low. The tropical humid heat is confined to the cages, the corridors being independently ventilated. In the new reptile house 20 miles of electric cable were required. The monkey house is roofed with vita-glass which is transparent to the ultra-violet rays from the sun. The monkeys sit on swinging perches underneath ultra-violet ray lamps. The swamp and the rocks and sand for the crocodiles are all electrically heated. About two hundred connexions are necessary to heat and control the temperature of this cage. In some cases bowl electric fires are fixed in the roof to warm the air. The new aquarium is electrically heated and the water is pumped, filtered, and aerated electrically. Hygienically, the new arrangement is greatly superior to the method of heating by steam pipes formerly used.

An interesting gathering of the members of the Research Association of British Paint, Varnish, and Colour Manufacturers took place at the laboratories of the Association at Waldegrave Road, Teddington, Middlesex, on Wednesday, April 18. It will be remembered that these laboratories were officially opened on Sept. 21 of last year by Dr. Weidlein, the head of the Mellon Research Institute of Philadelphia. At the meeting on April 18 a lecture was given by Mr. R. A. Coolahan upon "Cellulose Lacquers," which was illustrated by a short cinema film. After the lecture a tour of the laboratories was made, when it was soon apparent that considerable development has taken place since last September; a useful extension has been made by adding rooms for colorimetry, constant temperature and humidity, and for the testing of paint and varnish films by accelerated methods. In addition, a small open laboratory has been built to accommodate varnish and oil-treating plants. This should prove of great value in the examination of these and like products. Demonstrations were given of the investigations in hand. It is clear that this laboratory is rapidly becoming of first-class importance to the industry and will in time be the chief centre of all new developments.

The Italian Arctic expedition in the airship *Italia*, under General U. Nobile, left Rome for the north on April 15. The *Times* reports that the route to be followed was by Fiume, Zagreb, Vienna, Stolp, and Vadso to King's Bay, Spitsbergen. The *Italia* reached Seddin near Stolp on the following day, after sustaining some injuries in bad weather. A vessel of the Italian Navy will await the airship in King's Bay. General Nobile has with him several Italian scientific men, and the Swedish meteorologist, Prof. Malmgren. From the base in Spitsbergen several flights will be made during the two months of summer. These will include observations at Nicholas Land, Crocker Land, if that land exists, and at the Pole itself. The inability of the airship to descend at these little-known parts of polar regions will, however, militate against the scope and value of the scientific observations.

Col. the Hon. Fl. Vernon Willey, of Messrs. Francis Willey and Co., Ltd., Bradford, has been elected chairman of the British Research Association for the Woollen and Worsted Industries. Col. Willey is a past president of the Federation of British Industries and president of the Wool Textile Delegation. He succeeds Sir James P. Hinchliffe, who has presided over the Association since its establishment in September 1918 and has been responsible for the administration of an expenditure of more than £100,000 on research work for the wool textile industry during the past nine years.

At the meeting of the London Mathematical Society on May 10, at 5.0 p.m., at the rooms of the Royal Astronomical Society, Burlington House, Prof. W. E. H. Berwick will give a lecture on "Some Recent Advances in the Theory of Equations." Members of other scientific societies are invited to attend the meeting.

The eighteenth annual May Lecture to the Institute of Metals will be delivered by Prof. Cecil H. Desch, on "The Chemical Properties of Crystals," at the Institution of Mechanical Engineers, Westminster, S.W.1., on Tuesday, May 8. Cards of invitation to the lecture can be obtained on application to Mr. G. Shaw Scott, 14 Members Mansions, Victoria Street, London, S.W.1.

At the annual general meeting of the Physical Society, held on Mar. 23, the following officers for 1928–29 were elected: *President*, Dr. W. H. Eccles; *Hon. Secretaries*, Prof. A. O. Rankine and Mr. J. Guild; *Hon. Foreign Secretary*, Prof. O. W. Richardson; *Hon. Treasurer*, Mr. R. S. Whipple; *Hon. Librarian*, Mr. J. H. Brinkworth. Prof. Albert Einstein was unanimously elected an honorary fellow of the Society.

Applications are invited for the following appointments, on or before the dates mentioned:—A head of the Nautical College department of the Liverpool Central Technical School—The Director of Education, 14 Sir Thomas Street, Liverpool (April 30). A temporary research assistant to the advisory mycologist of the University of Reading—The Dean of the

Faculty of Agriculture and Horticulture, The University, Reading (May 1). A lecturer and demonstrator in organic chemistry in the University of Sydney—The Agent-General for New South Wales, Australia House, Strand, W.C.2 (May 7). An assistant keeper of the City Museum and Art Gallery (Natural History Department), Birmingham—The Keeper, City Museum and Art Gallery, Birmingham (May 11). Lecturers in philosophy (psychology), physics, and mathematics in University College, Rangoon—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (May 12). An assistant entomologist and an assistant mycologist at the Imperial Forestry Institute, Oxford—The Secretary, Imperial Forestry Institute, Oxford (May 12). An experimental officer in the acoustical section of the Air Defence Experimental Establishment, Biggin Hill, Kent—The Secretary, Royal Engineer Board, 14 Grosvenor Gardens, S.W.1 (May 18). A lecturer in botany at the University College of Wales—The Secretary, University College of Wales, Aberystwyth (May 31). An assistant lecturer in mathematics at the University College of North Wales—The Secretary, University College of North Wales, Bangor (June 2). A Research Officer at the Punjab Veterinary College, Lahore—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (July 31). A head of a new department of the British Cotton Industry Research Association to deal with fundamental scientific problems arising out of the use of artificial silk in conjunction with cotton—Dr. R. H. Pickard, Director of Research, Shirley Institute, Didsbury, Manchester. A physicist for work in connexion with explosives — The Manager, Research Department, Nobel's Explosives Co., Ltd., Ardeer, Stevenston, Ayrshire. A head of the explosives research branch, two assistants, and some junior assistants, in the Research Department, Woolwich (Directorate of Explosives Research)—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

Nova Pictoris.—Further telegrams from Johannesburg and the Cape announce that this star has further subdivided and is now in four nebulous portions; these are too small to be photographed separately, and the observations of them are wholly visual. On the other hand, the large rings round them are only observable by photography. They are three in number, the outer one having a diameter of 3′. It was at first thought that these were due to the outward travelling of the light waves rendering visible nebulosity that was already there, as in the case of Nova Persei in the autumn of 1901.

It is now suggested (according to the *Times* of April 21) that the star is much nearer than was supposed, and that the rings are the matter blown off the star by the outburst. On this supposition its distance from us is estimated as 40 light-years or 12 parsecs. This supposition would quite negative the suggestion of a collision of two stars; in that case the proper motion at such a small distance would be much larger than it is. In fact, the sun's motion foreshortened would give a shift of 5″ in 24 years, which is four times the observed shift, so that if the star is at that distance it must be travelling at a speed about the same as the sun's, in the same direction. Also its absolute magnitude before the outburst was about 12, so that it was an extreme dwarf (perhaps a white dwarf). The star has been put down for parallax measures, which apparently have not yet been made. Measures during the next few months may throw further light on the question.

ε Aurigæ.—*Harvard Announcement Cards 59* and *63* deal with the expected minimum of this star. At the Washburn Observatory it was observed to decline 0·12 mag. between Jan. 22 and Mar. 4. Measures at Detroit Observatory give a decline of 0·18 mag. between Jan. 17 and Mar. 16. On the other hand, Margarete Güssow at Neubabelsberg gives the decline as only 0·04 mag. between Jan. 25 and Mar. 20 (*Astr. Nach.*, 5555). She concludes that the real approach to minimum has not yet commenced, and that the present oscillation is one of shorter period. *Harvard Announcement Card 63* also directs attention to the fact that there is an oscillation of 150-day period superimposed on the principal one, of much longer period. The star should be carefully watched. Mr. McLaughlin at Detroit notes that on Mar. 16 the $H\gamma$ line had a well-marked satellite on the side towards the red, not seen on earlier plates.

The Ebro Observatory.—Father Puig has written an interesting volume on the work of this observatory, which has been in existence for more than twenty years ("El Observatorio del Ebro. Idea General sobre el mismo." By the Sub-Director, P. Ignacio Puig, S.J. Tortosa, 1927). Its work embraces seismography, terrestrial magnetism, and earth-currents, solar radiation, meteorology in all branches; solar physics, both visual and spectroscopic; time determination. The observatory was in the totality track in the eclipse of 1905; the results have been already published, but are briefly summarised.

An interesting investigation carried out at the Observatory is the apparent influence of the earth on the birth and development of sunspots; it was first suggested by Mr. E. W. Maunder in 1907 that such an influence exists; the present investigation tends to confirm it. The records show that the majority of spots registered had their birth on the hemisphere away from the earth; the actual ratio should be still higher than the observed one, since it would include short-lived spots that formed and disappeared on the invisible hemisphere. Further, the number of spots born on the eastern half of the visible hemisphere exceeds by 20 per cent. the number born on the western half. There seems to be a slight excess of spots when the earth is in aphelion; also, the northern hemisphere has an excess when the earth is south of the sun's equator, and vice versa. It is noted that it is very difficult to understand how the earth can have such an effect on the spots (which extends to the faculæ and prominences, as Evershed and others have confirmed). A magnetic or electrical interaction between sun and earth is suggested as the most probable explanation.

The curve of sunspot activity from the Ebro Observatory records shows a very flat minimum in 1913 (the preceding and following years being nearly as low), a sharp maximum in 1917, a slight hump on the downward curve in 1919, a sharp minimum in 1923, and a rapid, steady rise in the three following years. The volume is well illustrated with photographs of the buildings and instruments, solar prominences, etc.

Research Items.

The Dalleburra Tribe, North Queensland.—Mr. M. Bennett has published in the *Journal of the Royal Anthropological Institute*, vol. 57, pt. 2, an account of the Dalleburra, a tribe virtually extinct, from notes made by Robert Christison, who settled among them in 1863, and whose collection of Dalleburra weapons, with a series of fine photographs of members of the tribe, is now in the British Museum. It is probable that the Dalleburra had never seen a white man before. Christison got into touch with them only with extreme difficulty, but secured great influence through healing the broken leg of a small boy whom the tribe expected to die. The incident revealed the existence of a custom by which on occasions of both extreme sorrow and great joy the women gashed themselves with stone knives. He could not discover that they believed in one supreme being, though they did believe in supernatural beings. Tribal government was in the hands of headmen, and the chief offences were marrying within the prohibited degrees, abduction, and encroaching on others' hunting grounds. Message-sticks and smoke signals were the chief means of communication. The headmen pretended to be able to call down rain and to cure disease. They determined the distribution of food, getting the best for themselves, and indeed some of the tribe had never tasted emu. There was a regular marriage system, for which purpose the tribe was divided into four divisions, classified in pairs. The children belonged to different sections from their parents. Members of the same section of the same generation were brothers and sisters. All members of the Ko-bro section had the first joint of one forefinger cut off. Incest was punished by the death of the guilty parties, but the child was abandoned. Indicative of their intense feeling on the point is the fact that one case was still regarded with the greatest shame by a member of the tribe thirty years after the event. The youths of the tribe had to go through various trials and courses of instruction before they were regarded as grown-up men and qualified to marry; but no account of the initiation ceremony could be obtained.

The Coffee Mealy-bug in Kenya.—The common coffee mealy-bug (*Pseudococcus lilacinus* CK11) is prevalent in the most important coffee-producing area in Kenya Colony. It is very easily confused with the closely allied species *Pseudococcus citri* Risso, and it is probable that some of the records relative to the latter insect may really refer to *P. lilacinus*. In *Bulletin 18* of the Colony and Protectorate of Kenya, Nairobi (1927), Mr. T. W. Kirkpatrick provides an interesting and very practical study of this insect. In addition to coffee, it affects a wide range of other host-plants and is largely spread by the whirlwinds or 'dust devils,' especially prevalent in the warmer seasons. A whole complex of other insects live in association with the mealy-bug, including ants which attend that insect for the honey-dew it yields, together with various parasites and predators. The damage entailed to coffee by mealy-bug was estimated to amount to £100,000 during the first six months of 1927: the flower buds and young berries form an ideal food and in severe attacks all the leaves may be shed, the crop being ruined. One of the most important factors concerned in the life of the mealy-bug is the ant *Pheidole punctulata*, which attends and protects it in various ways, besides destroying large numbers of other insects which normally prey upon it. Since the presence of this ant involves grave risk of rapid spread and severe injury by the mealy-bug, and in its absence it is unlikely much damage will occur, control measures aim at excluding the ant from the coffee plants. It was found that if the Pheidole is kept off the trees, the mealy-bug is always almost completely destroyed by its natural enemies. Various methods of exclusion are discussed, and the most feasible is the use of paper cones soaked with a high boiling-point tar oil. The cones are fastened round the stems, where they should require no attention for two or three months, and they act as effective barriers to the progress of ants up the trees.

Liver Fluke Disease of Sheep.—The Ministry of Agriculture and Fisheries has issued a revised edition (January 1928) of *Leaflet No. 89* on this subject. A brief account in simple language is given of the life history of the fluke and of the symptoms of the disease. The destruction of the snail (*Limnæa truncatula*), which is the intermediate host of the fluke, is the obvious preventive, and this may be accomplished by drainage or by dressing the land and treating the water of ditches, ponds, etc., with copper sulphate. Dykes should be cleaned out and their sides made vertical, so as to do away with dead water under the banks in which the snail is commonly found. The details of treatment with copper sulphate are clearly set forth in the leaflet. The sheep should be kept on good, well-drained land during the autumn and winter months, the period when infection is likely to be acquired. Curative treatment with extract of male fern and with carbon tetrachloride is advocated and described. The last serious outbreak of liver fluke disease occurred during the winter of 1920–21, when in four counties in North Wales alone 60,000 sheep died or were killed. In a pamphlet on liver fluke disease recently issued by the Council for Scientific and Industrial Research of the Commonwealth of Australia, the loss directly attributable to this disease in Australia is estimated at £100,000 per annum. Treatment by carbon tetrachloride is strongly advocated, and various methods of administration are briefly described.

Hawaiian Barnacles.—Mr. Henry A. Pilsbry ("Littoral Barnacles of the Hawaiian Islands and Japan," *Proceedings of the Academy of Natural Sciences of Philadelphia*, vol. 79; 1927) describes some collections of littoral barnacles from the small islets and reefs strewn over the Pacific for two thousand miles between the Hawaiian group proper and Japan, and also some species from the larger Hawaiian Islands. As these regions, particularly the smaller islands, are practically unexplored for cirripedes, there is here a fertile field for naturalists. Among the many interesting species recorded is a new form, probably belonging to Darwin's *Pœcilasma fissa*, which is named *Trilasmis fissum hawaiiense*, the genus Trilasmus having priority over Pœcilasma. Darwin's species, based on a single individual attached to a spinose crab from Bohul, Philippines, is much larger than the Hawaiian form which was found frequently on the mouth parts of the crab *Dromia dromia*, and differs in other respects also. It is a question, however, whether these small specimens may be the young of a larger barnacle not yet found.

Burmese Myxophyceæ.—In the *Journal of the Burma Research Society*, vol. 15, pt. 3, vol. 16, pt. 3, and vol. 17, pt. 3, Dr. S. L. Ghose makes considerable contributions to our knowledge of the Indo-Malayan Myxophyceæ. At the present time, identification of the various genera and species of the group can only be carried on with the expenditure of a large amount of labour on account of the rather rare and much scattered condition of the literature. Dr. Ghose has taken upon himself the laborious task of making as complete a descriptive record as possible of the blue-green algæ of his region, so that the work of future systematic and ecological investigators will be considerably lightened. The species are listed according to locality, those treated so far being, Myxophyceæ from Rangoon 1, 2, and 3, Myxophyceæ from Maymyo, and Myxophyceæ from Mergui and some neighbouring islands. Genera and species are described critically, and illustrated by means of good plates with line drawings. A few new species and several new varieties are included in the lists.

Agricultural Research in Connecticut.—The fiftieth *Report of the Connecticut Agricultural Experiment Station* (for the year 1926) is a volume of more than 600 pages dealing with the various activities of that Institution. A large part of this publication is occupied by the report of the State Entomologist. The Asiatic beetle which appeared in 1925 in New Haven has received a good deal of attention as it is a new pest in the United States. Up to the present, its injury to plants is confined to grass lawns, where the larvæ live. Many experiments have been conducted with the view of finding a method of control of the oriental peach moth, while the birch leaf skeletoniser is the subject of a long and detailed paper on its biology. On the botanical side one of the most interesting facts brought to light is the discovery that tobacco leaves dried and preserved for twenty-four years still retain the active principle of mosaic disease and can be used to infect living plants. With regard to soil research, the subject of the phosphorus requirements of tobacco with particular reference to old soils is given special prominence. The Report mentions that the library of the Station now contains 16,400 volumes, and that 48,000 copies of bulletins were mailed during the year.

The Upper Waters of the Blue Nile.—An important addition to our knowledge of the Nile drainage system was made by Major R. E. Cheeseman in 1926–27 in his survey of the Abbai River, one of the Abyssinian headstreams of the Blue Nile. Major Cheeseman's account of his explorations and his map of the river from Lake Tana to the Wanbera country is contained in the *Geographical Journal* for April. Previous knowledge of the river and earlier maps were fragmentary, and based mainly on the routes of travellers who had crossed it at various fords. The explorations included an examination of the Tisisat falls, some twenty miles below Lake Tana.

Regional Survey.—An addition to the growing number of regional studies of Great Britain is made by Miss C. Pugh and Mr. G. E. Hutchings in "Stockbury: a Regional Study in North-East Kent," published by The Hill Farm, Stockbury. The study is divided into five sections: Geology and physical features, vegetation, animal life, historical geography, and the Stockbury district. The plants and animal life occupy more than half the book, and while a great deal of valuable matter occurs in these pages, much of it has little real bearing on the regional study of the area in the geographical sense which such work is generally taken to imply. The human part of the study, on the other hand, is disappointingly brief, but the work with its good maps is a careful introduction to the subject.

A Fossil Medusa.—Very few traces of the existence of Medusæ have been found in rocks of earlier date than the Upper Jurassic, so that interest attaches to the discovery of a specimen in the Carboniferous Limestone at Denée in Belgium, and described by V. Van Straelen (*Acad. R. Belg. Bull. Classe des Sci.*, p. 952; 1927). It is a cast of the upper convex surface, nothing being known of the oral surface. The specimen is provisionally referred to the Rhizostomidæ.

Protons in Metals.—In a letter in *Die Naturwissenschaften* of Mar. 16, Prof. A. Coehn announces that he has succeeded in effecting an electrolytic transport of hydrogen through palladium. A wire of the metal was charged with gas at the cathode of a cell containing decinormal sulphuric acid, and the subsequent diffusion of the hydrogen was followed by measurement of the electrode potential at various points on the wire. When an electromotive force was applied to the ends of the latter, the hydrogen passed preferentially towards the negative terminal, and could be moved to and fro by reversal of the field. The conclusion that Prof. Coehn draws from these results is that the hydrogen atoms, like those of the metal itself, are partly ionised, but that the resulting protons, not being bound in a space lattice, are free to be affected by an electric field.

Simple Microscope Projection Apparatus.—A simple and useful accessory to the microscope has recently been designed by Mr. J. F. Marshall, director of the British Mosquito Control Institute, Hayling Island, by means of which the enlarged image of any object inserted under the microscope can be projected directly upon a screen either for the purpose of demonstration, drawing, or photography. The apparatus, which is known as the 'Moscon Macrograph,' consists of a projection screen attached to a vertically adjustable rod carried in a light but rigid framework which may be clamped to any table, shelf, or other convenient support. The microscope and the illuminant are placed on the floor and the image of the object is focused on the screen. As the screen is horizontal and can be fixed at a convenient height, the apparatus is extremely well suited for drawing, the tracing paper being easily fastened on the clear glass screen by means of the frame clips. For photographic purposes a light-tight bag of black cloth is attached to the frame of the screen and to the tube of the microscope, and a plate carrier is substituted for the glass screen after the image is focused. In this carrier the plate is covered by a hinged lid which opens downwards and works more smoothly than the usual sliding shutter. The macrograph, which costs £5, complete with carrying case and two projection screens, but without the photographic accessories, is marketed by Messrs. W. Watson and Sons, Ltd., 313 High Holborn, London, W.C.1.

Thermal and Electrical Conductivity.—The paper on the thermal and electrical conductivity of some aluminium alloys and bronzes read by Ezer Griffiths and F. H. Schofield at the annual meeting of the Institute of Metals on Mar. 7 is of considerable practical importance. It is frequently stated that the Lorenz law, namely, that the thermal conductivity varies as the product of the electrical conductivity and the absolute temperature, fails when applied to data obtained with alloys. The results obtained by the authors prove, at least, that as a generalisation, this statement is erroneous. The error has probably arisen from the fact that the values usually given for the thermal conductivities of alloys are untrustworthy. The primary object of the research was to obtain the thermal conductivities of the alloys employed in the construction of aero-engines. Two different sets of alloys were investigated. The first group consisted of alloys rich in aluminium, and the second group those rich in copper. For the second group, it was found that the Lorenz coefficient had practically the same value within ± 2·5 per cent. from 75° to 250° C. This is probably within the limits of experimental error. It appears, therefore, that the thermal conductivity can be deduced from a measurement of the electrical conductivity. As the determination of the latter quantity presents far less difficulty than that of the former, this result will be of great practical use. For the twenty-one aluminium alloys experimented on, very consistent results were obtained, except with a 13 per cent. silicon alloy. A determination of the Lorenz coefficient for a single crystal of aluminium (99·6 per cent. aluminium) gave the value $5{\cdot}46 \times 10^{-9}$. This is in good agreement with that obtained for the alloys. The value of the Lorenz coefficient for very pure copper was $5{\cdot}89 \times 10^{-9}$, which is in close agreement with the values obtained for the bronze alloys, but is decidedly higher than that obtained for the aluminium alloys.

An Ultra-violet Lamp with New Electrodes.—The 'Uvir' lamp, made by Messrs. Bellingham and Stanley, Ltd., is interesting and of unusual design. The arc is formed between two parallel metallic electrodes mounted vertically in front of a radiator which constitutes the series resistance. The heating elements of this radiator are solid rods of a special composition which reach a higher temperature when running than is possible with wire spirals, and hence yield a greater percentage of radiant heat. The electrodes are rigidly mounted in a simple clamp, so that the arc has to be lit by placing a carbon rod across the points. A rod mounted in an insulating handle is supplied with each lamp. The electrodes are made of a special alloy which has been selected as giving an intense radiation over the range of wave-lengths 2900 A.–3100 A. For use on an A.C. supply, the metallic electrodes are replaced by carbon cored with the same alloy, but even so the starting of the lamp is found to be more difficult than on D.C. Both arcs burn steadily with less fume and oxide than tungsten, and can be blown out like a candle, but the electrodes require adjustment and turning round in the holder from time to time to keep them at the same height. The cost of the alloy electrodes is about half that of tungsten. The radiation generated by this lamp is of an unusual character, as a great percentage is concentrated round the wave-length 3000 A., a range which is generally regarded as being of great therapeutic activity. Further, the shorter wave-lengths, of more dubious value, are not present to any marked degree. The 'Uvir' lamp may therefore be described as an efficient source of ultra-violet radiation of therapeutic value. It is for that reason to be regretted that more attention has not been given in the electrical design to safety devices. The radiator heating elements are protected by a wire grid, but the arc, which reaches a higher temperature and may be equally 'alive,' is outside the grid and entirely exposed. It is claimed that the somewhat crude method of striking the arc described above has the advantage of eliminating moving parts which are likely to corrode or oxidise, and in one way or another get out of adjustment. It may be found that the public is shy of taking such liberties with the ordinary type of mains and will require some form of switch on their ultra-violet lamps. The current consumed is approximately 3 amp. and the price is £5 *5s.*

The Inflammability of Hydrogen.—The January number of the *Journal of the Society of Chemical Industry of Japan* contains a further account of the work of Y. Tanaka and Y. Nagai upon the inflammability of hydrogen–air mixtures. They have found that, as would be expected, the tetra-methyl compounds of tin and lead act as anti-knocking agents in internal combustion engines, but these substances do not produce so great an effect upon the limits of inflammability of hydrogen mixtures as do the corresponding ethyl compounds. This is attributed to the smaller cross-sectional areas, and hence the smaller probability of collision with activated hydrogen molecules, of the molecules of the methyl derivatives. The theory of active collisions in combustion, and a derivation of the effects of pressure on the limits of inflammability, have already been given by Y. Nagai in the *Journal of the Faculty of Engineering of the Tokyo Imperial University*, vol. 17, No. 3, 1927.

Developer Stains.—It is well known that in developing a photograph the oxidation products of the developer are deposited with the silver of the image and form a secondary 'stain image,' unless sufficient sulphite is present to prevent it. Messrs. Lumière and Seyewetz (*Brit. Jour. of Photography*, Mar. 11, p. 172) find that the colour of this image varies with the nature of the developer and sometimes with the alkali used, being orange yellow with pyrogallol and various shades of brown with other developers. The amount of anhydrous sodium sulphite necessary to prevent the formation of this stain image is generally 2 gm. to the litre, but pyrogallol requires 11 gm., pyrocatechin 6 gm., and glycin needs none, as it does not give this image at all. The formation of the stain image renders the gelatin insoluble in proportion to its intensity. This image is a mordant for basic dyes, and may be intensified by such dyes to a density even exceeding the density of the original image as developed. To isolate the stain image, the silver is dissolved away by means of ferricyanide and hypo.

Electrical Hardening and Annealing Processes.—Electric salt bath furnaces have been found to be very useful for heating metals up to the exact temperature required for hardening in the shortest possible time. They are largely employed for hardening cutting tools. The tool to be hardened is placed in the salt which is to carry the electric current. When the salt melts it makes good thermal contact with the metal, the required temperature being attained very quickly. The salt bath also serves as a heat accumulator. Air is not in contact with the heated metal, and so it is not oxidised on quenching. Owing to the excellent way they retain their heat, salt bath furnaces are particularly suitable for hardening metals on a large scale. In *A.E.G. Progress* for December, a description is given of electrical welding and hardening processes. The furnaces for 800° C. are used for hardening carbon steels, and those for 1300° C. for high alloy steels. The salt used for temperatures from 750° C. to 1000° C. is composed of a mixture of barium and potassium chlorides, and that from 1000° C. to 1300° C. of barium chloride only. Electric annealing furnaces are also described. For these furnaces chrome nickel has been found most useful for the conductor which converts the electrical energy into heat. These furnaces are generally designed for temperatures up to 950° C. and are specially useful for heating processes which have to extend over long periods. They are sometimes equipped with automatic temperature regulators and can be used for annealing metals in hydrogen and other gases. The tempering of hardened tools can also be effected in electric salt bath furnaces even when the temperature required is so low as 220° C. In this case the conducting salt is a mixture of sodium and potassium nitrates.

Pharmacological Research in Great Britain.

THE second Annual Report of the Pharmacological Laboratories of the Pharmaceutical Society of Great Britain (1927) gives a brief summary of the research work carried out during the year, and indicates the part the laboratory is beginning to play in the physiological standardisation of different drugs for commercial manufacturers. In February of last year the Vitamin-testing Department, under Dr. Katharine H. Coward, was ready to carry out its first tests, and these now occupy an important place in the laboratory's work.

The director, Dr. J. H. Burn, has continued his researches on the metabolism of rats on a fat diet: he has found that in summer the excretion of acetone bodies in the urine of a 100-150 gm. rat reaches a maximum of 50 mgm. in a day, whilst in winter the maximum may not be greater than 5 mgm. The summer acetonuria can be inhibited by injection of pituitary extract or adrenalin, indicating that these hormones control the metabolism of fat as well as that of carbohydrate. On the other hand, daily injections of insulin, after a day or two, increase the winter acetonuria, and this increase is not simply related to the fall in the blood-sugar, since the latter occurs to about the same extent on all days on which the injections are given.

Some work has been carried out on the assay and preparation of extracts of ergot, and also, in conjunction with Mr. A. Bourne, on the clinical value of pituitary and ergot extracts. It was found that during labour a dose of 2 units of pituitary extract was quite sufficient to hasten its conclusion, and also that of the possibly active substances present in extracts of ergot, the specific alkaloid ergotoxine or ergotamine produces, after a short latent period, a prolonged contraction of the uterus *postpartum*, whilst histamine causes an immediate powerful but short-lived contraction, and tyramine is inert.

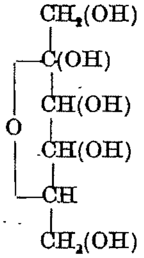
A paper on the œstrus-producing hormone has been published by Drs. Burn and Coward: it was found that the individual variation between different rats or different mice is as much as 1000 per cent. The authors therefore define the unit as the dose necessary to produce œstrus in 50 per cent. of ovariectomised animals. They have constructed a standard curve relating the percentage of rats in which œstrus occurs to the dose injected from observations on a group of 90 animals. A curious point that emerged from this work was that the mouse unit has exactly the same value as the rat unit, in spite of the difference in body weight between the two species.

In the vitamin department, a stock colony of Wistar rats is in process of being built up, by inbreeding the animals and maintaining them on a constant diet: the most suitable diet, however, has not yet been determined. A sample of irradiated ergosterol is being used as a standard for vitamin D assay: a unit has been defined as the amount of antirachitic activity contained in 0·0001 mgm. of this sample. This definition has been rendered necessary by the fact that certain workers are defining the unit of vitamin D as the least amount which will cure rats of rickets, when they are maintained on a rachitogenic diet: such a unit may vary by 400 to 500 per cent. in different experiments. It is hoped to use a sample of the unsaponifiable matter of cod-liver oil as a standard for vitamin A in the near future. The report also gives the number of samples of the different preparations which have been assayed during the year: approximately 170 were tested.

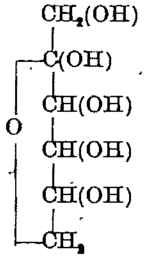
The Synthesis of Cane Sugar.[1]

By Prof. Amé Pictet and H. Vogel.

THE fine researches of Haworth and of Irvine have shown that fructose (levulose) does not possess the same chemical composition when it is in one of its natural combinations (cane sugar, inulin) as when it has been extracted. Hence it must be admitted that it can exist in two isomeric forms, one of which, to which the name of γ-fructose has been given, is unstable and changes spontaneously into the other, called normal fructose, as soon as it is set free. Haworth and his collaborators have made it very probable that the formulæ which should be attributed to these two forms are the following:



γ-Fructose.



Normal fructose.

It follows from these facts that if it is attempted to realise a synthesis of saccharose by the union of its two constituents, glucose and fructose, it cannot be effected by utilising the second of these sugars in its normal form, the only one available. It would be necessary to start with one of the artificial derivatives in which it occurs in the γ form. Some of these are known (methyl, ethyl), but none of these would be available for the operation in question, since the substituted groups that they contain are too firmly fixed to the rest of the molecule to permit of their being detached, once the condensation with the glucose had been carried out.

Hence the synthesis of saccharose necessitates the preliminary preparation of a derivative of γ-fructose containing only substituent groups relatively easy to remove. The following observation has furnished us with a substance which fulfils this condition.

We have found that when the tetracetate of normal fructose is prepared by the method of Hudson and Brauns (*Jour. Amer. Chem. Soc.*, 37, p. 2739; 1915), that is, by treating fructose at a low temperature with acetic anhydride and zinc chloride, on crystallising the product from alcohol, a second compound is formed in small quantity which remains in the mother liquors. On evaporating these in a vacuum a thick syrup is obtained which, on contact with cold water, is slowly converted into a solid vitreous mass. Up to the present, this substance has not been obtained in the crystalline condition, but its analysis, and the fact that it easily reduces alkaline copper solutions, proves that it consists of a second tetracetate. Moreover, its rotatory power, much lower than that of the normal tetracetate, would suggest that it belongs to the γ series.

The formation of a derivative of this nature would be explained by admitting (as already suspected by

---

[1] Translated from *Comptes rendus* for Mar. 19 of the Paris Academy of Sciences.

Ohle) that when fructose goes into solution, an equilibrium is established between its normal form and the γ form. This would take place in acetic anhydride as in any other solvent and each of these forms would then be acetylated on its own account. Under the conditions of our experiment, the equilibrium would appear to be approximately 97 parts of normal fructose and 3 parts of γ-fructose.

It would have been easy to prove the γ nature of the new acetate by methylating it, and then saponifying the product; the methyl-γ-fructoside prepared by Irvine should thus have been obtained. But there was another method, more simple still, and that was to combine it with glucose tetracetate: it should then, if really derived from γ-fructose, give rise to the octacetate of saccharose.

Glucose tetracetate + γ-fructose tetracetate = saccharose octacetate + water.

This experiment was carried out by dissolving in chloroform equal weights of our tetracetate and that of glucose (prepared according to the method of E. Fischer and Delbrück), and this solution was shaken for 15 hours with phosphorus pentoxide. On evaporation in a vacuum, it left a syrupy residue, which, taken up in warm alcohol, deposited fine crystals on cooling. These presented the principal characters of saccharose octacetate

Melting-point of our crystals	70° C.
„ „ of saccharose octacetate .	70° C.
„ „ of their mixture . . .	70° C.
Rotatory power in chloroform solution .	+ 59°·4
„ „ of saccharose octacetate	+ 60°·0

It may be noted that the same substance was obtained in two series of experiments, in one of which a fructose prepared by inversion of saccharose was the starting-point, and in the other a fructose extracted from inulin.

The saponification of the synthetical octacetate, carried out by Zemplen's method, finally gave an anhydrous, non-reducing disaccharide, of crystalline structure and very sweet taste. The comparison of its principle properties with those of cane sugar gave the following figures:

Analysis (per cent.) . .	C 42·3, H 6·6 (calculated for $C_{12}H_{22}O_{11}$: 42·1 and 6·5).
Cryoscopy in water . .	Molecular weight found: 344 (calculated 342).

Melting-point of our sugar	183° C.
„ „ of saccharose	184° C.
„ „ of their mixture . . .	184° C.

Rotatory power in aqueous solution	
of our sugar (C = 5·07)	+ 66°·3
of saccharose at the same concentration	+ 66°·5
of our sugar after inversion	− 20°·6
of saccharose after inversion . . .	− 20°·7

From the concordance of these figures the identity of these two substances must be regarded as proved.

We still have to clear up certain points concerning the intermediate products of this synthesis, and to give an account in greater detail of the whole of our operations. These results will be published in due course.

The Development of Cyclonic Depressions.

In the *Monthly Weather Review* for November 1927, two articles by W. J. Humphreys appear, both of which deal with the growth of cyclonic depressions in the United States and Canada.

The first article gives an explanation of the great increase in size and intensity of a depression that so often takes place when it moves north-east across the eastern parts of the United States or of Canada. Since such an increase of intensity with increasing latitude is not a world-wide phenomenon, the idea that it may be due to change with latitude of the deflective force of the earth's rotation is rejected. If, on the other hand, contrast of temperature is regarded as essential for cyclonic development, an obvious explanation is afforded by the fact that the farther north the depression goes, the shorter is the distance through which the incoming supply of polar air has to pass, and the colder that air will be on arrival, while the high temperature of the equatorial air is largely maintained by latent heat set free by condensation of its water vapour, even when the distance travelled from equatorial regions is very great, the result being an increase of temperature contrast between the parts of the depression fed, respectively, by these two supplies of air. Such opportunities for increasing temperature contrast as exist over eastern North America and the western part of the North Atlantic are available in few if any other parts of the world.

The second article seeks to explain why depressions moving north-eastwards across the United States in winter increase in size and intensity more rapidly by night than by day. Thermal considerations are again made use of: it is pointed out that the cold portions of the depression have as a rule clearer skies than the relatively warm portions, and consequently are far more strongly cooled by radiation at night, an increase of temperature contrast due to this effect being added to the general effect of latitude mentioned above. During the daytime, on the other hand, not only is the polar air with its clearer skies warmed more than the equatorial air, so as to reduce the contrast of temperature, but also, being so warmed, thermal convection will normally set in and obstruct to some extent the simple cyclonic wind-system.

It may be pointed out that the effect dealt with in this second article is not generally regarded as characteristic of depressions crossing the British Isles. This is not surprising, however, when we consider how comparatively small the nocturnal fall of temperature is in polar air that has been charged with water vapour, if not with cloud, during a long passage across the North Atlantic, as generally happens with polar air reaching the British Isles.

Earthquakes in the Crimea in 1927.

Prof. A. V. Voznesensky in *Priroda* (No. 12, 1927) gives the preliminary results of observations on the Crimean earthquakes of last summer. The data on which the account is based are admitted to be somewhat fragmentary and inexact, since the Crimea was considered not to be subject to earthquakes and there was no seismological station there before, though one is established now in Feodosia. Apart from that, observations on the spot during the earthquakes were not organised properly and have been made without system or knowledge.

The first tremor occurred on June 26, when many buildings were partially destroyed, and afterwards slight tremors were experienced for five months, until

November; during this period the second great earthquake occurred, on Sept. 12, which was still more destructive than that in June. The strength of the earthquake was estimated by local observers as 8, but the author is inclined to regard this figure as exaggerated and not exceeding 6, since not more than 20 per cent. of buildings were damaged, and those only partially and owing to their unsatisfactory state. The area of the June earthquake covered by the isoseist 6 occupied the south-western extremity of the Crimean peninsula; the area covered by the isoseist 2 is more or less triangular in shape and stretches from Kiev to Batum (1280 km.). The axis of the September earthquake was almost perpendicular to that of the June one, and the area of the isoseist 2 was about half as long again, but the epicentre could be determined as practically in the same spot, while the strength increased more than twice.

A comparative study of records from seventeen Russian and foreign observatories permitted the author to determine the epicentres in a preliminary way, for the June earthquake at 44° 30′ N. and 35° 50′ E., for the September one 44° 30′ N. and 35° 10′ E. Both these points are in the Black Sea; the first 53 km. from the shore south of Cape Tchauda; the second 43 km. south of the mouth of the River Otusa; both at the depth of 1·5 km. The depth of the epicentres is suggested by the author as about 25 km. Preliminary data of a hydrographical survey of these areas showed considerable alterations in the state of the sea bottom, since instead of soft mud found on previous occasions the survey discovered stony bottom. The probable cause of the earthquakes was purely tectonic, since there was absolutely no indication of volcanic action, though some vague rumours to that effect circulated amongst the panic-stricken population. Losses of life were negligible, which was explained by the fact that strong tremors were preceded by slighter ones and nearly everybody left buildings. On the other hand, the moral sufferings of the population were great, owing to the enormous number of successive tremors keeping the people in permanent suspense. During the first month as many as 265 tremors were registered, or 8·2 tremors daily, while on the first day their number was 41, and it is easy to understand the assertions of inhabitants that there was an incessant trembling for many days.

University and Educational Intelligence.

Glasgow.—At the Ceremony of Graduation held on April 21, the degree of doctor of science (D.Sc.) was conferred on Dr. R. C. Smith, for a thesis on "The Stability of Emulsions, with Additional Studies in Rates of Reaction."

Nottingham.—In our issue of Feb. 4, p. 190, reference was made to the opening of the new buildings by H.M. the King in July next. It is now announced that the opening ceremony will take place on July 10. Sir Jesse and Lady Boot are making further contributions to the new buildings. Sir Jesse will bear the cost of the great hall, and Lady Boot the expense of a women's hall of residence.

Dr. W. B. Crow, lecturer in botany at the University College, Cardiff, has been appointed head of the Department of Biology at the Technical College, Huddersfield, in succession to Dr. T. W. Woodhead, president of the British Ecological Society, who, at the end of the present session, will be retiring from the headship after thirty-two years' service.

Following upon the Hackett bequest of about £550,000 to the University of Western Australia, the Government has resolved to celebrate the centenary of the State in 1929 by erecting such buildings as will enable the entire University to be moved to its 165-acre site at Crawley. The Departments of Engineering, Biology, and Geology are now in their permanent buildings, and a building for physics, to be erected at a cost of about £32,000, should be completed by August 1929. The Anglican Church has commenced the erection of St. George's College—a residential college for students—the foundation stone of which was laid on Mar. 8. The central Winthrop Hall, with its adjoining administrative buildings and Students' Union, is being erected in accordance with a design by Messrs. Alsop and Sayce of Melbourne, whose plans were awarded the first prize last August in an Empire-wide competition. The late Mr. R. J. Gledden, who died towards the close of 1927, left his entire estate to the University for the promotion of the study of applied science, and this bequest will, when the property is realised, amount to nearly £100,000.

The eighteenth annual report of the University of Leeds on adult education work gives particulars of thirteen university extension lecture courses and forty-five tutorial classes, which cost £373 and £4931 respectively. Among the tutorial class subjects the natural sciences were represented by biology only. In this subject there were five classes with ninety-five members. As an indication of the interest aroused, mention is made of two public exhibitions of their work arranged by the students. The tutor in biology, Mr. Norman Walker, has demonstrated by the continuance of his classes for more than three years the effectiveness of his methods, an account of which is given in the recently published Report on Natural Science in Adult Education by the Board of Education's Adult Education Committee. He insists, above all, on the teaching being practical and never losing contact with life. "This aspect possesses great inspiration and is effective in mind training, while the intellectual satisfaction obtained secures the adult student's devotion and attention over several years, if not for a lifetime."

The Carnegie Trust for the universities of Scotland has published its twenty-sixth annual report, which gives particulars of grants made during 1926–27 as follows: grants to universities, £39,700; grants to other institutions, chiefly colleges, £8345; grants in aid of post-graduate study and research, £16,829; assistance to students by way of payment of class fees, £58,664. Among the new buildings for which some of the largest grants to universities were made are students' hostels and a students' union. Apart from a research lectureship in Scottish history, the assistance rendered to research by the Trust is in three forms: research fellowships, scholarships, and grants; the laboratory of the Royal College of Physicians; and teaching fellowships. A pleasing feature of the report regarding assistance to students is the unprecedentedly large amount (£2575) of voluntary repayments of their class fees by former beneficiaries. Of the total amount thus repaid since the trust began its operations, nearly half has been contributed by former students of the faculties of medicine. The policy of the trustees in dealing with applications for admission as Carnegie students has recently been modified. Instead of accepting without question declarations by applicants and their parents or guardians purporting that without the assistance of the Trust university education would be impossible, the Trust now inquires into the financial circumstances of the family. It finds that the circumstances of the great majority of applicants clearly justify any assistance which can be rendered to them.

Calendar of Customs and Festivals.

April 30.

Rood Mass. Walpurgis Nacht.—Believed to be one of the greater, if not the greatest, of the occasions on which a witches' Sabbat took place. According to one version, witches from all parts had to fly to the Sabbat on the Brocken, those arriving late being sacrificed to provide the ceremonial meal.

May 1.

May Day.—Among European peoples the first day of summer is, or was until quite recently, marked by customs, practically everywhere identical, which can be traced back over a considerable period of time. Ceremonies which can be paralleled in every particular among recent observances, including the ceremonial contest between representatives of summer and winter, are recorded by Saxo Grammaticus.

On the eve of May Day, or in the early hours of May morning before sunrise, parties went out to collect green or flowering branches, and brought them back to place before the doors or hang them on either their own houses or those of others. The fetching of the May was an occasion for merrymaking, not always too decorous, and was accompanied by music and the blowing of horns welcoming the summer. The custom in olden days was common to all classes. In Malory, Queen Guinevere goes a-maying with all her knights, and so did Henry VIII. with his Queen Katherine.

At times a sapling or tree took the place of green boughs and was erected in the middle of the village with more or less ceremony, in some places being brought in by teams of gaily decked oxen. From this grew the custom of erecting a more or less permanent maypole, gaily coloured in stripes and decorated on the day with flags and streamers and sometimes a doll. Several such maypoles existed in London, the most frequently mentioned long standing in the Strand. The origin of the maypole, however, as the annual revival of vegetation, continued to be indicated by a bunch of fresh leaves or a garland fastened to the top. The garland, conventional in form, was similar to those carried by children, one or two small hoops or wreaths of flowers and leaves, if two in number fastened at right angles to one another. These the children carried at the end of a stick or wand from door to door, singing a May song, with the object of collecting pence.

The maypole was the centre of the day's rejoicing, which embraced various forms of sport and Morris dancing. The Morris dances invariably included a principal man, a female character, a fool, and often a hobbyhorse. The best-known example of the last named was the Padstow hobbyhorse with its special song. In England the characters of the May Day dances are usually Robin Hood, Maid Marian, and their traditional followers, Little John, Friar Tuck, and Scarlett. Maid Marian became a travesty as the character was taken by a male dancer. At the same time she originally represented the female principal of Nature, which found more graceful expression in the election of a May Queen. The May Queen sometimes held authority not for the day only, but in all assemblies of young people throughout the year. The male principle was represented not only by the chief male character, but was also expressed in the pole itself, which undoubtedly had a phallic significance similar to that of the *lingam* in the religious observances of India.

A figure in the May observances to which reference is frequently made is 'Jack in the Green'—a man disguised and completely hidden in a framework of greenery. A pyramidal garland, six feet high, carried in the procession of the May Queen in Huntingdonshire, has clearly taken his place. The career of Jack in the Green sometimes ended by his being thrown into a pond or stream. Obviously he is a materialisation of the vegetation spirit and his end a rain charm.

The special virtue of the dew of May morning was recognised in the custom of dabbling the feet in the dew, and bathing the face and hands, the latter a beauty charm, but the whole observance originally a rite to secure fertility. A similar custom, to name an example, is the May Day evening practice of the women of the island of Syra in the Ægean, who go in parties to the seashore to bathe their feet, possibly as a tribute to ensure the blessing of fertility from the sea goddess Aphrodite.

Beallitainn or Beltane.—In both Scotland and Ireland, May Day was celebrated by observances similar to those of England and other European countries. It was also the first day of summer—Beltane, in the Celtic calendar, being, however, not the first, but the middle day of the month Céitein, which included fourteen days of April and fourteen days of May.

Beltane was pre-eminently a fire festival among the Celtic peoples, and akin to the Easter fires previously mentioned and the midsummer fires. Indeed it has been explained as meaning the Fires of Bel or Baal. The meaning is obscure, and an alternative, the separation or parting of the seasons, has been suggested. It is a time of purification by fire from the evil influences of the past winter in preparation for the summer of fertility and growth. On May 1, whatever the weather, the cattle had to be driven out to the summer grazing grounds. Before this could be done they were purified by fumigation or by being driven through the flames of burning straw, as in the south of Ireland. Pennant records that the herdsmen of the Highlands of Scotland, while standing round a fire built on turf in a surrounding trench, first poured a libation of eggs, butter, oatmeal, and milk on the ground, and then threw offerings of oatmeal cake over their shoulders with a request for the protection of their flocks, herds, and horses from eagles, crows, and noxious animals. In a similar observance by boys in Perthshire, one of the number had to leap through the flames of the fire.

May 2.

St. Helen's Day, Rowan Tree Day.—In Yorkshire rowan tree branches were collected in a certain prescribed manner and planted over each door and window of the homestead as a protection against witches. Small pieces were carried in the pocket or purse with the same object. In Aberdeenshire the twigs were made into crosses and suspended at windows and doors. Witches and fairies were especially feared at this time, and in Scotland on May Day eve the cattle were protected by tar smeared behind the ear and on the root of the tail. A churning and a cheese made before sunrise protected the dairy produce against fairies in the coming year. If fire or rennet were given away on May Day, it gave the receiver power to take away the substance of the donor's milk.

May 3.

The Day of Avoidance.—In Scotland during the May Day week it was considered unlucky to undertake field operations, but the third day of summer was considered particularly unlucky for any undertaking. This may be connected with the fact that it was sometimes believed that the great witches' Sabbat took place on this day instead of on April 30.

Societies and Academies.

London.

Geological Society, April 4.—G. W. Tyrrell: The analcite-syenites and associated rocks of Ayrshire. These rocks occur in differentiated intrusions along with analcite-olivine-dolerites or crinanites, as stratiform bands, schlieren, and veins. The principal occurrence is at Howford Bridge, Mauchline, where analcite-syenite forms a considerable part of the sill. In the remaining three described occurrences (Dippol Burn, Trabboch Burn, and Prestwick) the analcite-syenite is restricted to schlieren and veins. They all belong to the widespread suite of analcite-bearing igneous rocks of late-Carboniferous and Permian age in the west of Scotland. The most noteworthy mineralogical feature is the abundant occurrence of analcite, thomsonite, natrolite, and prehnite, which must be regarded as late primary crystallisations from the magma. A hypothesis for the development of schlieren and veins in the sills by the effects of the varying incidence of the pressure due to the superincumbent column of rock, upon a crystal mesh filled with interstitial liquid, is framed. The liquid is believed to be progressively driven towards the centre of the sill, and also laterally towards those places where the pressure is compensated in various ways, so that free contraction of the crystallising mass can take place.—**J. Parkinson**: A note on the Pleistocene history of western Buchivacoa (Venezuela). The area consists of alternating estuarine or fresh-water false-bedded sandstones, and sandy clays, folded along east-north-easterly axes in many places. Burdigalian and Aquitanian fossils occur in the eroded centres of the folds. There is an unconformity between the Miocene and the overlying strata, which appear to be of Lower or Middle Pliocene age. The Tertiary deposits are covered by Pleistocene pebble-beds. The latter are probably an old sea-beach. Subsequent elevation during a pluvial period allowed of a 'creep' of the pebbles northwards. Redeposition in successive stages was effected by eastward-flowing rivers of the Indus type. Since Pliocene times, an elevation of about 1000 feet has taken place along the southern edge of the district.—**A. Tindell Hopwood**: *Gyrinodon quassus*, a new genus and species of toxodont from western Buchivacoa (Venezuela): with a note on the reptilian remains by **W. E. Swinton**. Gyrinodon differs from Toxodon in its more primitive dentition, and in the characters of the skull-cap. It differs from Alitoxodon in the characters of the mandibular symphysis. This is the northernmost locality for toxodonts hitherto recorded n South America. Apparently the toxodonts followed a northward dispersal.

Royal Statistical Society, April 17.—**Major P. Granville Edge**: Vital registration in Europe. Modern public health work is largely directed and controlled by the conclusions reached after the study and analysis of data resulting from the careful collection of the vital facts of human life. Such records constitute a national system of book-keeping. Accurate and complete vital statistical records provide a means of discovering the principal factors responsible for the wastage of human material, the degree of success attending the introduction of various health measures, and promote research with the view of reducing sickness, controlling disease, and prolonging the average span of human ife. Although vital statisticians of various countries are engaged upon the study of similar problems, the nformation sought by the various national schedules, and the methods of procedure and classification, etc., differ so essentially that the resulting data are not comparable between one country and another. The official records of many European States contain serious and remediable defects, which increase the difficulties of securing comparability of data between one country and another.

Dublin.

Royal Dublin Society, Mar. 27.—**H. H. Dixon** and **T. A. Bennet Clark**: The influence of temperature on the responses of plant tissues to electrical stimulation. The view is put forward, on the basis of the work of Höber and McClendon in particular, that the sudden change in the electrical resistance of a tissue, brought about by the passage of an electric current through it, is caused by an increase in the permeability of the protoplasmic membranes and not by alterations in the concentrations of ions. Previous work on the relationship between the voltage and energy-content of the stimulus and the magnitude of the resulting change in permeability has been confirmed and extended. The sensitivity decreases extremely rapidly during November and increases as rapidly in December and January, after which a rather slow increase in sensitivity occurs. The response is of a dual nature. At a temperature of 0° C. the negative reaction is the greater; as the temperature is raised to 20° C. the positive reactions are increased more than the negative; further raising of the temperature causes marked predominance of the negative reactions. Continued previous exposure to various temperatures does not alter the sensitivity of tissues at a fixed temperature of experiment. It does, however, temporarily alter their resistance.—**W. D. Davidson**: (1) The rejuvenation of the Champion potato. The downfall of the Champion and other old varieties was, in all probability, due to the presence of one or more of the diseases included in the mosaic group. Almost all Champion stocks had become affected to the extent of 100 per cent. In an effort to propagate a healthy nucleus stock, nine plants were with great care selected from the best stocks procurable. These plants were apparently healthy, and were dug early to minimise the risk of infection. A tuber from each plant was tested for freedom from mosaic. The produce of all plants found to be healthy were grown in units among turnips well isolated from each other and from all other potatoes. This system of planting was followed for three seasons. During the first two seasons no trace of any of the mosaic diseases was discerned. In the third season a few plants had to be removed from three units. It is confidently believed that the selected stock is now quite as healthy as when it was put in the market more than fifty years ago. (2) A review of literature dealing with the degeneration of varieties of the potato.

Paris.

Academy of Sciences, Mar. 19.—**J. Costantin**: Contribution to the biological study of *Picea excelsa*. Two fungi would appear to grow in symbiotic association with the roots of this tree, *Polyporus ovinus* and *Pholiota caperata*. The fact was noted in the Savoy Alps, but direct experiments are necessary to prove the influence, if any, of the mycelium of each of these fungi on the development of the trees.—**Ch. Lallemand**: Against the legal creation of a new gold franc of reduced value.—**Amé Pictet** and **H. Vogel**: The synthesis of cane sugar (*v.* p. 689).—**Alex. Froda**: The ensemble of discontinuities of the first species.—**A. Kovanko**: Some generalisations of nearly periodic functions.—**G. Vranceanu**: Periodic solutions with very long periods.—**Belzecki**: The case of equilibrium of elasticity of a hollow cylinder.—**R. Wavre**: The figures of equilibrium of a heterogeneous fluid mass.—**V. G. Sladbey**: The orbit of Fmsler's comet, 1924 II. For this comet several systems of parabolic elements, and one hyperbolic, have been calculated by various authors. Taking the whole of the published data, a recalculation of the elements has been made. The most probable system appears to be hyperbolic, the constants of which are given.—**Al. Proca**: Some reflections on the foundations of dynamics. The fifth dimension.—**Nageotte**: The Brownian undulations of thin plates and of filaments in myelinic formations.—**Mlle. M. Chenot**: Higher order oscillations in an oscillating circuit.—**Mlle. St. Maracineanu**: Phenomena resembling those of radioactive substances presented by metals.—**A. P. Rollet**: The existence of the oxide of silver Ag_4O_3. The anodic oxidation of silver in an alkaline electrolyte of higher concentration than normal gives a peroxide Ag_4O_5, which is very stable in alkali solution.—**Paul Mondain-Monval** and **Paul Schneider**: The temperature of transformation of liquid sulphur into viscous sulphur. Curves are given showing the viscosity of sulphur, and of sulphur containing various proportions of various organic substances in solution, as functions of the temperature. The temperature of transformation of pure sulphur is 160° C., and this is raised by the presence of organic substances in solution.—**Mlle. Suzanne Veil**: Yellow ferric hydroxide, the result of the controlled oxidation of ferrous sulphide in suspension. An application of the changes in the magnetisation coefficient to the study of ferric hydroxides produced under differing conditions.—**P. Vaillant**: The composition of the Kundt displacements in an absorption spectrum with several maxima.—**Pierre Auger**: The directions of emission of the photo-electrons.—**Maurice Billy**: The composition of titanium peroxide. In an earlier paper the author indicated that the hydrate precipitated from a pertitanic salt had the composition Ti_2O_5, Aq. Schwartz and Sexauer, repeating these experiments, come to the conclusion that the composition is TiO_3, provided that the temperature is kept about 0° C. Additional experiments are given showing that at 0° C. there is more oxygen than corresponds to the formula Ti_2O_5, although far removed from TiO_3.—**A. Duboin**: The introduction of bromine and iodine into silicates. Definite crystals have been prepared of the composition KBr, K_2O, CoO, $4SiO_2$, and KI, K_2O, CoO, $4SiO_2$.—**Raymond Quelet**: The action of magnesium on some parabromoethylene derivatives of benzene.—**Marcel Godchot** and **Mlle. G. Cauquil**: The dehydration of the pinacone of cycloheptanone.—**J. Orcel** and **Gil Rivera Plaza**: The microscopic study of some metallic minerals of Peru.—**Louis Barrabé**: The tectonic of the region comprised between the Manambao and the Manambolo (west of Madagascar) and on its relations with eruptive phenomena.—**J. Thoulet**: The densimetric study of Humboldt's current and of the sea of Easter Island.—**J. Aloy** and **Jacques Averseng**: The radioactivity of some springs in the Pyrenees region.—**L. Éblé** and **J. Itié**: The values of the magnetic elements at the Val-Joyeux station (Seine-et-Oise) on Jan. 1, 1928.—**A. Eichhorn**: The various stages of mitosis of *Hyacinthus orientalis* and, comparatively, of *Allium cepa*.—**H. Belval**: The genesis of starch in cereals, glucides of leaves, and the stems of rice.—**Volmar** and **Jermstad**: Sclareol, the principal constituent of essential oil of sage. This substance, of the composition $C_{24}H_{42}O_2$, is a tertiary, polyhydric alcohol, unsaturated and similar to the phytosterins and cholesterins.—**Lucien Daniel**: New observations on the variations of descent in grafted Jerusalem artichokes.—**Cl. Fromageot**: The deviations which may occur in the hydrogen ion concentration of the soil at points close together.—**Tchéou Tai Chuin**: The absence of strobilisation and persistence of budding during the winter in artificially fed scyphistomes.—**E. Roubaud**: The reactivating anhydrobiosis in the evolutive cycle of the Pyralis of maize.—**A. Giroud**: The structure of the chondriosomes.—**Mme. Phisalix**: The power of destroying the virus of rabies *in vitro* of the venom from the aspic viper. This snake poison, heated to a temperature which destroys its toxic power, still possesses the power of destroying the virus of rabies *in vitro*.—**A.** and **B. Chauchard** and **J. Hurynowicz**: The measurement of the excitability of the vasoconstrictor nerves in man.—**Marcel Brandza**: Morphological and experimental researches on the sclerotes of the calcareous Myxomycetes.—**J. Magrou** and **Mme. M. Magrou**: The action at a distance of *Bacterium tumefaciens* on the development of the egg of the sea urchin.—**Lecomte du Noüy**: A spontaneous modification of the viscosity of blood serum. Some results obtained with an apparatus permitting a continuous observation of the variation in viscosity.—**H. Carré**: Acute parasitic infections.—**Ed.** and **Et. Sergent** and **A. Catanel**: A new parasite of paludism of birds.

Geneva.

Society of Physics and Natural History, Mar. 15.—**R. Wavre**: The deviation from the vertical wit depth. The author extends the formula of the deviation from the vertical to the case where there may b movements in the interior of the planet.—**Pierre Dive** A generalisation of a formula useful in geodesy The author shows that the rigorous formula for th increase of gravity with depth given by M. Wavr extends to any permanent rotation of a planet roun its polar axis.—**R. Chodat** and **H. Evard**: The distribution and localisation of tyrosinase in the highe plants. By means of the reagent *p*-cresol in 10 pe cent. sugar solution, the authors have been able t prove the presence of tyrosinase, which is foun localised in different parts of plants (leaves, peduncles roots).—**R. Chodat** and **A. Senglet**: The *sapécage* o 'Maté' and the presence of ferments in *Ilex paraguariensis*. True 'Maté' is furnished by *Ilex paraguariensis* (the 'Matés' of botanical gardens are mor frequently plants other than this). *Ilex paraguariensis* contains oxidising ferments; the operation o singeing, called *sapécage*, to which the plant is submitted, neutralises the action of these ferments. Th blackening of the plant and of the liquid obtained fro it is thus avoided.—**L. Duparc** and **E. Rogovine**: new indicator for the volumetric estimation of phosphoric acid. By the use of uranyl acetate wit sodium salicylate as indicator, the authors were abl to carry out an estimation of phosphoric acid whic can be applied to the examination of urine.

Rome.

Royal National Academy of the Lincei, Jan. 15.—**F. Severi**: Simple and double algebraic integrals (3).—**N. Parravano** and **G. Malquori**: Investigations on th sulphides of molybdenum (2). Equilibrium of th reduction of molybdenum disulphide by means hydrogen. This reduction, $MoS_2 + 2H_2 = 2H_2S + Mo$, a reversible reaction, equilibrium being established th more readily if the disulphide and hydrogen are take as starting materials. The values of P_{S_2} are calculate from the experimental values of P_{H_2S}/P_{H_2} at differen temperatures by means of the equation log P_{S_2} 2 log P_{H_2S}/P_{H_2} + log K, and the isochor equatio gives for the tonality at the reaction, $Q = -20{,}000$ ca at 805°-910°, −28,000 cal. at 910°-1005°, and −24,0 cal. at 1005°-1100°.—**L. Sabbatini**: Pharmacologic experiments with sodium permanganate injecte endovenously. When injected directly into the vein f the ordinary experimental animals, sodium permanganate acts simultaneously on the blood plasma, he histological elements of the blood, and the ndothelium of the vessels, but the greater portion s fixed on the red corpuscles, causing intense æmolysis, hæmoglobinæmia, hæmoglobinuria, and næmia, which, within certain limits, are proportional o the doses injected. At the same time, the salt ndergoes reduction to manganese dioxide, which emains colloidal. Thus, the action of the permanganate is at first limited to a local effect on the lood, which then reduces the salt and acts as an ntidote, preventing it from diffusing as such to the issues and organs and from giving the general action f permanganate. If the dose is small, the animal urvives, since the hæmatic lesion is slight. In a ashed red globule from the blood of the rabbit æmolysis is produced by $7\cdot9\times10^{-16}$ and complete ineralisation by 3540×10^{-16} gm.-mol. of the ermanganate.—G. **Palozzi**: Projective invariants of ontact between plane curves at a point of flexion.—. **Nalli**: Integral equation of the third species and pplications to differential equations (i).—G. **Wataghin**: he general integrals of some differential equations f mathematical physics. An attempt was made reviously to overcome some of the difficulties ttending the explanation of luminous interference n the basis of the hypothesis of the corpuscular tructure of light by considering the light quanta as sulting from the superposition of ordinary, plane, r spherical electromagnetic waves. This decomposition of the quantum into harmonic components akes it possible to show that the quantum hypothesis not contradictory to the undulatory theory of terference and may serve as a foundation for the terpretation of the whole complex of optical henomena. A demonstration is given of a theorem n the solutions of the equation

$$\Delta_2 f - \frac{1}{c^2}\frac{\partial^2 f}{\partial t^2} = 0,$$

hich permits of the construction of models of the ght quantum in conformity with the above views.—. **Raimondi**: Complements relative to the calculation the dynamic action of a current flowing between strip and an indefinite plane wall.—G. **Vranceanu**: he geodesic displacement in anolonomous varieties.—. **Persico**: Molecular velocities, conditions of extation, and probability of transition in a degenerating s.—A. **Quilico**: Action of aminosulphonic acid on saturated compounds. When heated at 140°-150° ith excess of anethole, aminosulphonic acid gives good yield of the ammonium salt of an acid, which converted quantitatively into anisic, acetic, and lphuric acids when boiled with alkaline permanganate lution and has the constitution, $CH_3 . O . C_6H_4 . CH:CH_2) . SO_3H$ or $CH_3 . O . C_6H_4 . C(SO_3H) : CH . CH_3$.—G. **Malquori**: The systems, $Cd(NO_3)_2 - HNO_3 - {}_2O$; $Zn(NO_3)_2 - HNO_3 - H_2O$, and $Mg(NO_3)_2 - NO_3 - H_2O$ at 20°. The salt $Cd(NO_3)_2, 4H_2O$ is in uilibrium with solutions containing up to 52·95 r cent. of HNO_3, the corresponding concentrations the acid for $Cd(NO_3)_2, 2H_2O$, $Zn(NO_3)_2, 6H_2O$, $(NO_3)_2, 4H_2O$, and $Mg(NO_3)_2, 6H_2O$ being reectively 60·01, 34·45, 59·21, and 49·12 per cent. us, whereas tetrahydrated cadmium nitrate may completely dehydrated at ordinary temperature nitric acid (*d.* 1·52), hexahydrated zinc nitrate es only two molecules of water, and hexahydrated gnesium nitrate remains unchanged, under the ne conditions.—F. P. **Mazza**: The rotatory persion of the alkyl aspartates.—Giambattista **l Piaz**: The gneissic digitation of Val Inferno ran Paradiso).—B. **Monterosso**: Observations on sexual biology of the Scytodoids.

Diary of Societies.

SATURDAY, April 28.

Royal Sanitary Institute (at Guildhall, Worcester), at 10 A.M.—T. Caink and others: Discussion on The Worcester Activated Sludge Plant.

Institution of Municipal and County Engineers (W. Midland District) (at Borough Hall, Stafford), at 11 A.M.—W. Plant: Recent Municipal Work in Stafford.

North of England Institute of Mining and Mechanical Engineers (Associates and Students' Section) (jointly with Graduate Sections of North-East Coast Institution of Engineers and Shipbuilders, and Institution of Electrical Engineers) (at Neville Hall, Newcastle-upon-Tyne), at 2.30.—L. H. Forster: Notes on the Conversion of Main Pumping from Steam to Electricity, with Special Reference to the Plant Installed at Messrs. The Stella Coal Company's Clara Vale Pit. —*Papers open for Discussion*:—Some Notes on Accidents from the Use of Explosives, by W. B. Brown; Roof Control on Longwall Faces, J. F. Q. Friend.

MONDAY, April 30.

Institute of Actuaries, at 5.—P. C. Crump: War-time Finance—A Résumé of Financial Conditions during and after the War as they affected Life Insurance Companies.

Royal Society of Arts, at 8.—A. G. Huntley: Applied Architectural Acoustics (Dr. Mann Lectures) (III.).

TUESDAY, May 1.

Royal College of Physicians of London, at 5.—Dr. E. P. Poulton: An Experimental Study of certain Visceral Sensations (Oliver-Sharpey Lectures) (I.).

Royal Society of Medicine (Orthopædics Section), at 5.30.—Annual General Meeting.

Zoological Society of London, at 5.30.—Dr. G. M. Vevers and R. A. Smith: Exhibition of Flint Implements, Flakes, and Cores of Human Origin but of Uncertain Age collected at the Society's Estate at Whipsnade.—H. B. Cott: Report on the Zoological Society's Expedition to the Zambesi, 1927.—O. W. Richards: The Species of Notogonia (Hymenoptera, Larridæ) occurring in the Mediterranean Basin.—Dr. J. Waterston: The Mallophaga of Sand-Grouse.

London Natural History Society (at Winchester House, E.C.), at 6.30.—Dr. S. A. Neave: Mt. Mlange in Nyasaland and its Insect Fauna.

Royal Photographic Society of Great Britain (Pictorial Group), at 7.—The late Mr. Greenall: Southern Italy.

Institution of Automobile Engineers (Luton Graduates' Section) (at Royal Hotel, Luton), at 7.30.—G. D. Ricketts: Modern Methods of Engineering Inspection.

Diesel Engine Users' Association (at 19 Cadogan Gardens, S.W.3).—M. Geroke: Some Considerations regarding the Peak Load Problem and High-powered Peak Load Diesel Engines.

WEDNESDAY, May 2.

Royal Society of Medicine (History of Medicine Section) (Annual General Meeting), at 5.—Papers on the Sources of Harvey:—Prof. F. J. Cole: The History of Embryology.—Dr. J. F. Prendergast: Galen.

Institution of Electrical Engineers (Wireless Section), at 6.—M. G. Scroggie and others: Informal Discussion on Screened-grid Valves.

Society of Public Analysts and other Analytical Chemists (at Chemical Society), at 8.—A. L. Williams: Locust Kernel Gum and Oil.—Dr. W. R. Schoeller and E. F. Waterhouse: Investigations into the Analytical Chemistry of Tantalum, Niobium, and their Mineral Associates. XII. Observations on the Pyrosulphate Hydrolysis Method.—D. B. S. Evans and S. G. Clarke: A New Precipitation Method for the Determination of Vanadium, and its Application to Steel Analysis.—Dr. P. Houseman: Method for the Analysis of Liquorice Mass.

Royal Society of Arts, at 8.—W. Taylor: Standardisation in Apparatus for Science Teaching.

Royal Microscopical Society (Biological Section).

THURSDAY, May 3.

Iron and Steel Institute (Annual Meeting) (at Institution of Civil Engineers), at 10 A.M.—Presentation of Bessemer Gold Medal to C. M. Schwab.—Presidential Address: The History and Latest Development of the Basic Open-Hearth Process.—E. C. Evans and F. J. Bailey: Blast-Furnace Data and their Correlation.—J. H. Jones, J. G. King, and F. S. Sinnatt: Reactivity of Coke.—T. Thomson: The New Plant of the Appleby Iron Co., Ltd.—J. E. Holgate and R. R. F. Walton: Blast-Furnace Practice in Natal.

At 2.30.—H. J. Tapsell: The Fatigue Resisting Properties of 0·17 per cent. Carbon Steel at Different Temperatures and at Different Mean Tensile Stresses.—J. A. Jones: The Properties of Nickel Steels with Special Reference to the Influence of Manganese.—A. B. Everest and D. Hanson: The Influence of Nickel in Iron-Carbon-Silicon Alloys containing Phosphorus.—J. Swan: The Effect of Silicon on Tungsten Magnet Steel.—A. Westgren, G. Phragmén, and Tr. Negresco: On the Structure of the Iron-Chromium-Carbon System.

Ceramic Society (at Atlantic Hotel, Newquay), at 10.30 A.M.—Prof. D. A. Moulton: Refractory Material used as Mortar for Laying up Refractories.—W. J. Rees and W. Hugill: The Effect of Substituting High Silica Sand for some Grades in Lime-bonded Silica Bricks.—G. M. Gill: New Developments in Gas Works Carbonising Plant, with Special Reference to Refractory Materials.—A. T. Green: The Vitrification of Clay Products.—P. Cooper: Refractory Formers for Electric Heating Elements; Some Problems in the Manufacture and Use. W. Emery: Notes on Refractories for Salt Glaze Kilns.

Royal College of Physicians of London, at 5.—Dr. E. P. Poulto An Experimental Study of certain Visceral Sensations (Oliver-Sharp Lectures) (II.).

Chemical Society, at 5.30.—P. D. Coppock, V. Subramaniam, and T. Walker: The Mechanism of the Degradation of Fatty Acids by Mou Fungi. Part II.—A. Robertson and R. Robinson: Experiments on t Synthesis of Anthocyanins. Part V. A Synthesis of 3-β-glucosidy pelargonidin Chloride which is believed to be identical with Cal stephin Chloride.—Dr. H. J. Emeléus: The Phosphorescent Flame Sulphur.—A. J. Berry and Prof. T. M. Lowry. Studies of Valenc Part IX. Molecular Structure of Thallium Salts. (a) Thallium T iodide (with Miss. R. R. Goldstein); (b) Alkyl-derivatives (with F. Gilbert).

Institution of Electrical Engineers, at 6.—F. H. Rosencrant Practice and Progress in Combustion of Coal as applied to Ste Generation.

Royal Society of Medicine (Tropical Diseases Section), at 8.15. Annual General Meeting.

FRIDAY, May 4.

Iron and Steel Institute (Annual Meeting) (at Institution of Ci Engineers), at 10 A.M.—Report of the Committee on Heterogene of Steel Ingots.—V. Harbord: A Comparison of the Most Importa Methods Employed in the Cleaning of Blast-Furnace Gas.—Dr. H. Hatfield: Heat-Resisting Steels. Part II. Mechanical Properti

At 2.30.—T. Swinden and P. H. Johnson: Chromium Steel Rails. Dr. J. Newton Friend: A Study of the Resistance of Over-Stress Wrought Irons and Carbon Steels to Salt-Water Corrosion.—W. Woodward: The Rapid Normalising of Overstrained Steel.—A. Norbury and T. Samuel: The Recovery and Sinking-in or Piling-of the Material in the Brinell Test and the Effects of these Fact on the Correlation of the Brinell with certain other Hardness Tests H. O'Neill: Twin-Lake Crystals in Annealed α-Iron.

Royal Astronomical Society, at 4.30.—Geophysical Discussio Meteors—Mr. Whipple, Prof. Lindemann, and others.

Royal Society of Medicine (Laryngology Section), at 5.—Ann General Meeting.

British Psychological Society (Æsthetics Section) (at Bedf College), at 5.30.—J. A. Thorburn: Is there a Logic of the Imaginatio

Royal Photographic Society of Great Britain (Informal Meeting Pictorial Group), at 7.

Junior Institution of Engineers, at 7.30.—F. C. Dain: The Appli tion of Electricity to Domestic Purposes.

Geologists' Association (at University College), at 7.30.—G. M. Le The Chert Beds of Palestine.—Dr. P. K. Ghosh: The Mineral-Assembl of the Falmouth Granite.

Philological Society (at University College) (Anniversary Meetin at 8.—Prof. D. Jones: Report on Progress of Phonetics.—N. Jopson: Report on Board of Comparative Philology.

Royal Institution of Great Britain, at 9.—Rt. Hon. R. McKenn Credit and Currency.

SATURDAY, May 5.

Royal Sanitary Institute (at Guildhall, Preston), at 10 A.M.—P F. H. Wynne and others: Discussion on The Present Position of Milk Supply.

British Mycological Society (at Cheshunt).—Phytopatholog Meeting.

PUBLIC LECTURES.

TUESDAY, May 1.

London School of Economics and Political Science, at 5.—Prof. Oppenheimer: Tendencies in Recent German Sociology. (Succeed Lectures on May 2 and 3.)

University College, at 5.—Dr. J. H. Burn: The Pharmacolog Evidence for Current Methods of Treatment. (Succeeding Lect on May 2 and 3.)—At 5.30.—Dr. D. R. Fox: Civilisation in Transit.

Gresham College, at 6.—Sir Robert Armstrong-Jones: Phy (Succeeding Lectures on May 2, 3, and 4.)

WEDNESDAY, May 2.

London School of Economics and Political Science, at 5.—Dr. Hall: Some Common Factors in the Economic and Social Devel ment of England in Medieval and post-Medieval Times. (Succeed Lectures on May 9, 16, 23, and 30.)

King's College, at 5.30.—Dr. W. B. Brierley: Present Tendencie the Study of Plant Disease.

THURSDAY, May 3.

East London College, at 5.—Prof. W. C. McC. Lewis: Some Phys chemical Aspects of Malignant Tissue (Cancer).

Institute of Pathology and Research, St. Mary's Hospital, at Prof. D. W. Carmalt-Jones: Iodine in Relation to Goitre.

FRIDAY, May 4.

Oxford University, at 5.—Prof. D. M. S. Watson: Palæontology the Origin of Man (Romanes Lecture).

Royal College of Science, at 5.—Prof. G. Elliot Smith: Conversno Science (Huxley Memorial Lecture).

King's College, at 5.30.—Dr. J. A. Bierens de Haan: Animal Psycho for Biologists. (Succeeding Lectures on May 9 and 11.)

SATURDAY, MAY 5, 1928.

Forestry and Agriculture in Great Britain.

A RECENTLY published part of the *Scottish Forestry Journal* (vol. 41, pt. 2) contains several articles of interest for those who have some acquaintance with forestry practice in Great Britain. Perhaps the paper of chief importance at the present time is that by Dr. John D. Sutherland on the "Economic Balance between Forestry and Agriculture." Dr. Sutherland's main theme revolves round the contention of the Forestry Commissioners that in view of the good work already accomplished, a larger grant should be made to them for the next ten years' work, allusions to which have already appeared in our columns. Dr. Sutherland in his opening remarks states that "there is the certain prospect of a world shortage of coniferous timber within the period of one forest rotation." Opinions differ, as can be readily understood, as to the exact significance to be attributed to the phrase "the threatened timber famine."

Some time ago, reference was made in some short paragraphs under the heading "Log Rolling," in the *Timber News*, to Lord Clinton's remark in a recent address on "Imperial Forestry" read at the Royal Colonial Institute. Lord Clinton stated that it was estimated that the quantity of timber used and destroyed amounted to eight times the annual growth. On this the writer remarks, with particular reference to the subject of timber famine in Europe:

> "This cannot go on for ever . . . we have no great faith—like the masters in the timber trade—in the belief of approaching timber famine . . . we are inclined to the impression that prices of timber will gradually rise after post-war stabilisation, and that in course of time there will be a shortage compared with the preponderating supplies of to-day, and it seems that in hardwoods, as with softwoods, those who warn us of a timber famine are nearer the truth than those who ignore the idea."

In his article Dr. Sutherland contrasts the Government expenditure in connexion with agriculture with that on forestry:

> "It is a fact," he says, "that both food and timber are essential to our existence, that our consumption of the former represents a value of £722,000,000, and the value of the timber used is £63,000,000 (figures for 1925) . . . is it too much to expect that when the subsidies and assistance to agriculture are £16,000,000 the amount presently devoted to the making of timber through the creation of forests might not in the same proportion be £1,300,000 annually instead of about £350,000? If further support of this suggestion

be necessary, it may be represented that the expenditure by the nation on forestry, whatever the amount, is for creative purposes and might be described as a national endowment, and one which will be productive of material absolutely essential, and in this process of production yield a return to the State."

Dr. Sutherland produces many sound arguments in favour of afforestation in his paper, but the one above quoted appears open to question. Both as individuals and as a nation we are greatly impoverished. However desirous individuals might be to form an endowment for the future of their children, let alone grandchildren (as is the case with forestry), their present circumstances preclude the idea. Much of the State expenditure on agriculture is at least profitable to the existing generation, and therefore the taxation imposed for this cause results in some direct return. Few at present alive can hope to share in any future benefits which may accrue from the afforestation work undertaken at the present day. In the opinion of many who have studied this question, the decision which faces the Government, in view of the fact that no very apparent alleviation to the taxpayer is in sight, is on what scale the afforestation work, with due regard to the interests of the taxpayer, should be carried on during the next ten-year period and whether some of the heavy overhead charges could not be curtailed.

Science and Policy in India.

The Development of Indian Agriculture. By Albert Howard and Gabrielle L. C. Howard. (India of To-day, Vol. 8.) Pp. vi + 98 + 6 plates. (London: Oxford University Press, 1927.) 3*s.* 6*d.* net.

THE Oxford University Press is to be congratulated on the foresight it displayed in 1924 in inviting Mr. and Mrs. Albert Howard to prepare a short account of the present position of agriculture in India, and Mr. and Mrs. Howard deserve the warmest thanks of all those interested in agricultural development and research, the education of the farming community, and the social institutions and economic life of the coloured cultivators of Great Britain's tropical and subtropical possessions, not only for the skill with which they have dealt with their subject matter, but also for its timely publication. Their hundred-page volume on "The Development of Indian Agriculture" is a model of compression, not merely a masterly summary, of the salient facts and current opinions regarding the past, present, and future of the industry upon which nine-tenths of the population of India is directly or indirectly dependent. It should prove invaluable as a guide to the labours of the Royal Commission on Indian Agriculture which at present, under Lord Linlithgow, is pursuing its investigations in India; it can also be warmly commended to the members of the Simon Royal Commission for their careful study, not because it deals with the constitutional issues which are their immediate concern, but because constitutional reform without economic and educational reform will do nothing to ameliorate the condition of life of the mass of the population of India, and this is what matters most.

Mr. and Mrs. Howard are concerned mainly with the problem of raising the standard of living of the rural communities of India. They write with an authority based upon twenty years' successful work in the country. They possess the cardinal virtues of faith, hope, and charity: faith in the scientific method, hope for the dawning of the day when the peoples of India possess the knowledge and determination to apply the discoveries of science to the soil which sustains them, and that charity born of sympathy and a ripe understanding of the peasants for whom they labour. They combine a *flair* for research with unusual gifts for administration, the enthusiasm to discover, coupled with the will, capacity, and determination to have their results applied. They are of a type with those public servants of Canada recently described by Prof. McLennan as working for meagre rewards and little recognition to confer incalculable benefits upon mankind. The very nature of their work makes them the architects of a new order, missionaries of an enlightened imperialism, statesmen of the world, not the instruments of parties, factions, or nations. Their function is so to direct the energies of man that he will no longer spend all his days in ceaseless toil for mere existence.

Nothing could illustrate the struggle for existence better than the statistics given in this volume. Out of the 316,000,000 people in India, about 225,000,000 are directly dependent on agriculture. The total area under food and fodder crops, for supplying the cultivator and his cattle with food, is only 220,000,000 acres, that under money crops —out of the proceeds of which the cultivator pays his land revenue and purchases a few necessaries other than food—is less than 40,000,000 acres. The average holding is thus extremely small, in some districts less than five acres in area, and the position is made worse because they are frequently cultivated by methods which are suitable only for large areas. Abject poverty is the result. The majority of the people of rural India live in houses built of mud, thatched with grass, and possess practically no furniture. Small wonder that people living under such conditions are unprogressive.

> They are "for the most part uneducated, illiterate, and almost incapable of thinking for themselves. The majority are born in debt, live in debt, and die in debt. Money-lending has become one of India's greatest industries. . . . Even the best cultivators have little or no capital for developing their fields. Everywhere agricultural land is regarded as a convenient means of investing money so that the rents can provide a certain income. Only in rare cases is money devoted to land improvement. In many parts of the country the pressure of population, both human and bovine, is intense, and but for the high infant mortality and periodical waves of pestilence the position would become desperate."

Keatinge estimates there are nearly 1,000,000 useless cattle in the Bombay Deccan alone—and these have to be fed: as the cow is a sacred animal, and the people mostly vegetarian, they cannot be used for food.

One fact is omitted in this volume which is of the greatest importance. Due largely to the application of the discoveries in medical and sanitary science, and the improvement in means of communication which enable food to be distributed in the event of the failure of the monsoon, the population of India has risen in the last fifty years from about 200,000,000 to its present total of 320,000,000. Now it cannot be pretended that the agricultural and allied services, in spite of their recorded triumphs, touch the fringe of the problem presented by this increase, or that the growth of manufacturing industries in India has done much to improve the general condition of the peoples. There is obviously an urgent demand for the acceleration of the work having for its objects the improvement of methods of agriculture, so that each unit shall yield "either more produce, more valuable produce, or an increased yield of a better quality than the average," and the increase of the area under cultivation. That this can be done is exemplified by some of the results obtained in the past fifteen years. 'Pusa wheats' now spread over an area of more than two and a quarter million acres in the United Provinces, representing a yearly increase of profit to the growers of £2,500,000: heavy yielding varieties of rice now cover 0·8 per cent. of the total area under this crop; 12 per cent. of the area under cotton, and nearly 10 per cent. of that under jute, is now raising improved types; improved varieties of sugar-cane, fodder-crops, ground-nut, and tobacco have also been introduced with successful results. At a conservative estimate, made in 1925–26, improved varieties covered no less than 7½ million acres, representing an enhanced yearly value of more than £5,500,000. Compared with the cost of the services which produced them, the results are a magnificent achievement, but

> "much greater progress could have been made," say our authors, "but for one great obstacle, namely, the fact that the Indian cultivator is uneducated and cannot be reached by the printed word. How greatly the illiteracy of the peasant has hampered the work of rural uplift [my only complaint against the authors is the frequent use of this word 'uplift'] in India will be realised if the spread of the new varieties of Pusa wheats is compared with that of Marquis varieties in Canada and the Northern States of the Union. . . . In 15 years the Pusa wheats have covered a little over 2 million acres. In about the same period the area under Marquis has exceeded 20 million acres."

Mass education of the Indian country-side is the obvious need. By no other means will a desire for progress be kindled among the inhabitants of the villages of India. Unless the educational level is raised it is impossible to achieve lasting results by mere demonstration, except at ruinous expense.

Two aspects of the problem of educating hundreds of millions of people have to be considered, the education of the adult and the education of the child. Grundtvig in Denmark, Plunkett in Ireland, and the General Education Board—the unofficial body which investigated conditions in the southern States of the United States of America—have dealt with the first aspect with such success that prosperity has been brought to peoples which were formerly distressingly poor and unprogressive. The experiments they tried were successful because official effort was deliberately limited to propaganda aimed at creating a demand on the part of the cultivators themselves for the education of their children and for better villages, rather than foisting upon them a programme of education and rural improvement from the outside, and as a first practical step to assist them by the inauguration of co-operative farm demonstration to make the soil yield a higher dividend. Above all, the problem of "rural development was surveyed as a whole, studied as a whole, and dealt with as a whole."

The efforts made in India for the past twenty years, which at first sight resemble closely those adopted elsewhere with success, have been ineffective because of the lamentable fragmentation of effort. "Moreover, the horde of minor officials (mostly townsmen) who now deal piecemeal with the problems of the villager is more likely to exasperate than to awaken him from his present attitude of indifference to all forms of progress." Consequently, just as Mr. and Mrs. Howard advocate a reform of the agricultural research services whereby the plant, for example, cotton, will be regarded as the centre upon which a knowledge of several sciences, of practical agriculture, and of the requirements of the trade will be brought to bear, its activities controlled by an unofficial organisation representing all interested parties, in place of the present officially controlled system based on the separate science, so they recommend the removal of the various agencies which deal with the problems of rural India from official to unofficial control and their consolidation under a Development Board of Rural Reconstruction, upon which the legislature, the executive, the local notables, and the most able of the workers could be represented.

For dealing with the problem of the education of the child in rural areas Mr. and Mrs. Howard suggest that full use be made of American experience. In America the inefficiently staffed, inadequately equipped and poorly built schools were abolished and replaced by a lesser number of central schools, well-staffed and equipped and well-built, the children being conveyed to them at the public expense. This system, it is suggested, could be adopted with great advantage in India. What is wanted is not

> "one poor little school in each of the 7,000,000 villages of India," but from "1,000,000 to 2,000,000 well-constructed central schools, each with suitable equipment, a number of well-trained teachers, and sufficient pupils to feed the classes. Each of these schools, under the guidance of a schoolmaster who should be drawn from a village—with adequate pay and a recognised position of honour in the community—could be the centre of progress of a group of villages. By its means such movements as Co-operative Credit, the Co-operative sale of produce, the establishment of better markets, the demonstration of simple improvements in cultivation, the distribution of improved seed, improved rural sanitation, better housing and better communications will be provided with a suitable meeting place. . . . The people generally will come in contact with the Government in other ways than through the policeman and the tax-gatherer."

In short, Mr. and Mrs. Howard believe that by the reorganisation of research, the concentration of the various departments at work for rural development into a single agency for each province, mass education for adults and children on lines similar to those followed in America,

> "the people [of India] could be taught how to help themselves and how to appreciate and make proper use of funds contributed by the State for the support of local movements. The gradual growth of the rural electorate, capable of intelligent co-operation with Government in the future development of India, would follow."

This volume should not only be eagerly read by the members of the two Royal Commissions dealing with Indian problems; it should also be in the hands of every statesman and politician in India, every student of rural education the world over, and of all those who wish to understand the problems with which administrators and other public servants in the various parts of the British Empire are faced. The problems facing India have been intensively studied for some years. They do not differ essentially from those facing our local governments in Africa. It has been said: "It is one of the defects of our system of State departments that the invaluable lessons of our Indian administration and economic progress—the result of much costly experience and research—and the history of its successes and failures, are not more readily accessible to other tropical dependencies, which are emerging from the state in which India was many years ago." Mr. and Mrs. Howard have done much to remedy this defect.

A. G. Church.

Stellar Thermodynamics.

Thermodynamik der Himmelskörper. Von R. Emden. (Sonderausgabe aus der Encyklopädie der mathematischen Wissenschaften.) Pp. iii + 373-532. (Leipzig und Berlin: B. G. Teubner, 1926.) 6·40 gold marks.

R. EMDEN is well known among students of theoretical astrophysics from his book "Gaskugeln," which summarised and extended the work done prior to 1906 on the problem of the internal constitution of the stars. The present book has many points in common with "Gaskugeln," but it covers a wider field, inasmuch as the recent development of the subject is also considered.

In its scope and arrangement of subjects the book appears essentially as a historic account of our ideas concerning the internal structure of celestial bodies since the foundation of modern astrophysics. The introduction is naturally concerned with the fundamental laws of thermodynamics and their applicability to stellar problems. Next comes a short review of earlier ideas concerning the origin of the energy radiated from the stars: the meteoric hypothesis of Mayer, and the gravitational contraction theory of Helmholtz; and the insufficiency of both, in accounting for the apparently long life cycle of a star, is pointed out. An interesting excursion on meteors in the terrestrial atmosphere closes this first section of the book.

The second section is concerned with the structure of gaseous stars in which the effect of transmission of energy by radiation is ignored. This was the point of view commonly adopted by the pioneer workers in this field in the past century, which led to the conception of stars in convective equilibrium. Most of Emden's work fell within this category, and was ably covered in his "Gaskugeln." By a rare caprice of Nature, it happened that much of this work retained some interest also in the theory of radiative equilibrium of the stars, such that an inclusion of this section in a modern work is justifiable. Besides, this section is concerned with a variety of allied problems in which it is essential to adopt the microscopic point of view of kinetic gas theory. An important problem of this type is, for example, the calculation of the loss of mass from the surface of a star due to random motion of the molecules.

In the third section a step further is taken, so as to include the effect of transmission of energy by radiation inside a star. We are here led through the different stages of development in this phase of the theory, as they are marked down by the names of Schwartzschild, Eddington, Milne, and Jeans. This section is written with sober judgment and becoming reticence with regard to doubtful points, which is much to be commended, considering the delicate nature of the questions involved. The fourth section is concerned with the application of atomic physics to stellar problems. Here is given, for example, a short exposition of the theory of thermal ionisation, which was initiated by Eggert and Saha, and has proved to be of great value in the interpretation of astrophysical facts.

The book thus covers a wide field and bears witness of being written by a broad-minded and intelligent observer. However, in view of the difficult aspects of most questions concerned with stellar constitution, we cannot help thinking that this book would have gained considerably in value if it had been written from an entirely different point of view. In fact, so much space has been spent on the historical side of the questions, that modern aspects of the stellar problems have received too scanty consideration. The author himself admits that the vital questions of stellar theory are really problems in atomic physics. If he had drawn the logical consequence of this recognition he would have devoted the bulk of the book to a thorough discussion of just these basic atomic problems, leaving earlier ideas, which we admit to be inadequate or unessential, to the care of the historian.

S. ROSSELAND.

The Streptococci.

Annals of the Pickett-Thomson Research Laboratory. Vol. 3 (containing a Historical Survey of Researches on the Streptococci). Published for the Pickett-Thomson Research Laboratory, St. Paul's Hospital, 24 Endell Street, London, W.C.2. Pp. vi + 316 + 57 plates. (London: Baillière, Tindall and Cox; Baltimore, Md.: Williams and Wilkins Co., 1927.) 42s. net.

ALL pathologists will agree that our present knowledge of the streptococci, the round-celled bacteria which form chains by successive division, is in great confusion, and that the reason for this is the lack of proper means of identification of the numerous streptococcal species. Yet the importance of the streptococci in both human and veterinary pathology is known to be very great and suspected to be still greater than has been actually established. Scarlet fever, puerperal fever, erysipelas, and the gravest forms of wound infection are accepted examples of streptococcal invasion, while acute and chronic rheumatism, in its many manifestations, heart disease, the enlarged tonsils and adenoids of youth, and the premature decay of teeth, are all diseases of possible streptococcal origin which, for elucidation of their cause, wait upon the identification of the infecting streptococcus by the bacteriologist.

Our authors, Drs. David and Robert Thomson, have attempted to bring some order out of the present chaos. They have assembled the widely scattered literature on the appearance, behaviour, and classification of streptococci, the more important papers being reviewed in great detail and illuminated by comments based on the authors' own observations. This review, which occupies 250 of the 300 pages of letterpress, would alone justify the very great labour and expense involved in the production of the book. Nothing comparable in extent has ever been published on the streptococci, and it may be taken as certain that bacteriologists who have been deterred from research on the streptococci by the thought of the arduous preliminary reading involved will now take up the problems thus prepared and set before them.

The review is followed by an article of 19 pages by Dr. Warren Crowe, giving an account of his methods of differentiation (with 5 full-page colour plates of colonies) and by the authors' list of the streptococci which they think can be identified and classified as separate varieties. They divide the streptococci into five main groups, distinguished from each other by the colour changes produced by the constituent varieties on agar containing boiled blood. Group A produces no colour, group B produces a faint green tinge, group C shows a narrow green or yellow zone, group D bleaches powerfully, producing a wide yellow zone, while group E blackens the medium. Each main group has 4 to 6 sub-groups, based on hæmolysin production, the appearance of the colony and the character of the streptococcal chains; the sub-groups comprise each from 2 to 16 individual varieties differing from each other in their power to produce acid from a set of 10 different sugars. Each of the varieties—there are above 100—is given, finally, 7 photographs (made up in 52 full-page half-tone plates) illustrating the appearance of its colonies under different conditions of culture and illumination and the microscopical characters of the constituent cocci.

Photographs have not hitherto proved of much value as an aid to the working bacteriologist, and it is doubtful whether those in the volume, despite the care and skill which have obviously been devoted to them, will be more successful.

It is perhaps regrettable, since, at least, it is an honest attempt at orderly arrangement, that the general body of bacteriologists are not at all likely to accept the classification proposed, and this for the reason that the characters on which it depends have not the validity required for the creation of bacterial types. The authors discuss this question and appear to conclude that, since cultivation and examination were in each instance performed by them under uniform and optimal conditions, the distinguishing features are stable and will reproduce themselves with all strains of the same type. They admit that strains which have been long in artificial culture may be found greatly altered, but that has not deterred them from classifying and figuring such altered strains on the basis of the latter findings. The consequence is that the hæmolytic streptococci which most probably do belong, for the most part, to one species, find themselves in all three of the main groups A, B, and C.

Bacteriologists are tending rather to admit a wider and wider range of possible variations in the cultural characters of even well-established bacterial species and to choose, as the nucleus of specific definition, the chemical reactions of the bacterial protein displayed in serological tests. It is true that variation is possible even in these, and it may turn out that there is a limbo of less differentiated bacteria from which emerge, and to which return, the definable species as met with in disease and other forms of special bacterial activity. But the serological basis of species differentiation has, at least, the virtue of depending on a single reaction instead of on a complex of characters which so easily leads to the simulation of innumerable varieties.

The volume includes a bibliography referring to more than a thousand original papers, a testimony, if further such were needed, to the industry and devotion of the authors.

In the preface the promise is made that volume 4 of these *Annals* will deal with the pathogenic streptococci, and bacteriologists in general may hope that it will furnish them with an equally useful tool for research on this highly important group.

W. M. SCOTT.

Descartes' Geometry.

La géométrie de René Descartes. Pp. iii + 91. (Paris: J. Hermann, 1927.) 21 francs.

THIS is a reprint—"nouvelle édition" it calls itself—of the great work of Descartes, giving the first exposition (such as it is) of the system of co-ordinate geometry since known as "Cartesian." The reprint comes only two years after another, edited by David Eugene Smith and Marcia L. Latham for the Open Court Publishing Company, and naturally provokes comparison with it. The Open Court edition has the text in the form of a facsimile of the first edition of 1637. The present reprint is not a facsimile, but a reprint in modern type, and it is made more modern by the substitution, *e.g.*, of a^2 for *aa*, and of = for Descartes' sign for equality (a symbol like that used in modern algebras for 'varies as,' but turned the opposite way); it has no historical or explanatory notes, no preface and no index; and it does not give even the date of the edition from which it is reproduced. The Smith-Latham edition, on the other hand, has an English translation facing the facsimile text, and a large number of useful notes, historical and other.

No doubt the present reprint is meant for the French reader, but the question arises, who nowadays is likely to read the "Géométrie" in the original, unless he is studying or writing on the history of mathematics, and wants to understand the exact stage of development represented by that work?—for no one would think of going to it for the technique of modern analytical geometry. As Prof. Loria has remarked, there is a greater gulf between Descartes' work and a modern treatise on analytical geometry than there is between an ancient (*i.e.* Greek) and a modern treatise on any other mathematical subject.

If the book is read from the historical point of view, the reader will certainly want much help in the way of notes showing the relation between Descartes' methods and those of other writers, ancient and modern. Such aids are all the more necessary with a book which is in any case difficult to read, because the author himself purposely left many things obscure or only half explained. There was a reason for this in the general attitude of the mathematicians of the time to one another. Every one wanted to get personal credit for discoveries, and to avoid giving anything away which another could use and then claim as a discovery of his own. So far does Descartes betray this anxiety that he even hints at things which he has not set down but could 'an if he would.' "I hope," he says, "that posterity will give me credit, not only for those things which I have explained, but also for those which I have voluntarily omitted in order to leave them the pleasure of discovering them," as if he wished 'to have it both ways'!

On the whole, the reprint before us seems rather to fall between two stools, unless indeed it is merely intended as a handy book of reference for those who, studying an account of Descartes' work in an ordinary history, wish to look up some particular point in the original. T. L. H.

Our Bookshelf.

Rasa-Jala-Nidhi: or Ocean of Indian Chemistry and Alchemy. Compiled in Sanskrit by Rasacharya Kaviraj Bhudeb Mookerji. With English translation by the Author. Vol. 1. Pp. v + xv + viii + 350 + v. Vol. 2. Pp. ii + 5 + 8 + 10 + 296 + 23. (Calcutta: The Author, 41A Grey Street, n.d.) 10 rupees.

THE author says that he has been a devout student of early Indian chemistry from his boyhood. By accident, he came into contact with a Yogi from whom he learnt much more than could be found in the existing books on Indian chemistry, which he considers to be incomplete, incoherent, incorrect, and in many cases misleading. The Yogi's teaching, however, enabled him to arrange methodically the materials found in the existing books on early chemistry, which were mostly in a chaotic state, and had been neglected for several centuries past. Unfortunately, the author gives no list of authorities for his facts and recipes, though he promises one for the concluding volume (the tenth); it is therefore impossible to assess the work properly from a historical viewpoint. Since, however, he maintains that Rasavidya, or chemistry, was cultivated by the early Aryas some 1950 million years ago, and states that fragments of two or three books written about 898,000 B.C. are still in existence, his claims to be treated as a serious historian are perhaps not very weighty. Mr. Mookerji dismisses Sir P. C. Ray's work on Hindu chemistry as that of an amateur critic, and says that it contains many misinterpretations of important principles, due to a hasty and superficial study of the subject.

It appears that the author is the principal of a college of medical chemistry, as testimonials of cures are given at the end of the first volume. Whether the remedies described in the book are those employed in practice by Mr. Mookerji does not seem clear, but if so, the Indian constitution must be remarkably resilient. Among other bizarre recipes we read that "essence of earth-worms is cool, and cures all sorts of carbuncles and leprosy," besides imparting to mercury the property of withstanding the heat of fire.

The 'chemistry' is equally startling—"mercury is in a state of swoon, when it succeeds in curing diseases without producing any after-effect. The processes of causing swoon of mercury, as known to the expert chemists, are many; of all these, heating with six times its weight of sulphur is the best of all."

It is not improbable that much of the material which the book contains may be of some antiquity, and it is to be hoped that the author will fulfil his promise of adducing his authorities. Until he does so, his book must serve merely to throw into relief the unscientific nature of a queer folk-pharmacology. E. J. H.

Mushrooms and Toadstools: an Account of the more common Edible and Poisonous Fungi of Canada. By H. T. Güssow and W. S. Odell. Pp. 274 (128 plates). (Ottawa: Division of Botany, Dominion Experimental Farms, 1927.) 1 dollar.

THE outstanding feature of this book is its price—one dollar! For a large, well-bound volume of 274 thick leaded pages, with 128 plates containing hundreds of unusually good photographs of fungi, two of these plates being in most delicate colouring, a price of one dollar is literally startling. The book is published by direction of the Minister of Agriculture, Ottawa, and if this is a sample of his direction, one can only fervently wish 'more power to his elbow.' The volume is really an extended bulletin of the Division of Botany of the Dominion Experimental Farms, the senior author being the Dominion botanist. It contains simple but adequate descriptions of the common edible and poisonous fungi of Canada, and although it is far from complete, few if any of what may be regarded as the commonest fungi have been omitted. It is in no sense a 'learned treatise,' and the arrangement adopted might cause a strict systematist to wilt. For its avowed purpose, however, which is "to appeal to students as well as nature lovers, who wish to know the many odd or beautiful forms of fungous growth they may happen upon in their country rambles," it is quite admirable. Four introductory chapters deal with the general structure of the fungi and useful practical hints to collectors. Following these are the illustrated descriptions of 160 species, and then brief but adequate accounts of the preparation and value of fungi as food, of poisoning by fungi, and of mushroom culture. A useful glossary and a good index complete the volume.

To criticise such a work is in very truth to look a gift horse in the mouth, and one can only admire and envy the skill of Mr. Clarke, chief of the Photographic Division of the Geological Survey of Canada, who took nearly all the photographs, and the energy and opportunities of Mr. Odell, who, "in his frequent jaunts through woods and meadows," collected the specimens.

Altogether, a book for every botanist to become possessed of with all possible speed, so that the Minister of Agriculture may be encouraged to direct the publication of others. W. B. B.

Die Tierwelt der Nord- und Ostsee. Herausgegeben von G. Grimpe und E. Wagler. Lieferung 9. Teil 6 c_1 : *Oligochæta*, von W. Michaelsen ; Teil 12 a_2 : *Thaliacea*, von J. E. W. Ihle ; Teil 12 f_1 : *Chondrostei*, von E. Ehrenbaum ; Teil 12 f_2 : *Teleostei Physostomi*, von H. M. Kyle und E. Ehrenbaum. Pp. 44 + 28 + 86. 13·60 gold marks. Lieferung 10. Teil 7 d_1 : *Gastrotricha*, von A. Remane ; Teil 11 c : *Halacaridæ*, von K. Viets ; Teil 12 h_2 : *Teleostei Physoclisti*, 11-15, von E. W. Mohr und G. Duncker. Pp. 56 + 72 + 61-140. 16·80 gold marks. (Leipzig : Akademische Verlagsgesellschaft m.b.H., 1927.)

That section of the present work dealing with the oligochætes contains a unique account of the marine and brackish worms belonging to that order and occurring in the North and Baltic Seas. All oligochætes living in, or at intervals submerged by, water, the salinity of which is greater than five parts per thousand, are regarded as coming within the scope of the present paper. Habitat receives especial attention. The section dealing with the Gastrotricha is very well illustrated and deserves no less praise than the last section.

The portions dealing with the systematics of fishes are, in our opinion, not up to the standard of the remainder of the work. Most of the figures are from familiar books. Nevertheless, the advanced students and amateurs to whom the work is mainly addressed could not be blamed if they failed to recognise some of their fish captures from the figures given. In accordance with the original plan of the book, those fishes of economic importance receive fuller treatment than the others, yet there is a good deal of recent and important work upon the herring which receives no recognition, and although there are references in the text to names apparently to be given in the bibliography, they are not to be found there. In a review of an earlier part of the publication, mention was made of the great usefulness of the table given for the identification of pelagic fish eggs. If this could be included, it seems a pity that there is not more information given upon the larval and post-larval stages of fishes.

Christ the Word. By P. E. More. (*The Greek Tradition : from the Death of Socrates to the Council of Chalcedon, 399 B.C. to A.D. 451*, vol. 4.) Pp. viii + 343. (Princeton : Princeton University Press ; London : Oxford University Press, 1927.) 18*s.* net.

Modern theologians who attempt the most necessary task of devising a scheme of Christian thought at once retaining all the traditional content and yet not incongruous in the light of scientific knowledge, tend more and more to utilise the Greek conception of the *Logos*. It seems evident that the Greek tradition in theology is the right one to follow. Hence the value of Dr. More's book for those students of natural science who take an interest in the problems of theology. It is a short history of the development of Christian theology from the Fourth Gospel to the Council of Chalcedon.

In reading these pages, students of science will find themselves in a world where much seems unfamiliar, but they will recognise the fundamental idea that the reason of man finds its counterpart in the essential rationality of existence. We cannot avoid the conviction that if men of science occupied some of their leisure moments in the study of the origin and development of Christian ideas, they would discover an unexpected source of intellectual interest, and perhaps find an atmosphere less alien than they had imagined, since both science and theology have their origins in Greek thought. J. C. H.

Lectures on the Religion of the Semites : the Fundamental Institutions. By the late Prof. William Robertson Smith. Third edition, with an Introduction and Additional Notes by Dr. Stanley A. Cook. Pp. lxiv + 718. (London : A. and C. Black, Ltd., 1927.) 12*s.* 6*d.* net.

A new edition of Prof. Robertson Smith's lectures was badly needed, for although they were first published in 1889, and the second edition edited by Sutherland Black appeared in 1894, they still hold first place as a classic study of the subject. But a vast amount of material dealing with the Semitic and other religions of the world has accumulated during the last thirty years, and cognisance of this must now be taken. In the new edition, Dr. Stanley Cook has provided a carefully considered introduction, in which he examines Robertson Smith's main conceptions in the light of later developments in the comparative study of religion, and in some two hundred pages of notes has added facts and bibliographical references to further information, which will serve to illustrate and define the position of the beliefs of the Semites in their relation to other systems, especially in the ancient world.

Letters to the Editor.

Coals as Colloid Systems.

IN a memoir on the geology and coal resources of Korea State, Central Provinces, published in 1914 (*Memoirs, Geological Survey of India*, 41, p. 180), I suggested that the bright coal of the Barakar series "judging from its brilliant conchoidal fracture is of the nature of a colloidal substance." I find that H. Potonié had noted the colloidal nature of humus in 1911, whilst Drs. Stopes and Wheeler, in their paper on the "Constitution of Coal," mention H. Winter as believing in the colloidal nature of coal in 1913, the reference quoted (*Glückauf*) not being, however, accessible to me. Later authors have referred to the same point, but I have not noticed accounts of any research specifically directed towards the study of coals as colloid systems. It may be useful, therefore, to refer briefly to data derived from a study of certain Indian coals that appear to provide definite evidence on this question.

For some years I have been interested in the relationship between the specific gravity and ash contents of Indian coals, and I have in particular collected data for the Bokaro (Bihar and Orissa) and Kurasia (Korea) coalfields. These data are discussed in a paper now in the press for the *Records of the Geological Survey of India* (vol. 60, pt. 4).

The most important fact that has been elicited by this research is that the coals from the Bokaro coalfield can be divided into two series according to their macroscopic aspect in hand specimens, and that the series so made are found to yield different types of density–ash curves.

The economically more important series is the *vitrain–durain series* ranging from *bright coal* with about 1 per cent. of ash through various types of *banded silky coals* to *dull coal* with ash contents up to about 40 per cent. For these coals the density–ash relationship is linear. If g be the specific gravity of any piece of coal in this series, k the specific gravity of ash-free vitrain, and a the ash contents, then it is found empirically that the following relationship holds:

$$a = 100(g - k).$$

For Bokaro $k = 1{\cdot}26$. Hence, if in the jungle a piece of coal is found to have a specific gravity of 1·50 (by means, for example, of Walker's balance), one can predict that the ash contents will be found to be $100 \times (1{\cdot}50 - 1{\cdot}26) = 24$ per cent. Actual analysis yields results often within 1 per cent. of, and rarely so much as 3 per cent. different from, the predicted value. Larger deviations than this can be attributed to special causes; for example, ash of unusually high specific gravity due to a high proportion of ferric oxide.

The second series contains types ranging from *shaly coals* through *coaly shales* to *carbonaceous shales*, in which layers of vitrain and carbonaceous shale are interlaminated in various proportions. The relationship between specific gravity and ash contents for this series is not linear, but is expressed by a curve of the same shape as would be obtained by mixing mechanically two substances of different specific gravities.

Searching for an explanation for the different types of relationship between specific gravity and ash contents in these two series, I find that an appeal to colloid chemistry appears to provide the answer, and that my empirical data are explicable if we regard the vitrain–durain series as a series of suspensoid colloid solutions, and the shaly coals, coaly shales, and carbonaceous shale as a series of coarse suspensions, often with layers of vitrain.

Reverting now to the vitrain–durain series, I may mention another curious fact. On comparing the proximate analyses and specific gravity of vitrain from various coalfields, I find that the specific gravity *increases* with the moisture contents, but not according to a linear rule as for the ash contents, the few data so far collected yielding a curve convex towards the density ordinate. These data find a simple interpretation if we regard the moisture as present in a colloidal state, as in a gel or in an emulsoid, in moisture-free vitrain.

Durain has been shown by various observers to contain both vegetable detritus and vitrain, as well as a variable quantity of 'ash.' Recalling this, it appears that on the basis of the data referred to above we can describe (1) *vitrain* as a colloid system (either gel or emulsoid) containing moisture; (2) *durain* as a disperse system in which vitrain is the dispersion medium, whilst the ash contents (suspensoid) and the vegetable detritus (coarse suspension) are present as disperse phases.

If these suggestions are well founded, then light may be thrown on certain practical aspects of coal (1) prospecting, (2) beneficiation, (3) coking, and (4) conversion to liquid fuel. The points are noticed in the paper mentioned and need not be discussed further here, except that, with reference to the coking coal, I may mention that my data indicate that high moisture contents are much more harmful to the coking properties than high ash contents. (These conclusions concerning coking coals are in harmony with results obtained by Mr. Balaram Sen, of the Tata Iron and Steel Company, as described by him at the recent meeting of the Indian Science Congress in Calcutta.)

The suggestions contained in this paper are really based on the consideration of coals as specimens representing points on density–concentration diagrams of various types of disperse systems. It appears that much valuable information would result from an exact study of the specific gravity of selected specimens of coal in conjunction with various properties both physical or chemical. In this letter, for example, vitrain has been treated as a homogeneous substance acting as the dispersion medium for the ash contents and vegetable detritus. That it is really extremely complex is of course well known; and various methods of attack have been devised in the attempt to solve its constitution. Little success, however, seems hitherto to have been attained. Perhaps a study of vitrain, and of coal in general, from the physico-chemical point of view might help. Thus, since the paper referred to above was sent to the press, I have been comparing analyses of similar coals from different fields. This comparison reveals curious relationships between 'volatile matter,' 'fixed carbon,' and specific gravity. Taking matched pieces of coals with almost identical ash contents, and not very dissimilar moisture, these comparisons indicate that for each pair higher specific gravity almost invariably means higher 'volatile matter' and lower 'fixed carbon.' We do not know the condition in which the 'volatile matter' and 'fixed carbon' is present in coals, but the facts exposed by these comparisons suggest several questions. Is the moisture-free vitrain itself a colloid system? Has the component of this system that yields 'fixed carbon' a lower density than that which yields the 'volatile matter'? Is there actually free carbon in colloid solution in the hydrocarbon complex, or are we dealing with a colloidal association of two series of compounds, one of which series yields the major portion of the 'fixed carbon' on the application of heat, whilst the other series yields the major portion of the 'volatile matter'?

In conclusion, one may say that the data to which reference is made in this letter seem to indicate that much valuable information might be obtained from a systematic study of coals as colloid systems; not being myself a student of colloid chemistry, but a geologist with no opportunity for physico-chemical research, I have, therefore, ventured to direct attention to these data and to make some apparently rash suggestions in the hope that they may attract attention to the subject and cause others more competent to undertake the careful research that the preliminary data seem to warrant. L. L. FERMOR.

Geological Survey of India, Feb. 16.

Light and Sight.

ALL the facts point to the conclusion that vision takes place by stimulation of the cones of the retina through photo-chemical decomposition of the liquid surrounding them which is sensitised by the visual purple. The rods are not percipient elements, but control the visual purple. Helmholtz stated that there was no evidence that the rods were percipient elements. This theory explains numerous facts which are otherwise inexplicable, such, for example, as the change in position in the field of vision of after-images on movement of the eye. Two after-images may combine into one, or a red after-image may go right through a green one. This proves conclusively that the stimulus is liquid.

Apart from the numerous facts against the duplicity theory, which supposes that the rods are percipient elements for perception in a dim light, it will be found that it is supported almost entirely by misstatements, namely, (1) that certain animals have only cones, and others have only rods; (2) that the periphery of the retina is colour-blind; (3) that the eye is totally colour-blind in dark adaptation; (4) that the Purkinje phenomenon and the recurrent image are not found with the fovea. With regard to these I offer the following criticisms:

(1) Though I have examined numerous collections I have never been able to find any animal with only rods or only cones, neither have I found anyone who has seen such a retina. The tortoise is the most quoted; it is stated to have only cones. The rods and cones in the retina of the tortoise are as clearly defined and distinct as in the human retina.

(2) The periphery of the retina is not colour-blind when colours of sufficient intensity are used. The reader can test this for himself with a doctor's red lamp. He will find he can see it as red to the extreme periphery.

(3) In dark adaptation the eye is not totally colour-blind. Further, there is no scotoma or blind area corresponding to the rod-free portion of the macula which is equal to a visual angle of about three degrees.

(4) The Purkinje phenomenon and recurrent image are found with the fovea.

Hess showed not only that the recurrent image was found with the fovea, but also that it was bent outwards at this region as it would be if the visual purple had to flow into the fovea.

F. W. EDRIDGE-GREEN.

London, April 21.

PROF. HARTRIDGE's letter in NATURE of April 21 is of interest if only for the reason that it exposes our ignorance of the history of human vision. Apparently those who have studied this problem have not yet established any conclusion which limits the field of speculation. It would scarcely be possible to find suggestions more diverse in character than the three already made in this discussion, and it is doubtless much easier to add to the variety than to demonstrate the impossibility of those already put forward. I do not claim to have shown that Sir John Parsons' suggestion is impossible; having pointed out that an additional link is needed to complete the chain of his argument, I merely venture the opinion that this link is very unlikely to be found.

In his third and fourth paragraphs, Prof. Hartridge attempts to provide this missing link, but since he prefers another theory he is perhaps conscious that something is still wanting. Unfortunately, I find his third paragraph unintelligible, and part of the fourth is so ambiguously worded that it would not be profitable to discuss it. It may, however, be as well to say at once that similarity of the two curves Sir John mentioned is not a factor in the problem; the only point under consideration is the occurrence in the same neighbourhood of the peaks of both curves. Since the distribution of solar energy is known, nothing can be gained by introducing into the discussion such foreign considerations as experimental apparatus.

Many readers of NATURE may like to see reproductions of Prof. Wood's photographs, and read his own explanation of these effects, before deciding whether Prof. Hartridge's assumption that they are faulty and misleading photographs is well founded. They will be found in the *British Journal of Photography* for Aug. 12 and Oct. 28, 1910. If, after reading and inspecting them, Prof. Hartridge has any lingering doubts about the reality of these effects, I suggest that he should himself take corresponding photographs through filters of the types used by Prof. Wood, utilising, of course, the much more convenient plates that are now available.

The explanation of our limited visual sensibility proposed by Prof. Hartridge scarcely seems to me compatible with an evolutionary outlook. The words 'difficulty' and 'absence,' suggesting as they do such questions as 'who found it difficult?' almost carry the discussion into the domain of theology. In any event, it is not a view of which my opinion is likely to interest others.

An inappropriate choice has been made in selecting the visibility of a thin dark line as an illustration of the finer powers of the eye; there is no mystery about the explanation. The phenomenon is independent of resolution, and, despite his penultimate paragraph, I can scarcely think that Prof. Hartridge commits such an error as making the line width a function of the resolving power. What is yet uncertain is how it comes about that the eye can detect want of alinement of two parallel lines when the displacement corresponds to an angle of about one second at the eye, and can discriminate between an outline formed by two perpendicular straight lines meeting in a point and another formed by two perpendicular straight lines joined by a circular arc of a radius so small that the separation of the pointed and rounded contours, if the straight lines were superposed, would be much less than the projection, on the plane containing the lines, of the diameter of a single retinal cone. Does Prof. Hartridge's theory give an adequate explanation of these facts?

Is the eye capable of making these refined judgments without moving in its socket, and can the unattached ends of the cones move? Is there any evidence which supports some of the theories offered to reconcile the appreciation of these small differences of position with the comparative coarseness of the unit retinal receiver, and tends to discredit the others? When we have obtained answers to such questions we may begin to feel more secure in our theories.

The distinction between the "Optical Paradox" and the problem of measurement has been discussed in my reply to Dr. Campbell. The word optical is of some significance, for the special conditions of this experiment enable us to disregard factors such as memory and fatigue, which introduce uncertainty into many other experiments on sensations.

The Polarisation and Fading of Short Wireless Waves.

The effect of the earth's magnetic field in altering the plane of polarisation and producing circular polarisation in a transmitted wireless ray has been fairly fully discussed recently by Nicholls and Shelling[1] and by Appleton.

Examples of this effect have been observed at night time when the ray from a vertically symmetrical aerial gives a received ray either partially or wholly horizontally polarised, and consequently an erroneous bearing. Further, rather more definite indications of these polarisation effects have been observed on very short waves in two sets of experiments originally started early last year. In these a receiver consisting of a vertical aerial coupled to a closed loop rotating about a vertical axis was used. Such a receiver has unidirectional receiving characteristics. The E.M.F. in the vertical aerial can be made to balance that induced in the loop when the plane of this is in the plane of the incoming ray, but maximum signals will be obtained if the loop is rotated 180°. The position of the loop when zero signals are obtained is an indication of the direction of the station. This arrangement can also be used to indicate the existence of a circularly or elliptically polarised ray to show the direction of rotation of this ray. In using this receiver in April of last year, on the short wave band between 14 and 50 metres, it was found that on certain occasions the received ray was circularly or elliptically polarised.

The results were not numerous, but quite definite, the conditions under which circular polarisation occurs being relatively rare. The effect has not been observed on long-distance stations, and it appears to be most marked on stations just outside the skip distance. The stations observed giving the effect were:

			Wave.	Direction.
(1)	PCMM	Kootwick, Holland	27 m.	East.
(2)	PCJJ	Eindhoven, Holland	30 m.	Slight S. of E.
(3)	Unknown	Station probably Belgian		S.E.
(4)	GBK	Bodmin[2]	26 m.	W.S.W.
(5)	GLQ	Ongar	24 m.	W. nearly.

The first three stations to the east and south of us always showed circular polarisation in a clockwise or right-handed direction; the latter two in a counter-clockwise or left-handed direction. The observations were all made in the daytime; unfortunately, there were no stations to the north on which to test, so that the information is rather incomplete. The explanation is obviously connected with the double refraction suffered by two circularly polarised components of the plane polarised wave emitted; one of the components being more bent than the other, the two will be separated near the edge of the skip distance where the effect is observed.

It has not been possible yet to trace the two rays which must pass through a medium of variable electronic density, partly along and partly across the earth's magnetic field, in sufficient detail to account for the difference in direction of rotation of the rays according as they travel eastward or westward. But it might be surmised that at greater distances, that is, well outside the skip distance, both the rays into which the original plane polarised wave is split will reach the receiver, where they will combine to produce a plane polarised ray, the direction of which will depend on the distance traversed by the ray through the medium and the strength of the magnetic field. This resultant direction will vary momentarily with slight changes in the path and the earth's magnetic field,[3] with the result that the vertical field will vary from time to time and produce fading. But fading from this cause, which is due to a bodily rotation of the electric vector, will produce opposite effects on a vertical and horizontal aerial perpendicular to the ray. In fact, the fading on one will be the inverse of the fading on the other, for when the vertical electric force is a maximum the horizontal force is zero and vice versa. Experiments made recently confirm this view, at least in certain cases. In Fig. 1, simultaneous fading records taken on a horizontal and vertical aerial are shown, and it is clear at a glance that these are opposite in phase.

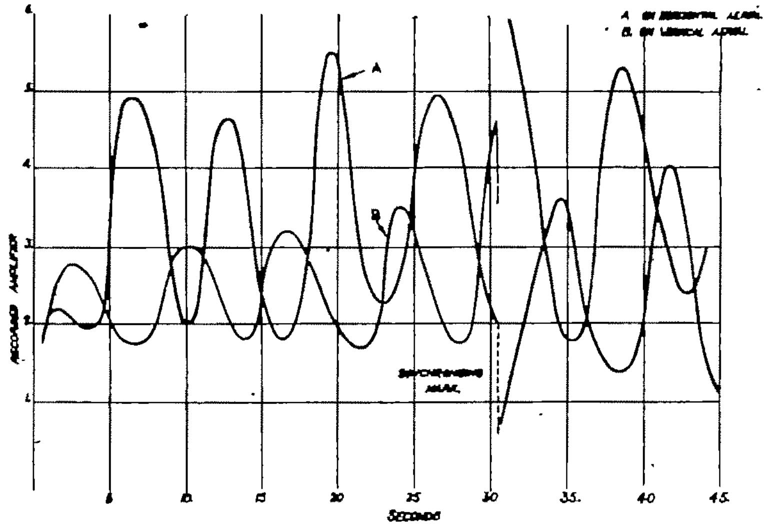

Fig. 1.—Strength of signals from PQW beam station, Lisbon, λ = 15·6 metres, sending high-speed dots.

The observations were made on PQW, a beam station at Lisbon, and many more records showing the same characteristics have been taken. Apart from the theoretical interest, these results have great practical value in devising systems which will eliminate, or at least reduce, fading.

Whether all short wave fading is of this type remains to be seen, but further experiments seem to show that this is not the only type of fading.

Thames Floods.

THE Thames flood of Jan. 6–7 last has served to direct attention to the conditions under which these visitations are developed. From the concluding paragraph of the review of Messrs. Loughton and Heddon's volume on "Great Storms" (NATURE, Mar. 31), the natural inference is that northerly gales are necessary to drive the North Sea tide into the Thames. The authors, however, do not limit themselves to northerly gales. At page 70 they again mention northerly gale floods, but they also bring in the Thames flood under the great storm of November 1703, in which the wind "did not veer to the north-west in time to produce the effect to its full extent."

Of meteorological information contained in the log books of more than a hundred ships of the navy of that period I made a special collection for an article on this great storm, which appeared in the *Cornhill Magazine* for November 1897. The records enable me to state definitely that throughout the night of November 26–27 the storm maintained its south-westerly direction, at no time veering beyond W.S.W., between Rye, the Downs, the Thames Estuary as far north as the Long Sand, 51° 50′ N., and on the Dutch coast. Farther north, off Harwich, the wind veered to W. and W.N.W. about 11 A.M. on Nov. 27; off Yarmouth, after 10 A.M.; off Haisbro', very violent from S.S.W. at 6 A.M., shifted to N.W., and continued very violent until 11 A.M., then it abated (time of the shift not stated); off Claypole (the Wash), extremely hard S.W. gale, apparently veered to N.W. at 6.30 A.M., when "our small bower cable parted"; off Grimsby, after a stormy night at S.S.W. the wind shifted to N.W. at 5 A.M. and blew a violent storm; off Scarborough, while at anchor, from noon until midnight, moderate and fair weather, wind S.S.W.–N.W.; sailed at midnight, and soon ran into hard gales with storms of rain, by 4 A.M. blowing very hard, wind W.N.W.–W. by S.

From these facts it is obvious that during both the rising and the subsequent falling of the North Sea tide, between the Wash and Harwich, the hurricane continued to blow hard from S.W., that is, dead against the rising tide. In these circumstances the Thames flood was an extension of the great floods raised by the violent storm along our south-western and southern coasts. This is practically on all fours with our experience in January last, when the country was swept by a violent south-westerly storm, with wind velocities ranging upwards to 85 miles an hour, and the veering to W. or N.W. on the North Sea being too late and not far enough north to affect materially the east-coast tide. As was stated in the *Times* of January 9, the heavy south-westerly wind "is thought to have been the determining factor, for it piled up the southward flow of the tide in the Straits, and so diverted an unusual quantity of water into the Thames Estuary."

As the coast from about Lowestoft into the Thames runs due south-west, gales from between N. and E. or S.E. are necessary to raise the river above the normal level. So long as our gales maintain a direction between S. and W., they keep in check the North Sea tide, and according to circumstances, as recently, flood the river from the Channel.

In the *Meteorological Magazine* for March 1927, p. 35, discussing the great storm of 1703, occurs the following: "Over England the storm was succeeded by an intense anticyclone, for on the 28th [of November] there was a north wind of unusual violence in the North Sea, which caused a very high tide in the Thames." The particulars in the ships' logs show that the south-westerly type of disturbed weather was maintained until the close of the month; the *Deal Castle*, which left Scarborough at midnight of Nov. 26, took 80 hours to beat down against the head wind, casting her anchor off Yarmouth at 9 A.M. on Nov. 30. Daniel Defoe, in his collection of information, prints in full communications he had received from three ships cast adrift early in the morning of Nov. 27 in the southern part of the North Sea, all helpless and carried away northward, one as far as Scarborough; another driven "at a great rate" before the storm to the Norwegian coast by Tuesday, Nov. 30; and H.M.S. *Association* drifting so far as Gothenburg by Dec. 11, the only northing in the wind during the fortnight being a brief interval of N.W. wind on Dec. 4, off the Elbe. These northward driftings would have been impossible against "a north wind of unusual violence," which itself would have been a very striking occurrence in an intense anticyclone, where naturally we should expect to find a dead calm and very light variable breezes.

HY. HARRIES.

April 12.

The Disappearance of Gases into Glass under the Action of the Electric Discharge.

THE passage of sodium through glass under the influence of the electric discharge is well known (Burt, *Phil. Mag.*, 49, 1168; 1925. Taylor, *Jour. Scient. Instrs.*, 3, 12, 400; 1926). The present writer showed (*loc. cit.*) that with neon lamps or discharge tubes the action was reversible. If the molten sodium nitrate, which is used as electrolyte, was maintained at negative potential with respect to the internal electrodes (about 300 volts negative), then the inside glass wall became covered with negative glow. A current of many milliamperes flowed initially, but fell off with time in an almost exponential manner to a constant smaller value. Similar results were obtained with other electrolytes and with conductors such as mercury.

The potential required to strike a discharge was independent of the temperature (60° C. to 400° C. examined), but the current fell off rapidly with decrease of temperature.

With such a discharge the hydrogen contained in the neon lamps—indicated spectrographically—disappeared rapidly and only a trace remained after a run of five minutes. On continuing the discharge the carbon monoxide bands appeared. The carbon monoxide arose largely from an electrical action, not from thermal decomposition.

Experiments were carried out in a specially constructed apparatus (soda glass) in which positive ions obtained in various gases at low pressures by means of a seven-metre wave electrodeless discharge were pulled out by an electric field to the walls of a thin-walled glass bulb immersed in molten sodium nitrate. The glass apparatus was thoroughly 'baked out' at high temperature and subjected to the action of the electrodeless discharge before results were taken.

The currents flowing through the glass walls of the bulb and the gas disappearance were measured concurrently. Experiments were made on hydrogen, oxygen, nitrogen, helium (mercury vapour frozen out in all cases by liquid air trap), and the results showed:

1. For hydrogen, oxygen, nitrogen, the quantity of gas disappearing is directly proportional, within the limits of experimental error, to the quantity of electricity transferred through the glass walls.

2. For hydrogen, every electron charge passed involves the disappearance of one hydrogen molecule.

3. For oxygen and nitrogen, every two electron

charges passed involves the disappearance of one atom of oxygen or nitrogen respectively.

4. For helium (continually purified by carbon in liquid air), a current flowed but no disappearance of gas took place.

Thus with hydrogen at an initial pressure of 2·5 mm., in 21 min. the pressure fell to 0·03 mm. The current through the glass (at 480 volts) was variable (6 to 16 m.a.) Assuming H^+ as carrier, then, from the electrical quantity, 1·16 c.c. at N.T.P. should have disappeared. Actually 2·05 c.c. disappeared. With initial pressure 0·057 mm. the current was 0·5 to 0·1 m.a. (500 volts), and the estimated disappearance was $22{\cdot}7 \times 10^{-3}$ c.c. at N.T.P. The actual disappearance was 41×10^{-3} c.c.

Experiments carried out on the conduction of glass and quartz at temperatures such as those used in the above experiments showed that the conductivity was considerable and the mechanism largely electrolytic. Only a relatively small quantity of the gas that had disappeared was recovered on heating, and the electrical action was not reversible (sodium was introduced on reversing). Experiments carried out to test whether the gas passed through the glass walls and could be collected have, up to the present, given negative or inconclusive results.

The non-disappearance of helium shows that the action is not an accelerated diffusion through the glass pores, for, in that case, helium should pass through about twenty times as quickly as hydrogen.

The action appears to arise from an electrolytic decomposition of the glass which probably results, in the case of hydrogen, in the formation of water which penetrates deep into the glass structure.

With mercury discharges gas is usually brought out of the walls.

The above actions are probably of fundamental significance in most phenomena of 'clean-up' or gas disappearance into glass walls.

JAMES TAYLOR.

Trinity College,
Cambridge, April 11.

Rare Fishes in the North Sea.

THERE are a good many North Sea fishes which never pass their whole lives in that sea, but only enter it for limited periods, in quest of spawning-grounds or of food. Amongst these are several important species, such as the hake and the halibut, the mackerel and the tunny; and others also of less importance, such as the gurnards, the anchovy, the horse-mackerel, and the monk or angler (Lophius). While all of these arrive in sufficient quantity to be more or less important to the fisherman, there are others which come in small shoals or as individual stragglers, and so come to be considered as rare and unusual occurrences. It happens that within the last couple of years or so some of these casual visitors have been unusually plentiful, and have attracted the attention of the fishermen.[1]

Among these recent visitors has been a number of sharks, of more or less uncommon species. The Thresher shark (Alopias) is one of these; another, and a greater stranger, is the great Basking Shark of Atlantic waters (*Selache maxima*). Another stranger to the North Sea is the Six-gilled Shark (*Hexanchus* or *Notidanus griseus*, L.), which has its home in the Mediterranean and neighbouring parts of the Atlantic, but has of late occurred in our home waters in quite unusual abundance. It has been caught especially on the Viking Bank, to the westward of the deep Norwegian Channel, and in such numbers as to become of almost regular occurrence in the fish-markets of Germany, where these and other sharks are in demand for food and fetch very good prices.

Even more remarkable perhaps than these is a long succession of captures of Ray's Bream, a fish of remarkable and striking appearance, which up to very lately had been but seldom recorded from the North Sea. Of late it has been taken in the English Channel and on the Viking Bank; and specimens have been caught or cast ashore in a large number of places all along the east coast of Great Britain from Cromer to the Dornoch Firth. One was lately caught in a flounder net on the Swedish coast of the Ore Sound; and there is an earlier record so far east as the Pomeranian coast of the Baltic.

In the past few months there have also been caught on the Viking Bank by German steam-trawlers certain other very rare species:

1. The so-called 'Devil-fish' (*Epigonus telescopus*, Risso; formerly wrongly named Pomatomus). This is a perch-like fish never before recorded from the North Sea; its true home is in the southern Atlantic, for example, near St. Helena. It is a dark-coloured fish, with enormous shining or luminous eyes. Our North Sea specimen was 57 cm. long, and was trawled at the very considerable depth of 230 metres.

2. The Blackfish (*Centrolophus pompilus*, Risso) belongs to the family Stromateidæ, and has a certain outward resemblance to some of the flatfishes. A specimen (53 cm. long) was caught recently in 59° 20′ N., 3° E.; and another a couple of years ago, on the Danish side of the Cattegat. It has been recorded before from the North Sea, but by no means often; it is an Atlantic fish, going as far south as Madeira. An allied species (*C. britannicus*) has occasionally been captured in the western part of the Channel.

3. The Snipefish, or Trumpet-fish (*Centriscus* or *Macrorhamphus scolopax*, L.), is a fish of curious appearance, with a small toothless mouth on a long tubular snout, well known in the Mediterranean. It has been observed a few times on the Cornish and on the Irish coasts, and on one previous occasion in the North Sea, near Arendal on the south coast of Norway.

All these rare Atlantic fishes come from the deep water of the Viking Bank; and it would seem necessary to suppose, in order to account for their presence there, that they had been transported by a submarine current from the Atlantic rounding the plateau of the northern North Sea and making its way into the Norwegian Channel. But while Ray's Bream, the Devil-fish, and the Blackfish may all be considered deep-water forms, and might well have come by such a deep-water under-current, it is somewhat remarkable that the Snipefish is known to prefer soft ground near to the coast in waters of only moderate depth—at least in its home in the Mediterranean.

Hamburg.

Stark Effect and Series Limits.

THE treatments of the Stark effect found in the literature concern themselves chiefly with the behaviour of atoms in the lower quantum states, a problem to which the theory of perturbations can be applied. Consideration of the effect of the external electric field on highly excited atoms necessitates the discussion of the complete equations, in particular with regard to the existence of conditionally periodic orbits. The investigation which we have carried out gives a negative upper limit for the energy of quantised orbits in a hydrogen-like atom, and shows that there exist various types of unquantised orbits which have negative energies.

---

[1] Cf. *Der Fischerbote* (Hamburg), p. 487, 1927; p. 126, 1928.

The energy of a periodic orbit must be less than

$$-\frac{3}{2}\left(\frac{eFp_\phi}{\sqrt{m_2}}\right)^{2/3} \quad . \quad . \quad . \quad . \quad (1)$$

where F is the magnitude of the applied field. This necessary condition is sufficient only for small values of F and of the angular momentum p_ϕ. There can, however, exist aperiodic orbits of less, as well as of greater, energy than this value, and in one class of these orbits the electron may approach the nucleus within distances comparable with the dimensions of the periodic orbits. The lower limit of the energy of these latter orbits is approximately

$$-2e\sqrt{eF} \quad . \quad . \quad . \quad . \quad . \quad (2)$$

As a result, the line spectrum will not be continued to the normal spectral limit, but will end to the long wave-length side at a point which depends on the field in the gas; the continuous spectrum associated with ionisation or recombination will also extend to the red of the limit.

Since any atom becomes hydrogen-like as one of its electrons is removed to higher quantum states, expression (2) can be used to calculate the apparent limit of any continuous atomic spectrum. The following table gives the observed maximum and calculated limit of the continuous spectrum for the available data for which an estimate of the mean field strength can be made.

Element.	Limit.	Field. (e.s u)	Maximum (cm⁻¹ from Limit).	
			Observed.	Calculated.
H	Balmer	6	330	270
He	$2s$	3	175	190
Cs	$2P$	8	250	310
Cs	$2D$	8	300	310

The data for hydrogen are taken from the measurements of Yü (*Lick Obs. Bull.*, 12, p. 104; 1926) on stars of class *A* and *B*. Russell's estimate (*Astrophys. Jour.*, 59, p. 197; 1924) of the field in the sun is used for these stars, since the ion concentrations may be considered the same in the two cases. The data for helium are from the work of Paschen (*Berl. Sitzungsberichte*, p. 135; 1926), and those for cæsium from the recent measurements of Mohler (*Phys. Rev.*, 31, p. 187; 1928). The field in this last case was estimated from Mohler's measurements of ion concentration in a tube similar to the one in which the spectrum was observed (as reported at the meeting of the American Physical Society, New York, Feb. 25, 1928), using the formula of Holtsmark (*Ann. d. Phys.*, 58, p. 577; 1919). Considering the rough methods of estimating the field and the fact that we have applied a theory of homogeneous fields to the stray fields arising in an ionised gas, the agreement is satisfactory.

A paper discussing this subject in more detail is being submitted to the *Physical Review*.

The Buoyancy of Whales.

The hydrostatic equipment of the whale would be incomplete without some means of enabling it to alter its buoyancy at will: these means are doubtless the lungs and chest.

The lungs and chest of whales are known to be very elastic and capable of great expansion and contraction. When the whale wishes to sink, it compresses its lungs, and allows them to expand when it wishes to rise or float. In whales that die at the surface and float, these organs are doubtless in a state of expansion, and in those that die at a depth in a contracted and airless one. In the latter, that is, in those that die at a depth, the chest and lungs are compressed; the blow-hole valves yield to the pressure from within (but not to that from without); the imprisoned air escapes; the chest contracts; and the body sinks. In the former, however, that is, in those that die at the surface, the chest and lungs remain expanded and the body floats.

In whales, in the intervals between the respirations, the air in the chest, for hydrostatic reasons, may be in a more or less compressed state. Consequently, when the whale dies at the surface, its chest may expand somewhat, but it is difficult to see why, and bearing in mind the mechanical nature of the valves, even to see how more air can enter it, as Mr. Taylor suggests.

Except in death from asphyxia, in which the animal's body doubtless sinks, no matter at what depth death takes place, the answer to the question at issue, namely, why do whales recently dead in some instances float, in others sink, appears to depend on the depth at which death takes place; for a certain degree of compression of the chest is necessary to overcome the blow-hole valves and cause the air imprisoned in the chest to escape. Given the necessary pressure, that is, if death takes place at a sufficient depth, the body sinks, but failing this, that is, if death takes place at or near the surface, the body floats.

Granted that the tendency of the whale's body to float or sink depends entirely on the state of its chest and lungs, and given the weight of a dead one that sinks, the lungs and chest of which are presumably in the fully contracted state, or the weight of the parts that in the living one appear above the surface when the animal is motionless and its chest and lungs are presumably in the opposite condition, it follows that the whale's 'vital capacity,' or the volume of the air it inhales and exhales when breathing deeply, is ascertainable. Making use of certain imperfect data, a large Greenland whale, estimated to weigh 70 tons, had a vital capacity amounting to about 250 cubic feet.

Whales struck with the hand harpoon probably never die at once, and when the simple gun harpoon was substituted against them, did so very rarely; but when they died under water, presumably from asphyxia, they did so irrespective of which weapon was used.

Of 203 Bottlenose whales captured in 1882, only one was shot dead and only one died under water; the former floated, the latter had to be hauled up (see Log of *Eclipse*, *Land and Water*, Dec. 1882). Of about the same number of Greenland whales captured by Scoresby senior in a number of years, a larger number died under water and had to be hauled up; but his catches largely consisted of young whales, and, as his son states, "it is not unusual for small whales to run downward until they exhaust themselves so completely that they are not able to return to the surface, but are suffocated in the water."

In conclusion, whales killed with the hand harpoon or with the simple gun harpoon usually die at the surface and float, while those killed with the bomb harpoon, as is well known, usually do so under water and sink. The latter appear to do so because death is seldom instantaneous enough to prevent them leaving the surface, yet the injury done them is usually so serious that they are unable to regain it and consequently die under water from asphyxia.

The Optical Analogue of the Compton Effect.

The presence in the light scattered by fluids, of wave-lengths different from those present in the incident light, is shown very clearly by the accompanying photographs (Fig. 1). In the illustration (1) represents the spectrum of the light from a quartz mercury vapour lamp, from which all wave-lengths greater than that of the indigo line have been filtered out. This line (4358 A.) is marked D in the spectrogram, and C is the group of lines 4047, 4078, and 4109 A. Spectrogram (2) shows the spectrum of the scattered light, the fluid used being toluene in this case. It will be seen that besides the lines present in the incident spectrum, there are several other lines present in the scattered spectrum. These are marked *a*, *b*, *c* in the figure, and in addition there is seen visually another group of lines which is of still greater wave-length and lies in a region outside that photographed. When a suitable filter was put in the incident light to cut off the 4358 line, this latter group also disappeared, showing that it derived its origin from the 4358 line in the incident radiation. Similarly, the group marked *c* in spectrogram (2) disappeared when the group of lines 4047, 4078 and 4109 was filtered out from the incident radiation by quinine solution, while the group due to 4358 A. continued to be seen. Thus the analogy with the Compton effect becomes clear, except that we are dealing with shifts of wave-length far larger than those met with in the X-ray region.

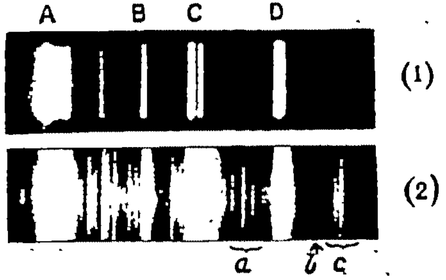

Fig. 1.—(1) Spectrum of incident light; (2) spectrum of scattered light.

As a tentative explanation of the new spectral lines thus produced by light-scattering, it may be assumed that an incident quantum of radiation may be scattered by the molecules of a fluid either as a whole or in part, in the former case giving the original wave-length, and in the latter case an increased wave-length. This explanation is supported by the fact that the diminution in frequency is of the same order of magnitude as the frequency of the molecular infra-red absorption line. Further, it is found that the shift of wave-length is not quite the same for different molecules, and this supports the explanation suggested.

Careful measurements of wave-length now being made should settle this point definitely at an early date.

Excitation of the Auroral Green Line in Active Nitrogen.

The auroral green line, which is now thought to be an arc line of oxygen, has been excited with considerable intensity in active nitrogen that was produced by a condensed discharge in a mixture of nitrogen and about 4 per cent. oxygen. Under the most favourable conditions for its excitation, the line was as intense as the afterglow band at 5442 A. Eastman astronomical plates were used because of their great sensitivity in the green. The spectrum was photographed on a small Hilger visible spectrograph. Because of the small dispersion of the instrument, the wave-length of the line could be measured only to within 0·1 A. Using helium standards the wave-length was found to be 5577·5 A. The measurements of Babcock and of others give this wave-length as 5577·35 A. It was shown definitely that with decreasing amounts of oxygen the line gradually disappeared. This and the fact that the wave-lengths agree fairly well, give sufficient proof that the line in question is the auroral green line.

Besides the green line, a red line having a wave-length of 6654·8 A. was observed in the afterglow under the same conditions as the green line. There is an unclassified line of oxygen at 6654·8 A. and it is thought that these two lines are identical. Amounts of oxygen too small to bring out the green line were found to be sufficient to bring out the red line. This observation is based on the fact that the red line was as intense as one of the afterglow bands in the red (6185 A.), the intensity of which was given by Lord Rayleigh as the same as the band 5442 A. mentioned in connexion with the green line.

Too little is known about the energy levels of the oxygen atom and about the spectroscopic origin of the green line for any hypothesis as to the process of excitation in this experiment to be of any value. The excitation of the line with an intensity comparable with that of one of the afterglow bands does, however, seem to indicate that the dissociation of the oxygen molecule and the excitation of the atom occur in a single act. Since no green line afterglow has ever been observed in oxygen discharge tubes, it is certain that the excitation in this experiment is due to the active nitrogen. It is interesting that the green line has been excited without the simultaneous excitation of the other strong arc lines of oxygen, a phenomenon that occurs in the night sky, where the green line alone has been observed.

Stellar Radiation and the Nature of the Universe.

Referring very briefly to Nature of April 28, p. 674, the reason Dr. Jeans and I agree to differ in our estimate of the possibilities of the universe is because he is dependent on matter for all energy, the rest being empty space; whereas I postulate a vast store of energy in a rotational ether, which only or mainly manifests itself in localised portions apprehended by us as particles or waves.

Similarly, a cyclically permanent universe would seem to him dull or dead; whereas to me it furnishes the mechanism apparently needed for the continued evolution of an entity known to us as life or mind, which, unlike its inorganic counterpart, is progressive.

Correlation Coefficients in Meteorology.

IN NATURE for Mar. 17, Mr. E. V. Newnham, in an interesting letter on "Correlation Coefficients in Meteorology," points out that if we wish to test if an observed value could reasonably have occurred in a sample from uncorrelated material, ρ should be put equal to zero in the formula

$$\frac{1-\rho^2}{\sqrt{n}},$$

and not equated to the observed value, r. So far as it goes, this advice is correct, but without other warning, and especially in conjunction with the example chosen, it is not a little misleading. The correction may be considerably greater, or less, than that required to give a reliable value.

Using $(1-r^2)/\sqrt{n}$, the probability that a correlation derived from 16 pairs of observations should exceed 0·70, would appear to be 0·000,000,02, or only one in 50 million trials; this, as Mr. Newnham indicates, would make the odds in favour of a genuine connexion "overwhelmingly great"; using the corrected formula, $1/\sqrt{n}$, it would appear to be 0·00256. However, if the odds are calculated by an exact method, it is found that the probability is actually a little more than 0·00127; the real odds happen in this case to be nearly double those which Mr. Newnham advocates.

The fact is that the distribution of the correlation coefficient from small samples is so far from normal that the use of any formula for the standard error is misleading. This is not to be regretted, since the exact test of significance is no more difficult to apply than the use of the standard error; indeed, special tables have been available for some time from which the level of significance of an observed correlation can be read off at a glance, and similar tables for the multiple correlation have already been prepared for publication by Dr. Wishart in this laboratory.

Since in nine cases out of ten only the small sample formula is exact enough for practical purposes, the formula for the standard error of the correlation coefficient may soon be classed among the things "which students have to know, but only a fool would use."

The Golgi Bodies of Plants.

I RECENTLY directed attention to the discovery of Golgi bodies in plants, which was made by Bowen, and is of interest to all botanists.

In this laboratory two of my senior students, Miss Patten and Miss Scott, have gone over a part of Bowen's work, and I have therefore had the opportunity of studying slides of plant tissues prepared according to the methods which Bowen has used. In hyacinth root, and pea root and stem, we have been able to conform Bowen's results, especially in material prepared by the Kolatchev method. Bowen's bodies are discoidal structures, or osmiophilic platelets as he calls them, and very like the hæmatids of mammals. There is a stainable cortex and a thinner, or at least less chromophile, central area. They are very small, but stain very sharply by the Kolatchev method, and there can be no doubt as to their presence. They are not osmium granulations.

For the benefit of those students of botany who may care to investigate these bodies, I give full details of the Kolatchev method; if it is carried out properly it never fails: Slit up root tips, etc., and fix in Champy's fluid, or the following modified Champy. Equal parts of 6 per cent. bichromate of potassium, 1 per cent. chromic acid, and 2 per cent. osmic acid. After 24 hours the material is washed overnight in a gauze-covered vessel, under a running tap. Transfer to 2 per cent. osmic acid, and keep at 30° to 35° C. for from 3 to 7 days, 4 days usually being enough. Wash in running water for several hours, transfer to 30 per cent. alcohol, upgrade and embed in wax. Cut sections thinly and mount unstained. The Golgi bodies are black discs, while the cell and nucleus are a more or less uniform yellow colour. As a control one may add to the pieces of plant tissue, fragments of mollusc ovotestis (in which Golgi bodies can be seen *intra vitam*), the intestinal tracts of centipedes, and pieces of dorsal root ganglion, or guinea-pig testis (in which Golgi bodies have been stained *intra vitam* by Subba Rau and Brambell (*Jour. R. Micr. Soc.*, 1925, p. 438)).

Thus in one operation it is possible to show Golgi bodies in a protozoon (Coccidium or Adelea, in the gut wall of the centipede), in an insect (gut cells), in a mammal, and in plant cells. The fragments, which must be small (⅛ inch in diameter), can all be carried through together, and cut in the same wax block.

Careful details of techniques suitable for plant tissues will be found in the last-mentioned of Bowen's papers: *Science*, vol. 64; *Anat. Record*, vol. 34, 1926; *Biol. Bull.*, vol. 53, 1927; *Zeit. f. Zellf. u. mikr. Anat.*, vi. Band 6, Heft 5, 1928.

Milk Pasteurisation and the Tubercle Bacillus.

MY attention has been directed to a paragraph in NATURE of Mar. 31, p. 513, referring to my recent research into the effect of pasteurisation on the bovine tubercle bacillus in naturally infected tuberculous milk. The note concludes with the words "we still seem to lack experimental information of the efficiency of a *commercial* pasteurising plant for destroying the tubercle bacillus in naturally infected milk."

While this statement is correct, I feel that it needs some amplification. In the laboratory experiments it was possible to maintain a constant temperature of 145° F., which in the commercial process is almost an impossibility—the temperature usually fluctuating from 1° to 5° F., which fluctuation usually tends towards the lower temperatures in an effort to use the minimum temperature in order to conserve the cream line of the milk. In addition to this tendency to subject the milk to the minimum temperature, there is the further possibility of mechanical defects in commercial plants—defects that were shown to be present in certain machines that were tested in connexion with an American investigation in 1924, the results of which are published in the *United States Public Health Bulletin, No. 147.*

In view of these facts, I think it is fair to assume that laboratory experiments may be taken as applicable only to perfect commercial pasteurisation, and that given perfect commercial pasteurisation at 145° F. for 30 minutes, we are still forced to the conclusion that this combination of time and temperature does not invariably kill the tubercle bacillus.

World Weather.[1]

By Sir Gilbert Walker, C.S.I., F.R.S.

The data recognised as necessary for the forecasting of weather come from a region that is ever widening. Before telegraphic charts were prepared the local observatory had to suffice; but the daily maps now used in predicting the weather of a single country of Europe may cover several thousand miles from west to east. Further, the desirability of warnings of the famines that have devastated semi-tropical and tropical countries has led to thinking in terms of seasons rather than days, and it soon became clear that seasonal variations over much of the earth are related to a surprising extent.

The first fact emerged in 1878 when Hoffmeyer pointed out the association between pressure in the North Atlantic and weather in Europe; and he was shortly followed by Blanford in India and by a group of continental meteorologists, including Teisserenc de Bort, Hann, Meinardus, and Pettersson. The far-reaching character of the subject was first visualised by Hildebrandsson, who in 1897 published the pressure data for ten years of 68 stations scattered over the world, and directed attention to certain relations between them as indicated by plotted curves. But in this and in his later papers the graphic methods used, and the shortness of the series of data available, generally prevented him from reaching final conclusions. In 1902 the Lockyers confirmed his discovery of the 'see-saw' of pressure in the Argentine and in India or Australia, and, still using purely graphical methods, they made it the basis of a classification of pressures over the world according as they oscillated with India or with Cordoba.

Since then, work on the Continent has been chiefly occupied with conditions in northern latitudes, and the more general problem has been mainly studied in connexion with Indian monsoon forecasting. For this purpose it was necessary to have quantitative information as to relationships, not merely visual impressions from plotted curves, and to work with seasonal, not annual, values. Also there was no hope of unravelling the tangled threads of causes and effects unless help was got by finding cases in which the conditions in one place were related with those in another in a subsequent season. Statistical methods were therefore indicated, and these efforts have culminated in the production of tables of relationships between conditions of pressure, temperature, rain, or river-flood at 32 centres scattered over the world. For each of these the correlation coefficient has been worked out for each quarter with those of contemporary quarters of the other stations, and also with those of one quarter before and after, and with those of two quarters before and after.

The total number of coefficients worked out is considerable, but simplification of the process has reduced the time spent on each to one or two minutes; also, by confining attention to those figures which are larger than the biggest that chance can be expected to produce, the number of significant figures is reduced to 396, and these fall very consistently into the scheme of oscillations indicated below.

The main conclusion reached is that there are three big swayings or surgings:

(a) The North Atlantic oscillation of pressure between the Azores or Vienna on one hand and Iceland or Greenland on the other;

(b) The North Pacific oscillation between the high-pressure belt and the winter depression near the Aleutian Islands; and

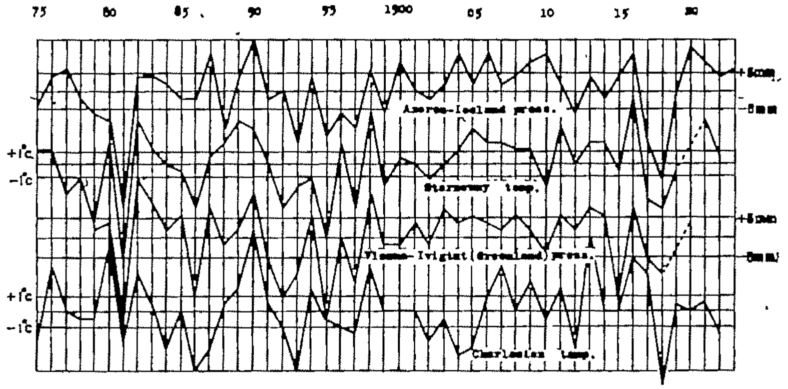

Fig. 1.—The North Atlantic oscillation.

(c) The southern oscillation mainly between the South Pacific and the land areas round the Indian Ocean.

Regarding (a), it is well established that a strengthening of the pressure gradients and of the ocean winds (indicated in Fig. 1 by the pressure differences Azores—Iceland and Vienna—Greenland) is associated with a strengthening of the Gulf Stream and higher temperatures in northern Europe (*e.g.* Stornoway in Fig. 1) and along the east coast of the United States (*e.g.* Charleston). The diagram shows the variations of these quantities in successive Januaries from 1875 for nearly fifty years, and the relationships are closer than is generally realised, the correlation coefficient (or degree of association) between the second and third curves being 0·88. Increased circulation goes also with higher temperature in Siberia and Java and less monsoon rainfall in India.

The North Pacific oscillation is rather like that of the North Atlantic, strengthening of the winter pressure differences and winds being associated with higher winter temperatures in central and western Canada, and increased rain in the North Pacific coast states.

---

[1] This article contains the substance of a recent presidential address to the Royal Meteorological Society.

The southern oscillation is more far-reaching than the two oscillations just described, and as the effect of an abnormal season is propagated slowly, it may not appear at the other side of the earth until after an interval of six months or more. In illustration we may see in Fig. 2 in the topmost curve the variations of the Nile floods of July to October in successive years from 1889 to 1925; they are, however, reversed, so that a dip below the normal line like that of 1916 means a high Nile. The next curve shows the variations of temperature at Samoa in the following summer, December to February, and the correspondence is obvious, the coefficient between the departures being 0·72. The third curve is that of Samoa temperature during the succeeding autumn, March to May, which brings out the great persistence of the ocean temperatures. Following this we have the pressure at Port Darwin in North Australia for September to November, six months before the third curve, yet with so close a correspondence that the coefficient between them is 0·80. Lastly, we have the pressure at Zanzibar of December to February three months later, and so three months after the third curve, with which its coefficient is 0·72.

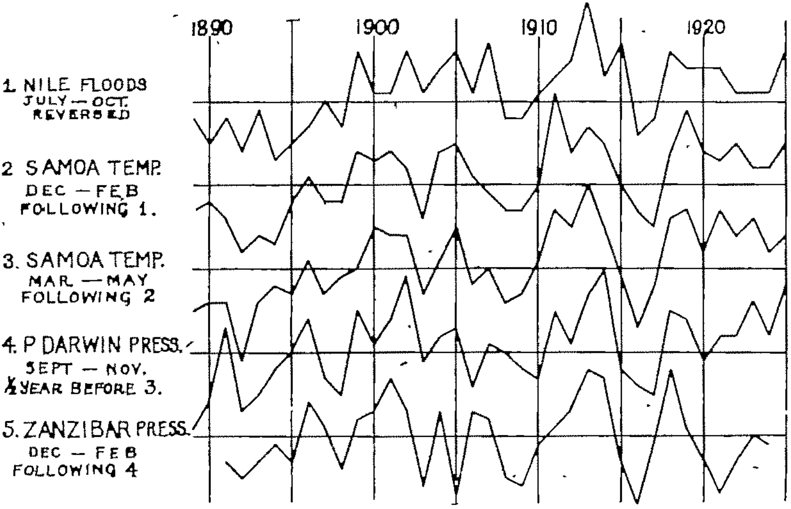

FIG. 2.—The southern oscillation.

The general character of the southern oscillation may be inferred from the statement that in the season June to August the first group of stations, *i.e.* that oscillating with pressure in the Pacific, is most clearly represented by pressure at Honolulu, Samoa, the Argentine, and Chile, by India monsoon rainfall and by the Nile floods; and the second group, tending to have departures of the sign opposite to those of the first, is represented by Port Darwin pressure, and by temperature at Batavia and Samoa. During the season December to February the most representative stations are materially different. In the first group there are only Samoa pressure and rainfall at Java; and in the second, pressure at Honolulu, Zanzibar, North-West India, Port Darwin, and the Cape, with the temperatures of central North America, Batavia, and Samoa.

The first question that arises is that of the mechanism that binds together the southern oscillation; we have seen that the North Atlantic and North Pacific oscillations implied variations in the strength of the air circulation in those areas, and there is a presumption that a similar interpretation is applicable here. Now where there are areas of low pressure and areas of high pressure in the same latitude, the former are in general relatively warm and the latter relatively cool; so that in winter, seas have low pressure and in summer high; and for land the opposite obtains. Thus the low pressures of Iceland and the Aleutian Islands are much more developed in winter than in summer, and, the high-pressure belts in the Atlantic and Pacific in summer than in winter. Accordingly, in the southern oscillation the first group consists of those areas the pressure of which will increase with increased temperature contrasts or increased circulation; thus, in the Pacific, Honolulu is in the first group in summer when the high-pressure area is more marked, and in the second group in winter when the reverse obtains; similarly, the Argentine and Chile as land areas are only in the high-pressure group in winter. Also Samoa as a high-pressure centre at times of increased circulation is much more marked in summer than in winter; and the Cape is only in the second group in its summer when pressure is relatively low.

This explanation is not complete, however, for Northern Australia is almost as strong in the second group in its winter as in its summer. Further, at times of increased circulation, when we should expect solar radiations to be stronger, temperatures are markedly lower except in higher latitudes. But here we are reminded of the old paradox, that at times of sunspot maxima, when there is a definite though small general increase of rainfall owing presumably to increased circulation, temperature is decidedly lower in the tropics and generally lower in the middle latitudes; and, going further, if we compare the relationships of sunspots with pressure, temperature, and rainfall, we find a remarkably close resemblance with those of the southern oscillation, extending in many cases into the detail. Thus if we consider our description of the southern oscillation in terms of representative centres, there were, in the season June to August, 5 centres in the first group and 3 in the second, while from December to February the numbers were 2 and 8; and without an exception we find the variations of centres of the first group associated positively with those of sunspots and those of the second group negatively, even when the members of the group change between summer and winter.

This correspondence would be explained if the southern oscillation were an effect of sunspots; but this hypothesis is untenable as the relationships between factors in the southern oscillation are much closer than those between the factors and sunspots. It seems too speculative to postulate some solar influence which should closely control terrestrial conditions and yet have but a small influence on the sunspot numbers. So we are led to the view that the southern oscillation merely expresses a natural oscillation or system of surges in the general circulation, and that, for example, the fall of temperature in the tropics is, on physical grounds, associated with an accentuation of low pressure in the Indian Ocean. If this is granted, we suppose that an increase in the number of sunspots or of solar radiation will increase slightly the general circulation and so bring about the observed relationships with sunspot numbers.

The belief held by Hildebrandsson in 1910 was that, in the tropical and temperate regions, circumstances were too regular to afford an explanation, and it must lie in the ice conditions of the polar seas; he believed also that in the southern hemisphere types of season were propagated eastwards like waves, the character of the pressure at the Cape during its summer appearing at Mauritius in the next winter, in Java and Australia the succeeding summer, and finally in South America six months later, or eighteen months after its original appearance at the Cape. This generalisation was founded on inadequate materials, and the feature which stood out most prominently in the first set of relations worked out in India was that while winter pressures in the Argentine and Chile were not controlled by any centre in the southern oscillation six months before, they controlled conditions six months later round the Indian Ocean, appearing as a reversed pressure wave which took six months to reach the Cape. It seemed therefore as if South America was the origin of the variations.

At first it appeared that a modification of Hildebrandsson's hypothesis would solve the problem. For, owing to the shape of the Antarctic continent, it would seem inevitable that the ice which flows in a westerly direction along the coast would be thrown off northwards into the Drake Strait by the projection of Graham Land, so that it would then flow north-eastward and eastward in the currents of the 'roaring forties.' The few data forthcoming from that neighbourhood indicated that a winter of low pressure in Chile was a winter of much ice at the South Orkneys, and as this would take some months to produce an area of chilled ocean and therefore of high pressure at the Cape, it seemed as if we might hope to understand how a period of low winter pressure in South America could produce a period of high summer pressure at the Cape. But subsequent examination showed that although low winter temperature at the South Orkneys produced low temperature at the Cape a year later, the coefficient between the two temperatures being +0·56, the effect six months later was small; and, apart from this, the explanation would break down because the effect of Cape temperature on Cape pressure proves on calculation to be negligible.

Unfortunately, it is easier to reject this hypothesis than to replace it. If we count in the tables the number of significant relationships, we find that pressure at Port Darwin has no less than 76 with other places, of which 32 are with subsequent seasons; next in importance come temperatures at Batavia and Samoa, each with about 60 relationships, of which only 13 are with subsequent seasons; and then come the pressures of North-West India and Samoa with smaller numbers. So pressure in the neighbourhood of Port Darwin seems to exercise more control over other regions than any other world factor, and its influence seems to be increased by Batavia temperature, which varies in close sympathy. Temperature at Samoa, the oscillations of which closely resemble those of Batavia temperature, is an equally important world centre, but belongs to the second group, while Samoa pressure belongs to the first group and has not more than half its influence. On the whole, then, although certain pressures appear to come earlier than any temperatures in the sequence of cause and effect, it is clear that ocean temperatures play a most important part in world weather. Their effectiveness may be due in part to their extreme persistence, so that successive seasons produce cumulative instead of antagonistic results.

Although it may be some time before we learn the processes by which Nature effects these enormous oscillations, and the relationships found must in general be regarded as empirical, there is no reason why they should not be utilised when possible for administrative or commercial purposes such as seasonal forecasting. Thus methods of predicting the general character of the winter and spring temperatures of a large part of northern Europe have been known for twenty years, and much additional knowledge has been won in recent researches by Brooks, Exner, Wiese, and others. The facts of the southern oscillation have been systematically utilised in predicting the rice crops of Japan, and the Java rainfall; and the recent tables have been shown by Bliss to have an immediate application to the Nile, the final relationship for forecasting being 0·72. The latest purpose to which they have been directed is in connexion with Ceara, a state in north-east Brazil liable to terrible droughts, and, as rainfall there belongs to the second group in the southern oscillation, a formula with a coefficient of 0·82 follows at once, the effect being shown in Fig. 3.

It must be admitted that a certain amount of scepticism over these matters is of great value as an antidote to rashness; for it is obvious that if we examine short series of data of pressure, temperature, and rainfall of hundreds of stations chosen at random, and look for similarities of conditions separated by all intervals of time up to five years, the laws of chance will provide one or two promising results. But, on the other hand, it is impossible to deny the validity of conclusions based on close relations over an adequate number of years, such as forty or fifty, and this view is confirmed by actual experience. For in 1908, in my early years in India, I published an admittedly imperfect formula for predicting the monsoon based on about 34 years of data; and its reliability can be definitely estimated by comparing the indications that would have been given by it if employed during the past 19 years with the actual rainfall. Now the coefficient expressing the closeness of fit between the results of the formula and past data in 1908 was 0·58, and I should have been satisfied under the conditions if the indications of the past 19 years had a closeness of fit of 0·48 instead of 0·58; actually, however, as will be seen from Fig. 4, the foundations of the relationship have proved sound and the coefficient has worked out as 0·56; so it may be claimed that our present improved formulæ based on 50 or 55 years instead of 35 years are worthy of confidence if used with due caution. It is in my view essential that forecasts should only be issued when the indications are well marked, and if during the past 19 years a prediction had only been made in the 11 years when an excess or deficit of one inch or more had been indicated, the character of the season's rainfall, expressed merely as 'in excess' or 'in defect,' would have been correctly given 9 times (Fig. 4).

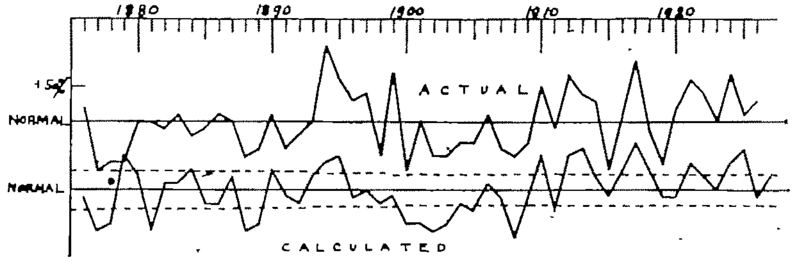

FIG 3.—Forecast on Dec 1 of Ceara rainfall, January–June.

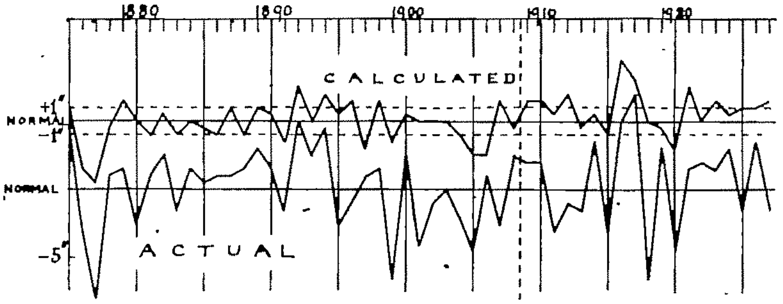

FIG. 4.—Forecast on June 1 of Indian monsoon, June–September. (1908 Formula, R = 0·58)

Since 1908 many new relationships have been ascertained, and the present formulæ for North-West India and for the Peninsula have coefficients of 0·76 instead of 0·58. Also, there is no reason whatever for thinking that finality has been reached; for with the seasonal changes in India are associated very big changes in the strength of the upper currents; and it is an obvious hypothesis that when the change in the upper currents takes place with unusual vigour the seasonal rainfall will be abundant. The pilot-balloon observations hitherto made strongly support this hypothesis, and what appears to hold in India very probably holds over a far wider region. Moreover, the idea that upper-air conditions are vital to the study of world weather derives support from the table of relationships with the Nile. The significant relationships with other stations for its single season number 31, while the greatest number for a single season at any other centre is 24; and as the corresponding number for pressure at Cairo is only 8, it seems likely that this effect of the Abyssinian rainfall is brought about by the agency of the upper air, not by surface conditions. Similarly, the monsoon rainfall of India has eight significant relationships elsewhere, but June to August pressure in North-West India only one.

It is to be hoped, therefore, that the tables of the *Réseau Mondial*, to which statistical workers have been enormously indebted in the past, will in future contain monthly means of air motion at fixed heights above such observatories as can provide the data.

Recent Earthquakes in Bulgaria and Greece.

By Dr. CHARLES DAVISON.

WITHIN the last year, destructive earthquakes have occurred in Palestine, the Crimea, Smyrna, and Asia Minor, and, so lately as Mar. 27, in north-eastern Italy. They have been followed, during the latter half of April, by a series of equally violent shocks in the south-east of Europe. Indeed, the close succession of earthquakes—and, since April 15, scarcely a day has passed without news of fresh shocks—has given rise to the impression that earthquakes have of late been more frequent than usual. There is nothing to support the impression beyond the clustering of shocks within a limited area. Assigning roughly the intensity according to Milne's scale for destructive shocks, it would seem that, in the first four months of this year, there have been one earthquake of intensity III (strong enough to destroy towns and devastate wide regions), perhaps two of intensity II (capable of shattering many buildings and overthrowing some), and two of intermediate strength. In each of ten years during the latter half of the nineteenth century there have, during the first four months, been from three to five earthquakes of intensity III, and in each of thirteen years from three to nine earthquakes of intensity II.

The earthquakes of April 14 and 18 are described as the most violent ever felt in Bulgaria, and this is not improbable. There is a centre of some importance near Plovdiv (Philippopolis), and there are a few minor centres to the south of the Balkans, but, in the area first struck, earthquakes are exceedingly rare, if not unknown. The earthquake of April 14 occurred at about 11 A.M., and it is to this no doubt that we owe the small death-roll. The area of damage is about 70 miles long from east to west (Harmanli to Plovdiv) and 25 miles wide. The epicentre lies near Chirpan, probably a few miles to the south and close to Borisovgrade, which is almost entirely destroyed. The second great earthquake came on April 18 at 9.24 P.M., again at a time when most of the inhabitants were able to escape from the falling houses. The shock was distinctly stronger than the first and the area of damage was somewhat larger. Near Papazli, the distortion of the ground is evident; ground-levels have been changed in some places by so much as six feet, whether by crushing of the surface soil or by distortion of the underlying crust is as yet unknown. In both earthquakes the wide extent of the area of damage seems to point to a considerable depth of focus.

By far the most interesting feature of the Bulgarian earthquakes is the great and rapid oscillation of the focus. The epicentre of the earthquake of April 18 was close to Papazli, about half-way between Chirpan and Plovdiv and 10 miles to the west of the first epicentre. On the evening of April 19 it was displaced to Haskovo, 30 miles to the east of Papazli; two days later, on April 21, it had retraced its steps about 60 miles to the west, to near Golemokonare; on April 23, back 36 miles to the east, to Stara Zagora, a few miles north of Chirpan; and, lastly, on April 26, it continued its easterly march, by 24 miles farther, to the neighbourhood of Harmanli.

According to the official reports, only 103 persons were killed and 700 wounded by these earthquakes, while the total loss of property is estimated at 3¾ million pounds. In Plovdiv alone, more than five thousand houses have been damaged and two-thirds of the town rendered uninhabitable.

Very different from the Bulgarian earthquakes were those felt at and near Corinth on April 22 and following days. In the first place, they visited one of the most seismically active countries in the world. Area for area, there are more than three times as many earthquakes, weak and strong, in Greece as in Japan, and more than thirty times as many as in Italy. Or, counting only shocks of the very highest intensity, there are more than four times as many as in Italy, and nearly seven times as many as in Japan. Again, in this active country, the isthmus of Corinth is one of the most active regions, being exceeded, according to Montessus, only by the Ionian Islands to the west of Greece and, though very slightly, by the island of Eubœa to the east. In the third place, the area of destruction is small. It includes Corinth itself, in which many of the houses are damaged, the small adjoining towns of Kalamaki and Loutraki, and some of the coast villages to the west of Corinth. At the most, it may be about 10 miles in diameter, for it appears that Isthmia, four miles to the east, escaped injury during the first shock. The small area of damage, and the high intensity near its centre, combine in pointing to a shallow-seated focus. Lastly, though the foci of the after-shocks were not stationary, the limits of migration were small. On April 25 there seems to have been a slight shift to the east, most of the houses in Isthmia being destroyed.

So far as our present information goes, the Corinthian earthquakes were less important than those in Bulgaria, and owed their destructive power chiefly to the proximity of the origin to the surface.

The Voronoff Operation in Stock-breeding.

THE claims made by Dr. Voronoff and others concerning the economic value of his method of reactivation in the field of practical livestock breeding have attracted so much public interest that it was considered desirable that an authoritative report should be prepared for the information of the Ministry of Agriculture and for the Board of Agriculture for Scotland. Delegates from Great Britain, with representatives of several other countries, recently visited Algeria to witness the operation of testis-grafting in animals of agricultural importance, to examine certain animals which already had been subjected to this technique, and to examine and to report upon the claims that have been made concerning the economic value of its application. Their report has now been issued.[1]

The Voronoff operation has been employed in the case of the senile male whose own testes have become insufficient in their physiological activity, and of the sexually immature male whose testes have not yet profoundly affected the developing characterisation of the individual. It is claimed that in the first case the old, decrepit and infecund male becomes reactivated, his reproductive powers becoming restored; and that in the second, growth and general vigour are stimulated to a fuller expression as evidenced by the attainment of a larger body size and a greater sexual potency. It is also claimed that these characters are, in part at least, transmitted to the offspring. The delegates were shown a bull which had been rejuvenated, and a number of sheep in which the operation had been performed upon the sexually immature male.

The conclusions at which the delegates arrived were as follows: The claim of Dr. Voronoff to effect rejuvenation of the aged and decrepit animal by the operation of testis-grafting is possibly justified, but the evidence presented has not been based upon critical experimentation. The delegates were not satisfied that this method, even if and when its merits have been fully demonstrated, can become of any great importance in a country such as Great Britain. The claim of Dr. Voronoff to increase the body weight and the wool-clip of the ram by the operation of testis-grafting applied to immature male, was supported by the data submitted and by the appearance of the sheep that were seen, but the conditions under which the experiments had been conducted, the inadequacy of the data submitted, and the method of the presentation of these data, made the forming of a critical opinion quite impossible. For the same reason, it was impossible to accept the evidence, which seemed to show that the improvements thus invoked were transmitted by the ordinary processes of reproduction. There is great need for repetition of these experiments with standardised material under controlled conditions of husbandry.

Obituary.

Sir David Ferrier, F.R.S.

The death of Sir David Ferrier in London on Mar. 19 removes from the roll of living neurologists a veteran pioneer, eminent in example and in service. He had reached his eighty-sixth year, and his life meant for those at work to-day a personal tie with a historic past which he conspicuously had helped to make significant.

Ferrier, as student in Aberdeen, his native city, had been a pupil of mark under the psychologist and philosopher Alexander Bain, and had graduated at the University with high honours. He had then entered upon medicine at the University of Edinburgh. The study of the nervous system attracted him early; and a gold medal was awarded to his M.D. thesis, "On the Corpora Quadrigemina." Later, in the reports of the West Riding Lunatic Asylum, where a centre of neurological research had arisen under Dr. (now Sir James) Crichton-Browne, Ferrier issued his first paper of experiments on the brain of some of the higher mammals. Hughlings-Jackson's observations upon localised discharging fits were being discussed in 1868; the famous "Study of Convulsions" followed from him in 1869. The experiments of Ferrier had for an object the "testing of the theory of Hughlings-Jackson that localised and unilateral epilepsies are caused by irritative or 'discharging' lesions of the grey matter of the hemispheres."

Ferrier's extension of these experiments to types of brain nearer the human was encouraged by the Royal Society with a grant in aid supplying the material for the work. Ferrier was able to establish that in the ape's brain, a considerable area of the surface sheet is excitable by faradism. Localised movements in the face and limbs, of the crossed side, were evoked with such definition and precision that "the experimenter can predict with certainty the result of stimulation of a given region." Ferrier described a 'motor region' stretching across the lateral aspect and thence over and upon the median aspect of the hemisphere. He pointed out that its extent was greater and its character more detailed in the ape than in any of the types less near to man. He then turned to determine the effects of localised destruction of portions of the cerebral surface. These experiments formed the main theme of a second Croonian Lecture following his earlier of 1874. He directed attention to the hemiplegic symptoms ensuent on injury of the motor region in the ape, symptoms in several respects indistinguishable from human symptoms familiar in the clinic. It is related by Sir Charles Ballance that at the International Congress of Medicine in London in 1881, on the appearance of one of the monkeys shown by Ferrier, Charcot of Paris, the physician, exclaimed, "It is a patient!"

Outside and beyond the region of cerebral surface which he termed 'motor,' Ferrier described further certain other regions which conversely he termed 'sensory.' He distinguished separate sensory fields severally related to the several special senses. Individual destruction of these entailed, he concluded, specific sensory defects and disturbances. His lectures upon all this work were followed in 1876 by a memorable volume, "The Functions of the Brain." The book reached beyond medical circles to a wide scientific public. It was translated into various languages. It and the work it embodied exerted decisive influence toward placing cerebral localisation in the forefront of movement in the physiology and medicine, and indeed in some respects in the psychology, of its time.

If we would seek to trace the origins of Ferrier's inquiry and the great and lasting effect it produced, we must pay regard to some contemporary circumstances. Current scientific opinion, both physiological and medical, had held that the cerebrum—'organ of mind' and mind a unity—revealed in its functioning no spatial differences. Further, current teaching had been that the cerebrum, unlike the spinal cord, remained in all appearance irresponsive to such stimuli, electrical and what not, as physiological experiment had resort to. There had, however, arisen recently the views of Hughlings-Jackson, based on clinical observation of epileptoid convulsions. Contrary to orthodoxy of the time, he taught the existence of motor centres situated in the grey matter of certain of the cerebral convolutions, namely, "the convolutions surrounding the corpus striatum." This teaching Ferrier's paper mentions as an impetus to, and its testing as an immediate object of, his first experiments. Ferrier's inquiry was also made in the light of observations obtained by Fritsch and Hitzig three years before, on the brain of the dog, with closing and opening of a galvanic current as stimulus. On that mode of stimulation the method adopted by Ferrier constituted an important advance. It enabled deliberate and sustained movement to be evoked and without damage to the cerebral tissue; it allowed elicitation and study of the 'march' (that is, the spreading) of movement which Jackson had noted to be of diagnostic value in the epileptoid convulsion; it brought the clonus characteristic of epilepsy under observation as a feature of cerebral 'after-discharge.' Ferrier's method of stimulation has been followed by all observers since.

A conception which Ferrier formed regarding the localisation of function in the cortex held it to be primarily 'sensori-motor.' He conceived this region which yielded, in such systematic order, purpose-like actions of limb, etc., to represent so to say a motor executive; and he distinguished outside it, in contradistinction to it, fields which he regarded as sensory inasmuch as he read them to be dominantly connected each with a special sense. In short, 'motor' and 'sensory' were the fundamental categories underlying the scheme of localisation in the cerebral cortex in his pioneer interpretation of it. Not 'motor' and 'sensory' of course with the crudity of the efferent and afferent sides of a simple reflex arc; but yet distinguishably 'motor' and 'sensory.' The problem thus entered upon has exhibited during the succeeding fifty years continual increase of complexity at every renewal of attack. None the less, in intrinsic conformity with Ferrier's original point of view regarding the 'motor region,' we have to-day the experience of so versed and highly qualified an observer as Dr. Gordon Holmes, to the effect that "the precentral gyrus [the motor region proper] has no sensory functions." In addition, Ferrier's scheme, which assigned the major part of the cerebral surface to specific sensory fields, can stand as a prototype of that which comparative anatomy and cytoarchitecture have step by step since then substantiated. Also, the modern finding of Pavloff and his school arrives no less at a functional scheme which, even more than did Ferrier's original, allocates the cerebral surface to territories representing the several specific receptor-systems, with exclusion and negation altogether of 'pure association' fields.

The interpretation of observations regarding cortical functions forms an arena which has seemed to invite conflict. Ferrier arrived at a conception with the fundamental simplicity of which there corresponds, very probably, a fundamental truth. As regards animal mind, analytic psychology has not yet reached the elements needed in application to the problem. Be that as it may, a tribute which was quickly paid to Ferrier's work was that subsequent investigation of the nervous system, whether by adherents or by opponents of his views, for many years did little else than search for 'localisation' of something. A tide of localisation flowed with subversion of other interests. A 'localisation' era followed on Ferrier's work. The vogue became, as time went by, tedious, and in many respects infertile; but the importance of the work which ushered it in can never be forgotten.

It is difficult now to think back to a functional neurology which resigned itself to picturing the cerebral cortex as an uncharted sea, an unknown uniformity. With Ferrier's experiments that state of things came to its term. There followed consequences theoretical and practical. One beneficent practical result was that the symptoms of certain brain tumours, etc., viewed in the light of his 'localisations' in the ape, allowed the physician to locate the seat of mischief within the skull and so sometimes enabled relief of the patient by surgery. An element of irony attaches to the fact that as a consequence of his experiments Ferrier was prosecuted by anti-vivisectionists. The charge against him fell unfounded.

If this brief notice has occupied itself chiefly with one outstanding achievement in the earlier career of a long and active life, that must not convey the impression that the subsequent years had not also their rich yield of labour given and worthy contributions made. It was as a lover of knowledge that Ferrier pursued knowledge. He had a share in many undertakings to foster and advance it. He was of those who at a meeting in London in the spring of 1876 founded the Physiological Society; the Society elected him to its honorary membership in January of last year. On the title-page of the *Journal of Physiology* his name has stood as a collaborator for thirty-four years continuously. He was one of the small band who in 1878 launched *Brain*. He was a founder of the Neurological Society in 1886; its president in 1894. His zeal and interest in neurology, and indeed other science, never staled. When he no longer himself carried on experimental research it afforded him pleasure to watch others experimenting. His talk possessed a certain penetrative piquancy partly veiled in simplicity; it had a knack of getting to bottom. In literature he enjoyed dipping within the ancient classics. He was of artistic taste, in pictures as in other matters. The sea and the sea-coast were his favourite setting for a holiday. Numerous honours came to him. He was elected F.R.S. in 1876, and he received from the Royal Society a Royal medal in 1890. He was a laureate in Paris in 1878. His knighthood was conferred in 1911. C. S. S.

MISS J. E. HARRISON.

WE regret to record the death of Miss Jane Ellen Harrison, which took place in London on April 16, at the age of seventy-seven years. She was born in East Yorkshire on Sept. 9, 1850. At an early age she showed a special aptitude for languages, which she maintained until the end of her life. Before she entered Cheltenham Ladies' College at the age of fifteen, she had already acquired a knowledge of Latin, Greek, German, and Hebrew; while after she had attained the age of seventy, she made herself acquainted with the elements of Persian.

Miss Harrison entered Newnham in 1874 and, it was stated privately, was at the head of the Second Class in the Classical Tripos in 1879. She returned to Newnham as a fellow in 1900. On the termination of her college course she took up the study of Greek art and literature, publishing her first book on the story of the Odyssey in 1882, her object being to elucidate the Homeric myths in the light of Greek art, especially as exemplified in the art of vase and gem. Other books on art and on the topography of Attica and primitive Athens followed; but as might have been expected from the bent of a mind which, tradition has it, would have preferred the Moral Sciences to the Classical Tripos, she found herself more and more absorbed in the study of Greek religion as time went on.

In her "Prolegomena to the Study of Greek Religion" (1903), and her admirable "Ancient Art and Ritual," Miss Harrison showed that she had given herself over to the study of Greek religion on comparative lines under the influence of Frazer and of Ridgeway's methods of utilising the customs and culture of primitive peoples in dealing with the problems of Greek archæology. Not, indeed, that she was attracted to the study of primitive custom as such, for she expressed herself as repelled by much of the material through which she had to wade. She always succeeded in keeping herself fully abreast of the literature and of the latest developments in theory in anthropology and psychology, and it is interesting to follow the development of her thought in her later books, "Themis" (1912) and "Epilegomena to the Study of Greek Religion" (1921), as she came successively under the influence of the French sociological school—Durkheim and Levy-Bruhl in particular—of Bergson, and later of Jung and Freud. Her last book, "Reminiscences of a Student's Life," appeared in 1925.

Even though Miss Harrison may have been apt to generalise too hastily and prone to allow herself to be dominated by a theory as if it were always of universal application, she was a pioneer in her field, and in the study of Greek religion her work will hold a permanent place.

WE regret to announce the following deaths:

Sir William Church, Bart., president of the Royal College of Physicians from 1899 until 1905, and a trusted leader of the medical profession in Great Britain, on April 27, aged ninety years.

Mr. A. J. Jenkinson, O.B.E., tutor, librarian, and senior dean of Brasenose College, Oxford, known for his work on philosophy and economics, on April 19, as the result of an accident, aged fifty years.

Prof. Theodore W. Richards, For. Mem. R.S., professor of chemistry at Harvard University since 1901 and director of the Gibbs' Memorial Laboratory since 1912, a distinguished authority on atomic weights, on April 2, aged sixty years.

Mr. F. W. Shurlock, formerly Principal of the Derby Technical College, on April 19.

Mrs. Sollas, wife of Prof. W. J. Sollas, and widow of Prof. H. N. Moseley, Linacre professor of human and comparative anatomy, Oxford, whose son, H. G. J. Moseley, the brilliant young physicist, was killed at Gallipoli in 1915, on April 28.

News and Views.

THE fifteenth International Geological Congress meets at Pretoria on July 29, 1929. As the British Association for the Advancement of Science is visiting South Africa at the same time, and has secured a large contribution from Government, professional people and the mining houses have raised a substantial sum privately as a guarantee for the Congress; the local committee is therefore able to offer subsidies towards the expenses of visiting members, as well as a reduction of from 35-50 per cent. in the railway fares. Negotiations are in progress with the shipping companies for similar concessions, the results of which will be announced later. So heavy have been the calls on the community in South Africa that an urgent appeal is issued to everyone who can, to apply for membership of the Congress, addressed to the General Secretary, Post Office Box 391, Pretoria, South Africa. The membership fee is one pound. The main discussions at the meeting will be on magmatic differentiation, pre-Pleistocene glaciation, and the genesis of petroleum, but the most attractive feature will be the excursions, which have been arranged so as to cover all the classic areas. At Cape Town will be seen the intrusions of granite into slate, described by Basil Hall in 1813, which were used by Dr. Hutton in illustration of his theory. North of this are the folded mountains, bringing down the Devonian beds, with fossils of an American type. On the margin of the Karroo occurs the Permian glacial deposit, the Dwyka Conglomerate, which will be seen in its full development. Later excursions will enable the members to see the Lower Cretaceous at Uitenhage, and the enormously fossiliferous Cretaceous rocks of Zululand. In the Transvaal, the Bushveld Lacoolite dominates the stratigraphy, with its margin of basic rocks containing platinum. Three subsidiary structures are of special interest, the Pretoria soda caldera, the Pilandsberg, and the Vredefort granite mass.

ECONOMIC geologists attending the International Geological Congress will have an opportunity, very rarely given nowadays, of seeing the full working of the Kimberley mines, and of comparing them with the Premier Diamond Mine. In Johannesburg the surface and underground workings of a mine in the central area and on the Far East Rand will be shown, while a comparison of the Rand section with that of Pretoria with the iron deposits will be demonstrated. In Rhodesia the Great Norite Dyke is of interest, but the Victoria Falls, with the vast chasm of the Batoka Gorge, will be the greatest attraction. All the mineral deposits, chrome, asbestos, and the various gold ores will be seen in specially favourable circumstances. Applications for these excursions must be received before April 1, 1929. The meetings will be held in Pretoria on July 29–Aug. 7, but the excursions will extend from July 16 until Aug. 24, beginning and ending at Cape Town. The secretary of the Geological Society of South Africa appeals at the same time for additional members. He points out that the publications of the Society are indispensable to anyone interested in the geology of Southern Africa and the mineral resources of that territory. The Society is dependent for its annual revenue upon subscriptions to defray the heavy cost of printing, and many who make use of, and derive benefit from the transactions, do not belong to the Society. The address is Post Office Box 1071, Johannesburg, South Africa.

In our issue of Jan. 21 (p. 110) reference was made to the offer by the Premier of Queensland to the Commonwealth Council for Scientific and Industrial Research of an area of about 25,000 acres of land at Saltern Creek, in the middle of the State, to be used as a central scientific station for investigations into problems of the sheep industry. It was mentioned also that the Land Settlement Advisory Board had expressed a hope that the offer would be accepted in whole or in part. As a matter of fact, the offer had been declined at the time the Board reported. The Council was convinced that it could not justify the stocking and equipping of a big research station on the proffered area. Nor was it impressed by the suggestion that it might run the station in part as a commercial undertaking and recoup itself in that way for a part of the expense.

To laymen, the refusal of the Saltern Creek area seemed rather puzzling. The land is excellent sheep country for Northern Australia, carrying one sheep to 2¼ acres. Its rental value is about 8d. per acre per annum, and the period of leasehold, offered free of charge, was thirty years. At first sight the offer appeared tempting, but further investigation convinced the Council that its acceptance would be very unwise. Just because the land is so good it is unsuitable for certain major lines of work. Thus, there are no parasitological diseases there at present, and it would be sheer folly to introduce them. The blowfly pest is prevalent, but so it is over vast areas in the Commonwealth, and work aiming at control can be carried out far more satisfactorily in more readily accessible places in New South Wales nearer to the Council's central entomological laboratories. For work on artificial feeding of sheep (which is generally quite unnecessary in this region) an area of poorer country would be more useful. Investigation of natural grasses best suited for wool production could be carried on there, but such investigations are needed all over Australia, and the Council hopes that pastoralists themselves will provide the necessary facilities in a great number of much smaller areas. Work on mineral deficiencies in pastures is already in hand in several places where it is urgently required. Saltern Creek has no special claim for immediate attention. The Queensland Government was disappointed at the refusal, but the scientific grounds upon which the Council based its decision have not been seriously challenged.

The Reports of the Zoological Society of London for the year 1927 tell of progress and prosperity which must be very gratifying to those responsible for the conduct of this great concern, and are a reward of fresh adventures in methods of exhibition, as well as an indication of the increasing interest taken by the populace in living animals. The number of fellows has mounted to 7687, and it is suggested that some mode of limitation and an increased annual subscription may have to be considered in the near future. The number of visitors to the Gardens in Regent's Park reached a record of 2,158,208, and to the Aquarium, 458, 936; the surplus of income over expenditure was £16,859, in spite of the fact that more than £57,000 spent on new exhibition houses, which might well have been reckoned a capital charge, was paid from revenue. A hint of the part the Garden plays in encouraging the holiday spirit is contained in the item of more than £3000 drawn from elephant rides and the like. The difficulty of acclimatising animals is still apparent in the high death-rate within six months of arrival, but the steady reduction during the past three years in the percentage of deaths is very satisfactory, and the management is to be congratulated on the astounding improvement in pulmonary conditions, the mortality having been reduced by more than 50 per cent. since 1925. It would be interesting, and of value to other zoological gardens in Great Britain and abroad, to know whether this improvement can be ascribed to the new installations which have been described in former reports, to special feeding and a rise in tone and resistance, or to generally more healthy conditions of ventilation and isolation.

The Zoological Society does not neglect the scientific opportunities which its unique collections afford: a new anatomist has been appointed, a panel of parasitologists, formed by the staffs of the Institute of Agricultural Parasitology and the London School of Hygiene and Tropical Medicine, has undertaken this important branch of research, and the biological investigations of the newly elected Aquarium Research Fellow should prove of scientific interest and practical value. During the year the scientific *Proceedings*, absorbed £2760, and the preparation and printing of volume 63 of the *Zoological Record*, a sum of £1928. It is regrettable that, in spite of the donations received towards the publication of this invaluable guide to zoological literature, volume 63 alone should involve a loss of £1042, and societies, institutions, and individuals who wish the *Zoological Record* to be maintained, are requested to give their support in the form of annual donations to the "Record Fund."

The frequency and sites of cancer in persons of different habits and following different occupations has from the first thrown important light on the conditions which lead up to the disease, and careful analysis of occupational statistics will be a fruitful line of further advance. One of the earliest associations to be recognised was cancer of the scrotum and chimney sweeping: with the change in the methods and personal cleanliness of chimney sweeps, their special liability of this form of cancer has disappeared. Most curiously, however, it has been replaced by the appearance of the same cancer in cotton operatives, which is variously attributed by those who have studied the matter in Lancashire either to the lubricating oil used on the machines or to ill-fitting overalls which the decencies of industrial life have introduced. That there was some connexion with the products of the distillation of coal and shale had been proved or suspected on clinical grounds before Yamagiwa and Ichikawa showed that by patience and persistence the carcinogenic activity of any substance could be satisfactorily explored experimentally by applying it to the skin of mice repeatedly over long periods of time.

BY experimental work of this sort it has been shown that tar and soot have a unique efficacy in producing cancer, which is no doubt why the industrial labourer is so much more liable to the disease than his agricultural brother. By this method, too, it is possible to analyse the injurious action of the various lubricating oils which are used on factory machines. Dr. Leitch has done this already, and has found that shale oil is far the most harmful, illustrating the thorough clinical demonstration of its association with cancer in the Scottish oil field which was given by Dr. Scott. The particular field of mule-spinners' cancer has again been explored by Dr. C. C. Twort and Mr. H. R. Ing, working for the Manchester committee on cancer (*Lancet*, vol. i. 1928, p. 752). Applying each of 12 oils twice a week to 100 mice for periods up to 18 months, they find that sperm oil is harmless, natural petroleum oils are slightly carcinogenic (especially their higher boiling-point fractions), and shale oils are highly efficacious and act like a weak tar. Harmless oils do not become injurious by passage through the machines, and the carcinogenic action of shale oil may be removed by extraction with sulphuric acid and possibly other methods. If, then, mule-spinner's cancer is due to the lubricating oil, it seems likely that it should be possible to get rid of it.

AT the centenary of the Cockerill Works at Seraing in October last, the King of Belgium pointed out the necessity for honouring science throughout the country, since pure science is the indispensable condition for applied science, and neglect of it leads to decadence. As a result of this speech, a meeting of authorities interested in university education was held in Brussels in November to consider how best to encourage scientific work. Since then two pamphlets dealing with the subject have appeared, "La détresse de l'enseignement supérieur en Belgique," by L. C., and "Notre misère scientifique," by Q. M. Quaeris and others. The second of these traces the present paucity of intellectual effort in the country to the smallness of the Government vote for higher education, which is 5 francs per annum per head of the population, that is, less than in South American or in the Balkan States. The pay of university professors is in consequence small, and it is not possible to attract the best men to university posts. The method of selection is such as to attach less weight to a candidate's intellectual powers than to his political friendships. A particular case is cited at great length. The success of the recently established "Fonds national de la Recherche scientifique" is regarded as a sign that the country appreciates the position and is determined to improve it.

THE problem of the safe use of coal-mining explosives was dealt with by Dr. W. Payman in a paper read before the Midland Institute of Mining Engineers on April 17. He regards the production of a flameless and therefore completely safe explosive as an improbability. In practice, the explosive must be safe in spite of its flame. Safety resulting from a reduction of flame temperature is gained only at the expense of the efficiency of the explosive. Care in shot-firing would probably lead to safety more than any other obvious means, for no explosion would occur if contact of flame and explosive mixture did not occur. It is, however, desirable to improve, if possible, the composition of explosives. Considering the stringency of the official test of explosives, it is often puzzling to account for actual ignition of gas in the mine. If, however, the test were made so rigorous as to cover every possible combination of circumstances, its operation would probably exclude the use of explosives underground altogether. After contemplating the large hot flame resulting from firing a 'permitted' explosive, it is perhaps more astonishing that ignition of the fire-damp–air mixture does not always occur in the official test. Dr. Payman outlined the programme of the Safety in Mines Research Station at Buxton, which necessarily involves the analysis of explosion phenomena and the ignition of gas mixtures. His lecture was illustrated with photographs of flames produced under various conditions.

SOME further details of Capt. G. H. Wilkins' polar flight were published in the *Times* at the end of last week. From Point Barrow to about lat. 75° N., the pack-ice was heavy and rough, with a few east and west leads of open water, decreasing in number towards the north. In lat. 73° N. there was some evidence of obstruction preventing a drift to the eastward, but no land was sighted. From lat. 75° to 77° N. there was much young ice, making good landing places, but farther north the pack again became ragged. Between 78° and 80° N. the flight was over clouds. Then it was clear again to 84° N., and there was no sign of Crocker Land. The pack-ice again was rough. North of Grant Land there were clouds, but north of Greenland the visibility was good and the ice was young and relatively smooth. From Greenland to Spitsbergen the flight was across much open water. Capt. Wilkins was tempted to descend north of Greenland, but held on in spite of bad weather. If he had descended he could have fallen back on foot on Etah or the Royal Canadian Police post in Ellesmere Island. He explains that a descent to take a sounding on the earlier stretches of his flight, where soundings would have been valuable, was impossible on account of the heavy load of his machine and consequent difficulty of ascending again.

HIS MAJESTY THE KING has approved the award by the Royal Geographical Society of the Royal Medals as follows: *Founder's Medal* to Dr. T. G. Longstaff, for his discovery of the Siachen Glacier and long-continued geographical work in the Himalaya; *Patron's Medal* to Captain G. H. Wilkins, for his many years' systematic work in Polar regions, culminating in his remarkable flight from Point Barrow to Spitsbergen. The Council has made the following rewards: *Murchison Grant* to Captain C. J. Morris, for his recent journey in Hunza; *Back Grant* to Mr. George Binney, for his journey across North-east Land and his successful conduct of the Oxford Expeditions to Spitsbergen; *Cuthbert Peek Grant* to Mr. H. G. Watkins, in recognition of his leadership of the Cambridge Expedition to Edge Island and to assist him in his proposed expedition to Labrador; *Gill Memorial* to Mr. C. P. Skrine, for his exploration of the Qungur area and his work on Chinese Central Asia.

A CORRESPONDENT has written pointing out an apparent discrepancy between a note entitled "The Cosmic Rays" in our issue of Mar. 24, p. 477, on Prof. Millikan and Dr. Cameron's work on cosmic rays, and a remark made by Dr. J. H. Jeans in the supplement to the same issue of NATURE. The note refers to the "progressive hardening of the [cosmic] rays in their passage through the air," while Dr. Jeans (p. 468) says: "There are many ways known to physics of softening radiation, but none of hardening it." It should be remembered, however, that Prof. Millikan and Dr. Jeans were discussing two different effects. The radiation with which Prof. Millikan is concerned is heterogeneous. During its passage through the air—or other absorbing media—the components of greater wave-length (the 'softer') are removed by absorption at a proportionately greater rate than those of shorter wave-length (the 'harder'). The result is that the fraction of the latter in the radiation increases as the rays pass through the air, which can be expressed in Prof. Millikan's own words, as ". . . a definite hardening of the cosmic rays . . . between 13 and 23 meters (of water) beneath the surface of the atmosphere" (*Physical Review*, February 1928, p. 170). Dr. Jeans, on the contrary, is referring implicitly to homogeneous radiation or individual quanta, for which any such effect as that considered by Prof. Millikan is out of the question. Homogeneous radiation can only be 'softened,' as, for example, by the type of scattering studied by Prof. A. H. Compton and Prof. Debye.

MAJOR P. H. G. POWELL-COTTON has recently presented to the Department of Zoology of the British Museum (Natural History) a selection from the collection of mammals shot by him in the Cameroons and Lake Chad district. The specimens are of great scientific importance, as they include the co-types of several new forms, including a new kudu. This animal is smaller than the eastern kudu and has smaller horns; its discovery extends the range of the species many hundreds of miles in a westerly direction. There are also some fine specimens of the western giraffe (*Giraffa camelopardalis peralta*) and of the Congo race of Lord Derby's eland (*Taurotragus derbianus congolanus*). The collection is one of the most important additions to the study series of Ungulates and Primates that has been received by the Museum in recent years. Another important gift to the Department comprises the greater part of the scientific collections of the late Mr J. J. Lister, presented by Mrs Lister, including 700 microscopic preparations of Foraminifera, together with a series of notebooks relating to them. The Department of Entomology of the Museum has received the Eustace Ralph Bankes collection of British Lepidoptera, presented by Mrs Grace Bankes, which includes many of the tiny moths of the families Tortricidæ and Tineidæ, among which are several type specimens. From Mr Arthur Lea, entomologist to the South Australian Museum, there have been received some remarkable cocoons, many of them larger than a fowl's egg; they are the abandoned cocoons of beetles, which have become filled with sand and afterwards solidified by the infiltration of lime in solution. A very fine example of the fossil fish *Lepidotus elvensis* (Blainville), from the Upper Lias of Holzmaden, Würtemberg, measuring 2½ ft. in total length, has been purchased for the Department of Geology.

ACCORDING to a *Daily Science News Bulletin*, issued by Science Service of Washington, some concern is being expressed on the present condition of the giant sequoia trees in the Yosemite National Park, California. Dr. E. P. Meinecke, of the U.S. Forest Service, states that they are suffering from the trampling of the thousands of tourists, which has in part destroyed the fine root endings. Some five and twenty years ago, 'Grizzly Giant,' one of the finest of the big trees, was similarly threatened, but by loosening the soil, and placing additional soil to a depth of 3-4 ft. around the tree, the veteran has regained its vigour.

THE issue for March of *The World's Health* (vol. 9, No. 3) contains an article by Dr. Roeschmann on the new German law against venereal disease, which was approved by the Reichsrat last year. Coercive measures are dispensed with as much as possible. A sufferer is required to submit to treatment by a qualified doctor, whose duty it is to make his patient fully conversant with the nature and dangers of the disease. So long as the patient follows his doctor's orders, he is not notified to the health authorities or molested in any way. If he fails to do so, the national insurance agencies first summon him to report for treatment. If this summons is neglected, a report is made to the health authorities, who then direct the patient to submit to treatment. If this should fail, coercive measures may be taken, involving compulsory treatment. The law contains special provisions for the protection of new-born infants and wet nurses, and a complete reform of the regulation of prostitution.

THE Department of Terrestrial Magnetism of the Carnegie Institution of Washington has a total staff of nearly sixty, of whom more than twenty are trained scientific workers. The *Annual Report* of the Director for the year 1926–27 indicates that the chief recent activities of this important body of investigators have been varied, but largely consisted of the reduction and preparation for publication of former observations made by the Department, and of numerous special researches of a non-routine character; no great programme of surveying on land or at sea was in progress, though the non-magnetic ship *Carnegie* was being prepared for a new three-year cruise. The principal observing work of the Department consisted in the maintenance of two magnetic and electric observatories at Watheroo, Australia, and Huancayo, Peru. Among the special researches were included investigations into atomic physics, correlations between magnetic variations and the transmissibility of radio signals, and soil-resistivity surveys in Australia and at Ebro in Spain.

FROM the Bulletin of Information with regard to Professional Courses in Optometry at Columbia University, New York, in 1928–29, it appears that in the United States and in Canada opticians are required to pass through an extensive course of training before they receive a licence to practise. Before entering on the prescribed course of professional training, candidates are required to have attended an accredited high school for four years and to have been awarded a qualifying certificate. After attending courses on optometry for several years, and gaining the Certificate of Graduation, a candidate is eligible to take the licence examination. After 1930 a candidate must have spent four years in professional study, and must have graduated either B.A. or B.Sc. before he is eligible. At Columbia University the work is done in the physics building under the direction of Prof. P. C. Southall. University fees amount to £60 per annum, and board and lodging to £150 per annum as an average. The courses are open to men and women on the same terms.

THE eighty-first annual meeting of the Palæontographical Society was held in the rooms of the Geological Society, Burlington House, on April 20, Dr. F. A. Bather, vice-president, in the chair. The annual report recorded the publication of further instalments of the Monographs of Gault Ammonites, Macrurous Crustacea, and Palæozoic Asterozoa, and the beginning of a new Monograph of Dendroid Graptolites by Dr. O. M. B. Bulman. It also announced the preparation of a Monograph of the Irish Deer by Prof. S. H. Reynolds, and of the Corallian Lamellibranchia by Mr. W. J. Arkell. The Council especially regretted the resignation of Mr. E. T. Newton from the office of president, and expressed its deep appreciation of his valuable services since his election in 1921. Dr. W. D. Lang, Mr. W. E. F. Macmillan, Mr. R. W. Pocock, and Mr. W. P. D. Stebbing were elected new members of Council. Dr. F. A. Bather was elected president, and Dr. F. L. Kitchin new vice-president. Mr. Robert S. Herries and Sir A. Smith Woodward were re-elected treasurer and secretary respectively.

AT the meeting of the Illuminating Engineering Society on April 24, a discussion on "Daylight, Artificial Light, and Artificial Daylight" was opened by Mr. J. S. Dow. In the first section of his paper Mr. Dow directed attention to the chief respects in which daylight differed from artificial light, pointing out that natural lighting in most buildings is far from ideal. It was suggested that in general, owing to the eye being adapted to the bright sky overhead, somewhat higher illuminations are required by natural than by artificial light. The difficulty of working in a mixture of natural and artificial light was also analysed, the author suggesting that one of the chief causes of the feeling of discomfort is the progressive diminution in daylight intensity during the twilight period. It was pointed out that in many buildings, especially offices in congested areas, artificial light has to be frequently used to supplement daylight. There is therefore some reason to advocate the adoption of a form of 'modified artificial daylight,' that is, lamps so screened that the light is visually a match for daylight, provided the absorption of light occasioned is not too high. The Council Room of the Chartered Institute of Secretaries was mentioned as an interior in which this method has been followed with happy results. Mr. Dow also touched on the debatable question whether light resembling average daylight in colour is more favourable to acuteness of vision than uncorrected artificial light. Detail illuminated by red light is most distinct when viewed at a distance, whereas for very close vision the reverse is often the case. The effect is apparently associated with the chromatic aberration of the eye, and it is probable that this explains to a great extent why some people find reading by daylight easier than by artificial light of similar intensity.

THE first conversazione this year of the Royal Society will be held on Thursday, May 17, at 8.30 P.M.

SIR JAMES WALKER will deliver the Arrhenius Memorial Lecture of the Chemical Society on Thursday, May 10, at 5.30 P.M., in the theatre of the Royal Institution. With regard to ordinary scientific meetings, it has been decided to hold the May and June meetings of the Society at 5.30 P.M. instead of 8 P.M.

THE British Aquarists' Association will hold its third annual exhibition at Trinity Hall, Great Portland Street, W.C.1, on July 24–28. The exhibition will be of an international character, intending participants including exhibitors from Germany, Holland, America, Italy, and Japan.

MAJOR WALTER ELLIOT will give a Chadwick Public Lecture on "Sunlight—Natural and Manufactured—and its Use in Modern Medicine," at the house of the British Medical Association on May 15 at 8.15 P.M. He will review some recent research work and discuss the experience of certain local authorities.

A CORRESPONDENT points out, with reference to the lately announced death of Lord Eversley, that before elevation to the peerage, and when known as Mr. G. J. Shaw Lefevre, he was elected (in 1899) a fellow of the Royal Society under the old statutory provision relating to the occasional inclusion of privy councillors. This was during the presidency of Lord Lister. Later, Lord Eversley withdrew from the Society.

THE proceedings at the annual conference of the Institute of Quarrying at Blackpool, June 4–9, include papers by Prof. P. G. H. Boswell, University of Liverpool, on "Silica—its Commercial Properties and Markets," and by Mr. W. J. Rees, University of Sheffield, on "Commercial Sands." Among other papers to be read are "Electric Traction as Applied to Quarries and Slate Mines," by Mr. M. L. Williams-Ellis; "Cutting Costs in Slate Quarries," by Mr. T. R. Druitt; and "Research," by Mr. Hadleigh S. Seaborne.

SIR THOMAS ARNOLD, professor of Arabic, University of London; Mr. W. R. Halliday, Principal of King's College, London; and Prof. A. G. Tansley, F.R.S., Sherardian professor of botany in the University of Oxford, have been elected members of the Athenæum Club under the provisions of Rule II. of the club, which empowers the annual election by the committee of a certain number of persons of distinguished eminence in science, literature, the arts, or for public services.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A fully experienced and capable designer at the Admiralty, intimately conversant with design and detail of small turbines and internal-combustion engines—The Secretary of the Admiralty (C.E.), Whitehall, S.W.1 (May 7). A warden of the Hostel for Men Students of Stranmillis Training College, Belfast—The Principal, Stranmillis Training College, Queen's University, Belfast (May 15). Lecturers in physics and botany respectively in the Durham Division of the University of Durham—The Head of the Department of Science, University of Durham, South Road, Durham (May 19). A professor of physiology in the University of Hong-Kong—The Chief Medical Officer, Ministry of Health, London, S.W.1 (May 21). A half-time assistant in the department of mathematics of the University College of Swansea—The Registrar, University College, Swansea (May 23). An Academic Secretary of the University of Wales—The Registrar, University of Wales, Cathays Park, Cardiff (June 8). A wheat chemist at the Wheat Research Institute, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2 (June 30). A lecturer in experimental psychology in the Queen's University of Belfast—The Secretary, Queen's University, Belfast (July 1). A professor of pathology in the Queen's University of Belfast—The Secretary, Queen's University, Belfast (July 16). A master to take entire charge of teaching and supervising chemistry and physics, with some mathematics, at the King Henry VIII. School, Coventry—The Headmaster, King Henry VIII. School, Coventry. A metallurgist (or engineer with metallurgical training) having a thorough knowledge of the theory, treatment, and application of alloy steels, and a technical assistant, each for the Mond Nickel Company, Ltd.—The Secretary, Research and Development Department, Mond Nickel Co., Ltd., Victoria Station House, S.W.1. A teacher for building subjects at the Derby Technical College—F. C. Smithard, Education Office, Derby. An assistant physiologist in the Clinical Laboratory of the Sheffield Royal Hospital—The Supt. and Secretary, Royal Hospital, Sheffield. An assistant, and junior assistants under the Directorate of Ballistics Research of the Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

METEOR SHOWERS OF APRIL AND EARLY MAY.—Mr. W. F. Denning writes: "The April shower of Lyrids appears to have formed a display of minor importance this year. Mr. A. King watched from near Scunthorpe, Lincolnshire, on April 21, and recorded 12 Lyrids from a point 272° + 33½°, and on April 22 he noted 5 meteors from 273° + 33°. Bright meteors were observed on April 16 about $12^h\,44^m$ P.M., on April 19, 12.21 P.M., and on April 21, 12.21 P.M. At Bristol, on April 19, an assistant of Mr. Denning's observed for 4 hours, but saw only 14 meteors, and on April 21 in 2½ hours about 10 meteors were noted, the radiant being at 270° + 35° on April 19 and 273° + 34° on April 21. A brilliant Lyrid equal to Venus was seen at both places on April 21, and its real path will be computed.

"The Aquarid meteors of Halley's Comet are due on the mornings of May 2–7, but the moon will be near the full at the time. This need not, however, interfere materially with the display, for the meteors are often very bright and traverse considerable arcs. The shower apparently returns annually, but can only be witnessed in the couple of hours preceding sunrise, as the radiant is below the horizon in the earlier hours."

THE STRUCTURE OF THE GALACTIC SYSTEM.—An important paper by Dr. Seares on this subject appears in the current number of the *Astrophysical Journal* (vol. 67, p. 123). The problem is treated by statistical methods, based on assumptions concerning surface densities (expressed as logarithms of the number of stars of different apparent magnitude per square degree), and space densities, of stellar distribution.

The conclusions, which seem to satisfy all known peculiarities of stellar distribution, imply that our galactic system closely resembles the highly resolved spiral nebulæ such as M. 33; consisting of a central condensation and 'knots,' as well as scattered stars and diffuse nebulosity. The diameter of the system is 80,000 to 90,000 parsecs, and the central condensation is situated in longitude 325° at a distance of about 20,000 parsecs from the sun, though the effect of this condensation on the apparent surface density is masked by the dark nebulosity comprising the rift in the Milky Way. The sun is situated exactly in the galactic plane, except as defined by Cepheids, faint *B*-type stars, and other special objects.

There is also a smaller local cluster, forming an outlying aggregation or 'knot' of exceptional size and density, with a central condensation 100 parsecs from the sun. This is spheroidal in shape, 6000 to 8000 parsecs in diameter, with its centre in longitude 230° and 40 to 50 parsecs south of the galactic plane. The bright helium stars form a nucleus of this local cluster, which includes stars so faint as mag. 16 and has a dominating effect on the apparent stellar distribution, being responsible for three-quarters of the total space density near the sun, and one-half the mean density at distances of 700 parsecs in the galactic plane.

Research Items.

Candles and Lamps.—Mr. Walter Hough, in *Bulletin 141* of the United States National Museum, has described the collection of heating and lighting utensils in the Museum—a collection which was begun about forty years ago by bringing together specimens from the ethnological series and other material acquired by the Museum. It numbers at present about 1000 specimens. Mr. Hough's description of the collection is in reality a study of a very interesting and suggestive by-path of human invention, in which the significant element is that not only did it give scope to considerable inventive ingenuity, but also that ingenuity is still constantly being exercised. From observation of peoples of low culture to-day it is conjectured that the use of fire was primarily for light giving. The series epitomising the use of the candle begins with the firefly, and the burning of fat bodies of fishes or birds, and of faggots of resinous woods. Then follow torches consisting of rudely aggregated slivers of wood or sheets of bark, passing to torches made of wax or resin enclosed in palm leaf forming an exterior wick, torches of rope or cord soaked in wax or resin—the crude candle; and then formed candles, dipped candles, and moulded candles to the art candles of to-day. In the line of development the lamp comes at the stage when oils and fats come into use. Interesting examples of the natural torch are the bark of the Mexican candle tree (*Jacquinia pungens*), naturally so waxy that a small piece will give a good light, and, in another category, the stormy petrel of the Shetland islanders, who used to thrust a wick down the throat of the dead bird and applied a light. A wide-spread form of illuminating device is made from the candlenut (*Aleurites triloba*). Meats are strung on a strip of bamboo and the topmost lighted, when they burn to the bottom of the strip. This is generally in use among the Polynesians, and the Tule Indians of San Blas, Panama, use the palm nut in identical fashion.

Studies in Tropical Wasps.—Bulletin 19, Entomological Series of the Experiment Station of the Hawaiian Sugar Planters' Association, contains a series of very interesting articles by Dr. F. X. Williams on the habits of tropical wasps. The importance of this group of insects to the sugar industry of the Hawaiian Islands is well illustrated in the species *Scolia manilæ*, which is now so valuable an agent in controlling the introduced Asiatic beetle (*Anomala orientalis*). The publication affords a striking example of the wise policy of the Planters' Association to encourage and foster the prosecution of fundamental research bearing upon all insects affecting, or likely to affect, the sugar and other industries of the Islands. Dr. Williams provides an admirable account of the part played by fig-wasps in the fertilisation of wild figs in the Philippines, which is of special interest in connexion with the recent introduction of such insects into Hawaii to ensure the maintenance of fig-trees in that territory. The greater part of the publication, however, is devoted to an account of the family Larridæ, and more especially of the Philippine species. At least ten species of the genus Larra are known to prey upon mole crickets, which in many parts of the world are agricultural pests of some importance: in the Hawaiian Islands the species *Gryllotalpa africana* frequently attracts notice by destroying newly planted sugar cane. A small experiment, attempting the introduction of *Larra guiana* Cam. from Brazil into the island of Oahu, is mentioned. Among other articles Dr. Williams has some interesting field observations on wasps which prey upon cockroaches, and others which attack the giant South American avicularíid spiders.

Staining and Structure in Microscopic Anatomy.—For his presidential address to the Royal Microscopical Society (*Jour. R. Micr. Soc.*, March 1928) Dr. J. A. Murray chose the subject of staining and structure, for discovery in microscopic anatomy has been closely bound up with advances in the technical manipulation of the material which formed the subject of investigation. Tissues were at first examined in their own watery fluids, and this method is still practised, in fact probably to a greater extent than ever before because of the enormous improvements in present-day optical methods. Then came the development of methods of fixation, hardening, staining, and mounting, which was briefly traced. The methods devised for producing thin sections not only accelerated discovery in all branches of microscopic anatomy, but also exercised a profound effect on every branch of microscopical manipulation, more especially on methods of staining and mounting. The most important advance in staining methods was the iron-alum hæmatoxylin of M. Heidenhain, the special advantages of which were considered. Dr. Murray instanced an application of this technique to the age-old microscopic problem of the nature and form of the markings on diatoms. Cleaned diatoms were immersed in a solution of gelatine for several days, and samples were then spread on slides, fixed in formol, stained with iron-alum hæmatoxylin and mounted in euparal. The markings on the diatoms were then seen as very dark lines and dots, and the appearances suggested that the characteristic markings are indentations on the inner surface of the frustule which are filled during life with protoplasmic processes. In conclusion, Dr. Murray said that it might appear inappropriate to many in the Society, so largely representative of the amateur element, that he should have devoted his address to a subject which mainly concerns the professional biologist. But the so-called professional microscopist must be in a very real sense an amateur if he would go far in the science. "If he has not the humble enthusiasm which is sustained by the pleasure in viewing microscopic images pushed to the limit of technical perfection in every way, the path of discovery in microscopic anatomy is not for him."

The Penetration of Methylene Blue into Living Cells.—Much use has recently been made by American physiologists of the alga Valonia, on account of the suitability of its large cells, for studies on the permeability of protoplasm. A single cell contains enough sap for the colorimetric and spectrophotometric examination of the contents. M. M. Brooks (*Proc. U.S. Nat. Acad. Sci.*, 13, 821–23; 1927) has found that though the rate of penetration of the dye depends both upon temperature and the hydrogen ion concentration of the external medium, yet the concentration found in the sap when equilibrium has been attained is independent of the external hydrogen ion concentration. The methylene blue, moreover, penetrates as such, and it is not the lower homologue, trimethylthionine, that penetrates as Irwin thought. The latter is found in sap which has stood for some time after being expressed and arises from oxidation of methylene blue.

Sex Chromosomes in Empetrum.—*Empetrum nigrum* is a well-known Ericaceous plant found in Europe and circum-polar in its distribution, extending into the mountains of South America. A variety *hermaphroditum* has long been known, and is now recognised by Mr. O. Hagerup (*Dansk Botanisk Arkiv*, vol. 5, No. 2) as a separate species. He found it common in Greenland. It is also circum-polar, but in higher latitudes, being found in Newfoundland, Iceland, the Faroes, Scandinavia, Finland, Spitsbergen, and Siberia. It occurs also at high altitudes in the Alps, Vosges, and Auvergne. The species is stouter than *E. nigrum*, with shorter internodes, and the flowers are nearly always hermaphrodite, whereas in *E. nigrum*, which is the only form occurring in Denmark, the sexes are separate. Hagerup finds that the haploid number of chromosomes in *E. nigrum* is 13, and that there is an unequal XY pair of sex chromosomes. *E. hermaphroditum* is a tetraploid cell giant having 26 pairs of chromosomes. According to his account, there are two XY pairs; but they are arranged inversely on the heterotypic spindle, so that each pollen grain gets an XY pair. If the eggs also have an XY pair, the resulting plants might be expected to be hermaphrodite. This new sex chromosome situation is of much interest. It would appear that a tetraploid mutation has produced a form which is adapted to colder conditions and has acquired a balance of its double set of sex chromosomes, giving a stable bisexual species. It is possible that similar conditions may explain the peculiar behaviour of some of the polyploid willows.

Silurian Corals.—Although much attention has been paid in recent years to the Rugose Corals of the Carboniferous and Devonian, but little work has been done on those of earlier formations. Revived interest is shown by the publication by R. Wedekind of a monograph on the Rugose Corals of Gotland *Sveriges Geol. Undersök*, Ca, No. 19, 1927). He divides these corals into two sub-orders, the Streptelasmacea and the Cystiphyllacea, and describes several new genera. The stratigraphical significance of the coral faunas is discussed. The Lower Gotlandian is characterised by the occurrence together of the last of the Streptelasmacea and the first of the Cystiphyllacea, and the genera Dinophyllum and Chonophyllum are dominant at this stage. The Middle Gotlandian is dominated by the Cystiphyllacea, and there is no Streptelasmid except the long-lived Calostylis; this division of the Silurian is divided into three stages, each with its characteristic coral fauna. The Upper Gotlandian is distinguished by the Omphymatids, especially by the genus Omphyma. Other recently published papers on Silurian Rugose corals are: 1) Revision of the Rugose Corals described in Murchison's Silurian System, by W. D. Lang and S. Smith, *Quart. Jour. Geol. Soc.*, 83, p. 448; 1927. 2) *Tryplasma rugosum*, by S. Smith and W. D. Lang, *Ann. Mag. Nat. Hist.*, 20, p. 305; 1927. (3) Ptilophyllum and Rhysodes, by S. Smith and R. Tremberth, *ibid.*, p. 309. (4) Structure and Development of Stauria, by S. Smith and T. A. Ryder, *ibid.*, p. 337.

The St. Lawrence Earthquake of Feb. 28, 925.—This remarkable earthquake has already been noticed in these columns (vol. 116, pp. 56 and 948), and a detailed report on it by Mr. Ernest A. Hodgson, seismologist in the Dominion Observatory of Ottawa, has recently appeared in the *Transactions of the Royal Society of Canada* (vol. 21, pp. 145–52; 1927). The earthquake was felt strongly in eastern Canada and the New England States, and slightly as far as Virginia and the Mississippi, and even at Duluth, about 1200 miles from the origin. The disturbed area may thus have contained more than a million square miles. The damage caused by the shock was confined to a narrow belt, about 20 miles long, crossing the St. Lawrence near Rivière Ouelle (about 90 miles below Quebec), the epicentre (as determined by instrumental observations) being near the centre of this band, in lat. 47°·6 N., long. 70°·1 W. The earthquake was probably due to a sharp upward thrust on the north-east side of a fault traversing the band, coupled with a horizontal movement of the south-west side towards the north-east. The only line of levels in the district was one made in 1915 from Levis to Rivière du Loup. A series made in 1925 after the earthquake showed no displacements exceeding the order of the errors of observation, but, assuming that the Levis end of the line was undisturbed, it is worthy of notice that the differences to the east of St. Pacome and Rivière Ouelle were all in the same sense and upwards, while those to the west were in the opposite direction.

Incipient Ionisation.—A process described by Prof. J. Franck in the *Zeitschrift fur Physik* of Mar. 6 shows how it is possible for an electron to part with more energy than is needed to produce ionisation when it collides with an atom, without the actual formation of new charged particles. The electron which would be liberated normally is supposed to pass into one of the exterior quantum orbits which is usually vacant, and to emit in the form of radiation the excess energy that it could have carried away from this position to a point outside of the sphere of influence of the positive residue. Such radiation would be mainly in the infra-red, but arc lines would be emitted in the subsequent return to the normal state, and it is suggested by Prof. Franck that this explains why the intensity of the latter varies with the energy of the impacting particles in much the same way as the number of ions produced.

Large Mercury Arc Converters.—For several purposes, notably in connexion with storage, railway, and tramway traction, direct current supply is better than alternating current supply. Hitherto machines for converting alternating current into direct current, called rotary converters, have been generally used. Now, however, judging from an article which appears in the March number of the *Brown Boveri Review*, the mercury arc rectifier, which twelve years ago was a modest piece of laboratory apparatus, has developed into a formidable rival of the rotary converter. Continuous research on the phenomena which accompany the working of the electric arc has enabled the difficulties in the way of designing large current rectifiers to be overcome. Now rectifiers having outputs so great as 16,000 amperes are made. It is claimed that all risks of 'back-fires' have been eliminated, and that this static converter, the depreciation of which is very small, surpasses all types of rotary converter. It is possible to convert alternating currents at the very highest pressures into direct current by its means. Continuous tests have been made on a rectifier having an output of 200 amperes at 16,000 volts. At present, however, there is no great demand for conversion at very high pressures. When speaking of the rating of a rectifier, the current for which it has been designed is understood, as by merely altering slightly the current input it can be used over a wide range of pressures. In the 16,000 ampere mercury arc rectifier with steel cylinder there are 24 anodes.

Railway Electrification.—As it is highly probable that in the immediate future extensive developments of main line railway electrification will be made, it is necessary for traction engineers to study very carefully the working of the electric railways of all countries. Unfortunately, very different systems are in use, and the solutions which are successful in one country may be quite unsuited for another. A paper by F. Lydall on the electrification of the Pietermaritzburg—Glencoe section of the South African railways was read to the Institution of Electrical Engineers on Mar. 29. It describes the electrification of 170 miles of narrow-gauge railway which runs through difficult country. Glencoe is approximately the centre of the Natal coalfields, and most of the traffic consists of coal consigned to Durban. As most of the line is single track and very powerful locomotives (3600 horse-power) had to be used, it was necessary to use a pressure of 3000 volts owing to the limited carrying capacity of the rails. The power station is close to Colenso and is about 60 miles from Glencoe. The river Tugela supplies the necessary cooling water. The station generates 3-phase 50-frequency current at 6600 volts. The power is then stepped up to 88,000 volts, at which pressure it is transmitted to 12 substations spaced about 15 miles apart. This distance is very short compared with the Chicago and St. Paul Railway, where the average spacing is about 35 miles, but it was chosen in view of the density of the traffic and the necessity of working to schedule speeds. All the substations are fully automatic, so that attendants are not required. As thunderstorms in Natal are frequent and severe, their effects on the overhead equipment caused some dislocation of the service during the first two summers. The lightning flash sometimes caused a spark over an insulator, and this started a 3000-volt arc. By the adoption of high-speed automatic circuit breakers, it was found that this arc was prevented from doing damage, and so it was unnecessary to use special lightning arresters.

Electric Furnaces in Metallurgy.—A pamphlet recently issued by the Birmingham Electric Furnaces, Ltd., is an indication of the rapid strides which are being taken in connexion with the application of electric heating in the metallurgical industries. Photographs of quite large, internally heated electric furnaces with automatic charging gear are shown which have recently been installed in Birmingham and, in simplicity of design and convenience of operation, would appear to be of high promise. A feature of particular interest is the type of door fitted in these units. This is, in general, both a source of loss and at the same time one of inconvenience to the workers. The patented design adopted in these furnaces swings outward with a parallel motion, so that the hot face is never presented to the operator. It is counterbalanced to facilitate movement and well lagged to minimise heat losses. By means of a door switch, the furnace is rendered electrically dead immediately the door is opened and any danger to workmen thus removed. The material used for its framework is nickel-chromium.

The Effect of Quenching and Tempering Non-ferrous Alloys.—Two papers read at the spring meeting of the Institute of Metals, by T. Matsuda and A. L. Norbury respectively, both deal with the effect of quenching and tempering on non-ferrous alloys, and in both papers it is shown that in certain cases it is possible to bring about a very considerable increase in the hardness and strength by tempering the quenched alloy at an appropriate temperature. For example, a brass containing 60·44 per cent. of copper, which when quenched at 800° C. has a Brinell hardness of just above 90, attains a hardness of about 125 when it is afterwards tempered at 300° C. There is corresponding increase in the tensile strength, very little change in the elongation or the Izod-value, but a very profound increase in the Stanton impact-number. In the quenched state this was about 3800; tempered at 300° C., it had risen to nearly 6000. Norbury, dealing with standard silver (92·5 per cent. silver, 7·5 per cent. copper), has shown that when quenched from 770° C., the alloy is about 30 per cent. softer and 20-30 per cent. more ductile than it is in the ordinary annealed condition. On tempering the quenched alloy for about half an hour at 300° C., its Brinell hardness is about trebled, the tensile strength being increased by about 50 per cent. At the same time, however, the ductility falls by about 50 per cent. The hardening obtainable by tempering is uniform throughout the sample, and is superior, therefore, to the similar hardening effected by cold-working operations, which set up internal stresses. It is possible to harden the quenched alloy by cold-working and then further harden it by suitable tempering. When in the quenched and tempered condition, the alloy is more resistant to oxidation and tarnishing than when it is in the annealed state.

The Purification and Atomic Weight of Erbium.—In the *Journal of the American Chemical Society* for February, A. E. Boss and B. S. Hopkins describe the preparation of pure erbium compounds from yttrium erbium mixtures by fractional decomposition of the nitrates by fusion and by treatment with sodium nitrite. The ratio of erbium chloride to silver was determined, and the average of six analyses gave the value 167·64 for the atomic weight of erbium. This is in close agreement with the previously accepted value of Hofmann, namely, 167·68.

The Position of the Rare Earth Elements in the Periodic System.—The difficult problem of the position of the rare earth elements in Mendeléeff's system is discussed in an interesting paper by Prof. J. F. Spencer in the *Journal of the American Chemical Society* for February. Apart from scandium and yttrium, which can be easily accommodated in the periodic system, there is a series of fifteen elements from atomic number 57 (lanthanum) to atomic number 71 (lutecium), between barium (56) and hafnium (72). Since these elements are basic and tervalent, they must be placed in the six places of the periodic system in Groups III and IV, Series 8, 9, and 10. They can be divided into two groups according to the ionic magnetic moments and the solubilities of their compounds, and Prof. Spencer discusses the distribution of the rare earths among the possible places, taking into consideration these characteristics, together with such chemical evidence as is available.

The Action of Active Nitrogen on Iodine Vapour.—In the *Proceedings of the Royal Society o Edinburgh*, vol. 48, Part 1, L. H. Easson and R. W Armour describe a spectroscopic investigation of the effect of active nitrogen on iodine vapour. The authors support Willey's view that the glow of active nitrogen is due to the recombination of nitrogen atoms, while the complex band spectrum is due to nitrogen molecules in many different states of activation. A line at 185$\mu\mu$, corresponding to an energy content of 6·7 volts (equivalent to 154,000 gm. cal.) was observed in the spectrum of iodine excited by active nitrogen. The shortest line previously known to be excited by active nitrogen was the iodine line a 206$\mu\mu$ observed by Lord Rayleigh. In view of the very low pressures used during this work, it is considered that no chemical action took place, the iodine merely receiving and radiating energy. When the iodine pressure was about the same as that of the active nitrogen, the blue glow produced on mixing with iodine vapour was only visible as an instantaneou flash, the duration of which was found by the use of kinematograph camera to be less than 1/100 sec.

The Steam Wells of California.

THE utilisation of the steam of the *soffioni* of Tuscany as a source of mechanical power has steadily developed since 1904 when the first pioneer experiments were carried out at Larderello by Prince Ginori Conti. The remarkable results which have since been achieved were described in NATURE of Jan. 14 last. Similar sources of geothermal energy were first tapped in California in 1921, and since then several deep wells have been successfully sunk, some of them being superior both in pressure and steam output to any yet reported from Italy. The active region is known as 'The Geysers,' and lies on the western side of the St. Helena Range, one of the coast ranges of California. Along a line some twenty-five miles in length, which appears to mark a fault or shatter belt, hot springs, some of which are associated with quicksilver deposits, occur at intervals. There are no actual geysers at 'The Geysers,' but over an area of thirty-five acres the ground is dotted with hot springs and fumaroles and salt patches, and steam and gases are constantly seeping through the surface. A thorough investigation of the locality has been made by Dr. E. T. Allen and Dr. A. L. Day, and the results, beautifully published by the Carnegie Institution of Washington,[1] add very materially to our knowledge of subterranean supplies of magmatic steam.

The hot springs mainly occur where the groundwater drainage would naturally be expected to emerge; they are clearly related to a thin zone of groundwater and show seasonal variation with the rainfall. Some of the waters are acid, and contain acid sulphates produced by the oxidation of sulphuretted hydrogen. Others have become alkaline through their prolonged action upon the superficial rocks, this leading to the production of neutral sulphates, and allowing the alkaline character of the bicarbonates in the water to make itself felt. The fumaroles, known as the Smokestack, the Safety Valve, and the Steamboat, and the steam vents, are unrelated to the topography; and neither these nor the artificial wells are affected by the weather. The exceptionally dry winter and spring of 1923–24 had no measurable influence on the steam flow, and all the evidence bearing on the origin of the steam points conclusively to a deep-seated magmatic source.

In all, eight wells had been sunk by June 1926, at depths gradually increasing from 200 to 650 feet. There is a marked temperature gradient, measurements revealing a rise of 130° to 165° C. within a depth of 500 feet from the surface. As at Larderello, and also at Katmai and Lassen National Park, the steam is supersaturated as it rises from the depths, but becomes saturated eventually after it has stood in a closed well for some time. "The opening of a well after the tools are removed presents an imposing spectacle. As the valve is opened steam and hot water rush violently out with a great roar, rising in successive leaps like a geyser and carrying a shower of sand and loose rocks which bombard the steel frame of the derrick with a rattle like a fire of musketry. The column quickly reaches its maximum height of 200 to 300 feet, and in a few moments much of the excess water and loose debris are cleared out, leaving a huge jet of intensely hot roaring steam rushing from the well at high velocity, the noise of which can be heard for several miles and which at close range is absolutely deafening." Considering that the pioneers of so dangerous an enterprise had no previous experience of the kind and were even unaware that similar projects had been carried out in Tuscany, it is remarkable that the first wells were completed without serious accident.

Gases accompany the steam, making up between 1 and 2 per cent. of the whole. Carbon dioxide is, as usual, the dominant gas, but hydrogen and methane are present to the unusual extent of about 15 per cent. each, and there are smaller quantities of sulphuretted hydrogen, nitrogen, and ammonia. This is a characteristically volcanic assemblage, and taken together with the meagre supply of meteoric water, and the enormous volume of high-pressure steam rising in a superheated condition, it points indubitably to a magmatic source. In general, it is found that the deeper the well the hotter the steam, but not uniformly from well to well, indicating that the rock is not equally pervious to steam in all directions. The steam probably rises through a fault zone of shattered rocks which interpose a resistance that is generally, but not everywhere, completely effective. Only so can the difference in activity in the different fumarole and hot spring localities along the St. Helena Range be explained.

Following along the lines justified by their earlier investigations, the authors direct attention to the profound significance of the occurrence of volcanic gases as "the one thread logically connecting all phases of igneous activity, the cause alike of the volcanic explosions with their imposing steam clouds, the rise of lava in craters, the intense surface temperatures in some volcanic eruptions, the formation of fumaroles with their various characteristics, and finally of the heat of hot-spring waters and of the distinctive features in hot-spring areas."

ARTHUR HOLMES.

Movements of British Industry and Trade.

THE latest report of the Committee on Industry and Trade, entitled "Further Factors in Industrial and Commercial Efficiency," provides much useful information regarding the important and far-reaching changes which have recently taken place in the relative prosperity and the geographical distribution of British industries.

Between 1901 and 1911 the number of persons employed in the main export industries increased by 20 per cent., as compared with an increase of 12½ per cent. in the total occupied population. In the next decade (including the abnormal War period) the total occupied population grew by 5½ per cent., but the rate of increase in the great industries was 21 per cent. In particular, coal mining and the metal and engineering trades increased much faster than industry as a whole. In the earlier decade the increase can be accounted for by the normal development of overseas trade. In the later period expansion was mainly in the munition industries, so that after the War Great Britain was left with an unduly expanded group of 'hypertrophied' industries. Statistics based on returns relating to the number of insured workers show that from 1923 to 1927 the number of persons engaged in the insured trades increased by nearly 6 per cent. from about 11½ millions to about 12 millions. This increase was, however, very unevenly distributed. Coal mining, iron and steel, general engineering, shipbuilding and marine engineering, and the woollen and worsted trades accounted in the aggregate for a decline of 200,000 persons. The only important export industries to show substantial increases were the electrical trades (27 per cent.), the motor industry (21 per cent.), and artificial silk (48 per cent.), all comparatively new and progressive branches of production. Among non-export industries which have shown a high rate of expansion are the distributive trades (25 per cent.) and the building and furnishing trades (19 per cent.). That the old established exporting industries have not kept pace with other trades is borne out by statistics of unemployment. Between 1923 and 1927 the percentage of unemployment averaged 13·5 per cent. in the exporting group, and only 9·2 in other insured industries.

GEOGRAPHICAL REDISTRIBUTION.

The migration of industry from the northern to the southern counties of England is perhaps the most interesting development in post-War Britain. The tendency has been noted by a number of observers, but it does not seem to have received the attention which it deserves. The Committee on Trade and Industry points out that in July 1923 the insured persons were divided between the southern and northern sections of the country in the proportion 45·7 (south) to 54·3 (north). In 1927 the proportion in the south had increased to 47 and in the north had declined to 53. Still more striking figures are obtained when smaller areas are examined, as will be seen from the following table:

PERCENTAGE INCREASE, 1923–27, IN THE NUMBER OF INSURED PERSONS.

London . .	7·29	Midlands . .	6·03	Wales . .	1·81
South-Eastern	15·83	North-Eastern	3·09	Scotland . .	1·38
South-Western	8·60	North-Western	3·73	N. Ireland .	0·47

The figures for unemployment tell the same tale of greater economic activity in the south than in the north.

PERCENTAGE UNEMPLOYED (MID-YEAR).

	Whole Country.	North.	South.
1923 . . .	11·3	13·1	10·2
1925 . . .	11·9	14·3	8·0
1927 . . .	8·8	12·6	6·7

Statistics show that certain industries, for example, stove, grate, pipe, and general iron founding, glue, soap, ink, match, and carpet manufacture, have expanded in the south but have declined in the north. Other trades, such as constructional engineering, bleaching, dyeing, furniture making, motor vehicle construction, silk, electrical engineering, etc., have increased more rapidly in the south than in the north. Even the steel industry has shifted southwards, Lincolnshire and the Midlands having increased their steel production by 700,000 tons, while on the east coast and in Scotland output declined 500,000 tons. The coke industry has tended to follow the movement of iron and steel, and the coke production of Durham has declined relatively to that of Yorkshire, and the industry has appeared in Lincolnshire.

The Committee considers that an important cause of the shift southwards has been the exhaustion of the northern ores, which in 1924 supplied only one-third of the national output as compared with one-half in 1913. In other industries, different, but no less potent, causes of migration have been at work, among which the Committee cites the greater freedom in the south from restraints due to hard-and-fast trade customs and the desire to obtain the full benefit from more economic organisation. Another probable cause which does not seem to have been directly considered by the Committee is the fact that local rates are generally lower in the south than in the north.

Further industrialisation of non-urban areas in the south of England will probably be stimulated by the development of electric power distribution and other forces, such as the development of road transport, making for de-centralisation. It would seem that now the process of concentration of industry in the north which commenced in the eighteenth century may be reversed, and a gradual though perhaps partial process of de-centralisation substituted.

Tobacco Culture.

TOBACCO is no exception to the rule that plants require phosphorus for growth, but it needs little compared with other crops. Under certain conditions, the growers may profitably take advantage of this property. Field tests have been carried out at Windsor, U.S.A. (Report for 1926 of the Connecticut Agricultural Experiment Station), on *old* tobacco land which has carried the same crop for a long period of years regularly manured with a complete fertiliser. On such land, no response to phosphorus treatment was obtained, neither the yield, quality, nor burning properties of the tobacco being affected by withholding the application. This is considered due to the fact that, as so little phosphorus is taken up by the crop, and only a small quantity removed by leaching, a surplus supply has been built up through the continued manurial treatment. Growers on this land can therefore effect considerable saving by omitting phosphate from their fertiliser mixtures for an indefinite number of years without incurring any risk, as the organic constituents of the manure applied are considered capable of supplying sufficient phosphorus to guard against depletion. However, on tobacco land where some rotation of crops is practised or on new fields, the same conditions do not obtain, and it would probably not be economic to omit the phosphatic dressings.

Experiments have also been carried out on the new Heber process of sweating tobacco recently developed in Germany. After the leaves are cured, a fermentation or sweating process is necessary before they are suitable for manufacture into cigars. The two methods in common use are the 'bulk' and 'case' processes. In the former, large piles of tobacco are allowed to heat up to 120° F., then shaken out and repiled, the process being repeated a number of times and requiring three to six weeks. In the 'case' method the tobacco is tightly packed in wooden cases and kept artificially heated at about 100° F. for six weeks or longer. The Heber process is applicable to either method, and consists in spraying the layers of tobacco, as the 'bulk' or 'case' is being made up, with a solution containing an 'active principle,' fermentation being by this means completed in eight days. In a control test where water was substituted for the solution, the tobacco was still very raw when the treated tobacco was completely fermented.

Besides the immense reduction in time and labour obtained by using this process, further advantages noticeable were that the leaves were lighter in colour and incurred less breakage and loss in weight. On other points, however, such as aroma and burning properties, no consistent differences were found between leaves sweated by the old or new processes.

University and Educational Intelligence.

Aberdeen.—Lord Meston has been elected by the General Council to the Chancellorship of the University in succession to the late Duke of Richmond and Gordon.

Cambridge.—Honorary degrees are to be conferred upon Prof. A. Einstein, Prof. Cumont, Prof. W. A. Craigie, Lord Lugard, Lord Justice Scrutton, Sir Cecil Hurst, and Sir D. Y. Cameron.

The Linacre lecture is being delivered on May 5 by Sir George Newman, chief medical officer, Ministry of Health, on "Linacre's Influence on English Medicine."

Emmanuel College announces a scholarship of £120 a year for mathematics, founded by Mrs. Braithwaite Batty in memory of the late Rev. R. B. Batty, second wrangler in 1853 and a fellow of the College. Preference will be given to candidates who are sons of clergymen or of certain officers in His Majesty's Army or Navy.

The continued generosity of three anonymous benefactors to the University, who have increased their contributions to the building and upkeep of the extension of the Fitzwilliam Museum to £37,000, £37,000, and £26,000, is announced in a Grace by which the University expresses its thanks.

Oxford.—The subject of the Halley Lecture to be delivered on Monday, June 18, at the University Museum, by Dr. Harlow Shapley, Director of the Harvard College Observatory, will be "A Search for the Centre of the Milky Way," instead of "The Extent and Structure of the Milky Way," as previously announced.

The latest date for the receipt of applications for grants from the Thomas Smythe Hughes Fund for assisting medical research is June 15. They should be addressed to the Academic Registrar, University of London, South Kensington, S.W.7.

Applications are invited by the Senate of the University of London for the Laura de Saliceto studentship for the advancement of cancer research, tenable for not less than two years and value £150 annually. Applications must reach the Academic Registrar, University of London, South Kensington, S.W.7, by July 1.

Applications are invited by the Salters' Institute of Industrial Chemistry for a limited number of fellowships of the normal value of from £250 to £300 each. The fellowships are open to chemists of post-graduate standing who are desirous of adopting a career in industrial chemistry. The latest date for the receipt of applications by the Director of the Institute, Salters' Hall, St. Swithin's Lane, E.C.4, is June 1. Forms can be had upon request.

The British Institute of Philosophical Studies has arranged a course of six lectures on "Mind in Nature," by Prof. C. Lloyd Morgan, which began on May 1 at 5.30 p.m., and will continue on succeeding Tuesdays. Prof. Clement C. J. Webb will deliver a course of four lectures on "The Philosophy of Religion" on Wednesdays at 5.45 p.m., beginning on May 23. Both courses are being given at the University of London Club, Gower Street, W.C. Particulars can be obtained from the Director of Studies, British Institute of Philosophical Studies, 88 Kingsway, London, W.C.2.

We have received from the University of Leeds a copy of its report for 1926–27—one of the most eventful, the report says, in its history. Conspicuous among the events of the year are Sir Edward Brotherton's gift of £100,000 for the new library, the definite adoption of a design for the future University buildings (a bird's-eye view of which forms the frontispiece of the report), the completion of the University playing fields and of a new building for the Department of Agriculture, the acquisition of a house for the Department of Geology, and the institution of a chair of experimental pathology and cancer research. Progress was made with the building of additional hostel accommodation for women students and with the dental block of the medical school. Arrangements have been completed for beginning during the current year the first unit of the new University buildings—the mining block—and a new wing for the textiles section of the clothworkers' buildings. This new wing will provide increased accommodation for the Dyeing Department and will also be able to house the laboratories of the British Silk Research Association. A scheme has been elaborated for enabling graduate students to carry on research work for higher degrees in the laboratories of the British Research Association for the Woollen and Worsted Industries. Day students numbered 1366, of whom 80 per cent. belonged to Yorkshire, 12½ per cent. came from other parts of England, and 4½ per cent. from Egypt, India, and the Far East. There has been a small but continuous decrease in the number of full-time day students from 1922–23 (1559) to 1926–27 (1366). The staff list contains the names of a fair number of Leeds graduates, but many more who have taken degrees elsewhere, including graduates of every university of Great Britain and Ireland except Sheffield and Reading.

Another milestone on the road to educational progress was reached at Kingston-upon-Hull on Saturday, April 28, when Their Royal Highnesses the Duke and Duchess of York visited the city, and the Duke placed in position the foundation-stone of Hull's new University College. This has been possible through the generosity of the Right Hon. T. R. Ferens, who has given nearly £300,000 towards the scheme; the Hull Corporation, which has given £150,000 and an annual grant of £2500, as well as 18½ acres of land (originally a gift to the city by Mr. Ferens), and by several other generous gifts made by prominent citizens and firms of Hull. A list of the various donations was handed to the Duke by Principal Morgan. The building of the College is well advanced, and it is expected that part will be ready for occupation by October. The College is extending its site to close upon seventy acres, all within the residential area of the city, and a large house and estate has also recently been secured at Cottingham, a neighbouring village, for residential purposes. Most of the professors have been appointed. A circular route of six miles was planned for the Royal procession, thus enabling a crowd estimated at 200,000 to view it without overcrowding in any part. At the College the chairman of the Council, Archdeacon J. M. Lambert, gave an address, after which the Archbishop of York dedicated the stone. The Duke of York replied and placed the stone in position. The Duchess hoisted the College flag, which had been presented by the Hull Women's Co-operative Guilds. Among those present were the Lord Mayor and Sheriff of Hull, the mayors and principals of neighbouring towns and universities, local members of Parliament, Sir W. Henry Hadow, the Right Rev. Bishop Shine, Lord Deramore, and Prof. A. C. Seward.

Calendar of Customs and Festivals.

May.

Addenda.—It is perhaps more than a coincidence that the stories of a disproportionately large number of the saints whose days fall at the beginning of May are obscure or legendary. In Ireland they are perhaps more frequently associated with holy wells and, significantly enough in relation to the prominence of goddesses in Celtic religion, female saints, often known only by name, are numerous. The lives of these early saints frequently record contact with paganism in various forms. Serpent worship, for example, appears in the story of St. Philip (May 1), whose martyrdom was a consequence of his opposition to the idolatry of Hierapolis in Phrygia, and especially to the worship of a huge serpent of which he procured the death by his prayers. The life of St. Amator, Bishop of Auxerre (May 1, A.D. 418), records an interesting conflict with pagan observances in the story of Germanus, chief man of Auxerre, who used to hang up the heads of the wild boars and stags he killed as offerings to Woden on the branches of a large pear tree in the middle of the town, which Amator caused to be destroyed.

St. Marculf (May 1, A.D. 558), of Frank parentage, as his name (Forest Wolf) shows, is connected with the last ceremony of touching for the king's evil. The relics of the saint were preserved at Corbeny in the diocese of Laon, and the French kings, after their coronation at Rheims, used to make a pilgrimage to Laon, and, after touching the relics of Marculf, heal the king's evil. This was observed for the last time by Charles X. in 1825, at Rheims.

An annual ceremony still commemorates the death of St. Evermar and his companions, who were slain at a fountain while on a pilgrimage through Belgium (May 1, 700). In each year, on May 1, a procession takes place which is headed by two 'greenmen' representing savages, clothed in leaves and armed with clubs, followed by seven pilgrims, and then by Hako, the robber chief, and his men. After High Mass the murder is re-enacted, Hako shooting one of the pilgrims with a pistol as he runs away.

A saint who is more obviously connected with well-worship is St. Fumack (May 3), of uncertain date and unknown history, who is said to have bathed every morning in a well situated in what is now the manse garden at Botriphnie, then to have dressed himself in green tartans, and crawled round the parish bounds on his hands and knees. The image of the saint in wood was long preserved and became degraded into a local idol. In 1726, it was still washed on May 3 in the well with much formality by an old woman.

On two occasions in each year, of which April 30 or May 1 is the first, the dried blood of St. Januarius, the patron saint of Naples, is liquefied. In the morning a golden bust of the saint, and in the afternoon the blood in two phials, is carried in procession. In the evening, at about 7 o'clock, prayers begin in the Church of Santa Chiara and the liquefaction of the blood takes place after a longer or shorter interval, any unusual delay portending ill-fortune.

May 6.

St. Avia.—Of uncertain date, possibly beginning of third century A.D. After her death she is said to have appeared at Ploermel in the diocese of Vannes, Brittany, and to have touched a stone and a fountain. Thereafter infants were laid on the stone, which is hollowed in the centre, and dipped into the fountain to enable them to walk.

May 7.

St. Domitian of Maestricht (A.D. 560), according to a popular tradition, delivered the neighbourhood of Huy from an enormous serpent which infested the waters of a fountain with venom. He is invoked against fever, and on May 7 his shrine is borne in procession around Huy and to the fountain where he slew the serpent, while all the fever patients of the town follow in their shirts and carrying candles.

St. Stanislaus, A.D. 1079, was flayed and miraculously restored to life. A pious legend explains that a votive offering of a wax horse to St. Stanislaus at Cracow was dedicated by the head of a family whose horse died while they were on their way to the elevation of the remains of the saint to a new shrine in 1254. The sacrifice of the horse was a feature of Nordic ritual which long survived and was expressly forbidden in churchyards.

May 8.

The Apparition of St. Michael on Monte Gargano, near Manfredonia.—A bull when wounded by an arrow took refuge in a cave. When the herdsman attempted to withdraw the arrow it spontaneously sprang from the wound and wounded him. After a supplication and fast of three days at the instance of the bishop, the saint appeared to the prelate and informed him that the cave was his favourite resort, over which he wished a shrine to be erected. The story is curiously reminiscent of the Mithraic cult.

Helston Furry Festival.—At Helston, in Cornwall, this day was celebrated as a general holiday. At dawn it was greeted with the music of drums and kettles and the singing of the well-known Furry Song. Anyone who attempted to work on this day was ridden on a pole to a brook over which he was compelled to attempt to jump, but usually failed. An excursion was made to the country (known as to *fadé*), from which flowers and oak branches were brought back worn in the hats. All then took part in dancing up and down the street, and passing through any, or perhaps originally every, house.

May 10.

St. Comgall, A.D. 601.—An Irish saint, a member of a Dalriadha family, of whom many stories are told. One nearly parallels the myth of Bishop Hatto. When the saint endeavoured to obtain corn from a noble in a time of scarcity, he was refused on the ground that the owner required all for his mother 'Old Mouse,' whereupon mice devoured all his grain. Several other stories turn on the magical ideas connected with saliva. Saliva ejected by the saint while fasting, when gathered from the ground, healed a leper. On another occasion it turned to a gold ring in the pocket of a beggar; and it changed the obdurate heart of a king when the saint spat on a stone and it split into pieces.

May 12.

St. Epiphanius, A.D. 403.—A protagonist in the controversies relating to heresy of this time. Of the Apollinarianism which assumed definite shape about 369 as the result of an extreme view of the divinity of Christ, one form was a denial of the perpetual virginity of the Virgin Mary, while by reaction another made her an object of idolatrous veneration. The influence of pagan ideas is to be seen in the custom adopted by the women first of Thrace, and afterwards of Arabia, of placing cakes (collyrides) on a stool covered with linen, offering them to the Virgin, and then eating them as sacrificial food. This custom was denounced by Epiphanius.

Societies and Academies.

LONDON.

Physical Society, Mar. 23.—**W. D. Flower**: The terminal velocity of drops. The distance a drop of given volume has to fall through in order that it may attain a constant terminal velocity has been determined for both water and methyl salicylate. The terminal velocities have been determined for drops 0·2-0·55 cm. in diameter.—**Satyendra Ray**: The longitudinal wave along a rod. That longitudinal waves are propagated with the same velocity for all wave-lengths only when the waves are 'geometrically similar' is here proved in exactly the same manner as for either strings, air columns, or transverse waves along stretched strings. The expression for the velocity is of course different.

Royal Meteorological Society, April 18.—**C. K. M. Douglas**: Some Alpine cloud forms. 'Banner clouds' are formed as the result of an eddy drawing air up the lee side of a steep mountain in a strong wind, and are very turbulent. Lenticular caps, or 'föhn clouds,' are smooth in appearance, and are formed in a damp current crossing the mountain top with vertical displacements, which do not seem to be large as a rule, most of the air apparently flowing round the mountain. Banner clouds appear to draw their moisture from lower down than caps, so that the two forms often exist independently, though both are produced by strong winds. The existence of caps, but no banners, may be attributed to a damp layer with dry air below, a condition known frequently to exist.—**N. K. Johnson**: A strong wind of small gustiness. Records of wind velocity and direction obtained at Leafield, Oxon, on two days in December 1926, are discussed. On the first day the weather was that corresponding to equatorial air, with overcast sky, slight rain, and a strong wind. The autographic traces of wind velocity and direction possess considerable width. The second occasion relates to polar air, the sky being practically clear but the wind velocity being approximately equal to that on the first occasion. The records of wind velocity and direction in this case are characterised by the extreme narrowness of the traces. Whilst polar air normally gives somewhat narrower traces than equatorial, the great difference found in the present examples is to be attributed to the difference in the lapse rates. During the clear night an inversion of nearly 3° F. existed between heights of 1 m. and 87 m. in spite of the wind velocity being 18 m./sec. (40 miles/hour).—**T. N. Hoblyn**: A statistical analysis of the daily observations of the maximum and minimum thermometers at Rothamsted. An account is given of the work carried out on 48 years' temperature records at Rothamsted. At this station, both maximum and minimum temperatures vary significantly from year to year at all periods of the year, although the variation is much greater in some months than in others. The correlation between the different measures differs quite definitely in the various months.

PARIS.

Academy of Sciences, Mar. 26.—**A. Mesnager**: The thickness required in triangular barrages; deduced from the official report of the failure of the reservoir barrage of Oued Fergoug (Perrégaux). A discussion of the effects of water pressure from below, and the effects of such pressures on the formulæ ordinarily in use. The usual factor of safety is insufficient in such cases.—**P. Helbronner**: The common sides of the fundamental Italian triangulation and the detailed geometrical description of the French Alps. The French and Italian measurements are fundamentally based on slightly different metres, and a minus correction of 1/74,000 must be applied to the Italian metre, to make the two series strictly comparable. The improvement produced by applying this correction is shown in tabular form.—**E. L. Bouvier**: The Saturnian Lepidoptera of the family of the Hemileucidæ.—**Pierre Weiss** and **R. Forrer**: New measurements of the atomic moments of iron and nickel at low temperatures. The experiments were carried out with the purest iron obtainable (Heraus), and two specimens of nickel containing 99·91 per cent. nickel (Heraus) and 99·76 per cent. nickel (Mond). The possible errors in the extrapolations involved are discussed and shown to be small. The atomic moments of iron and nickel are, with high accuracy, integral multiples, 11 and 3, of the same moment, the experimental magneton.—**A. Kolmogoroff**: A limiting formula of A. Khintchine.—**Finikoff**: The intrinsic equation of a surface.—**Bertrand Gambier**: Convex closed surfaces; ds^2 of Liouville; geodesic antipodes.—**A. Buhl**: Permutable operators and mobile trihedra.—**Renato Caccioppoli**: A general theorem for the passage to the limit under the sign of an indefinite integral.—**Soula**: Remarks on the principle of M. Picard.—**Paul Flamant**: An idea for integral functions analogous to that of the normal family for holomorph functions.—**S. A. Gheorghiu**: The growth of the denominators $D(\lambda)$ of Fredholm.—**Serge Bernstein**: Some asymptotic properties of the best approximation.—**R. Swyngedauw**: The characteristic differences presented by the movement of a pulley belt approaching and leaving the pulley.—**Jacques Mesnager**: The theory of heavy masses of masonry submitted to pressure from below and its application to the stability of barrages.—**Baticle**: The theory of equilibrium of heavy massifs submitted to pressures from below, and its application to the stability of barrages and talus.—**V. Nechvíle**: The theory of two star streams and the ellipsoidal theory. The frequency curves given by the ellipsoidal theory (Schwarzschild) for certain values of ϵ assume forms exactly similar to those of the two stream theory (Eddington).—**Eligio Perucca**: The triboelectrical effect between solid bodies and gaseous bodies. Experiments are described proving that the electrification produced by a jet of mercury vapour impinging on a metal plate cannot be attributed to contact of mercury droplets with the collector, and the electrification produced must be regarded as due to the vapour.—**R. de Mallemann**: The electro-optical theory of quartz. The theory suggested by the author is confirmed by experimental results recently published by Ny Tsé Ze: the theory is developed in more detail in the present paper.—**Jean Rey**: Comparison of glass and metallic reflectors for lighthouse use. The metal reflectors are superior to glass.—**René Lucas**: The action of temperature on the rotatory powers of optically active substances.—**Jean J. Trillat**: The study of cellulose and the acetates of cellulose by means of X-rays. Cellulose, the oxycelluloses, and the hydrocelluloses, give similar X-ray diagrams. As regards the acetyl celluloses, the variations on the diagrams are sufficiently marked to serve as a control on chemical analyses.—**G. Guében**: The action of radioactive radiation on the dielectric constant of dielectrics. Various solid dielectrics were examined, paraffin, glass, celluloid, bakelite, sulphur, ebonite, wax, etc. No variation of the dielectric constant was produced by irradiation with the rays from radium. If any such effect exists, it is less than one-thousandth of the value of the dielectric constant.—**Paul Bary**:

A new property of certain silica gels.—**Trividic**: The absorption of iodine by carbon in some organic solvents. The solvents employed in these experiments included ethyl, methyl, and isoamyl alcohols, benzene, toluene, the three xylenes, chloroform, carbon tetrachloride, and carbon disulphide. The progressive increase of iodine absorption with the time observed by Davis could not be confirmed. Contrary to the views of Davis and of Schmidt, the general formula due to Freundlich fully expressed the experimental results.—**Jean Cournot**: The action of small additions of tin and cadmium on the qualities of lead. A series of nine alloys was prepared containing up to 3 per cent. of cadmium and 3 per cent. of tin, and the breaking load, elongation, elastic limit, crushing load (at two temperatures), and hardness determined for each. An improvement in strength and elastic properties is produced by addition of cadmium. To give good malleability, some tin as well as cadmium is required: the ternary alloys are also less oxidisable when fused.—**P. Cordier**: Phenylethylmaleic acid and its *cis-trans* isomer phenylethylfumaric acid.—**L. Palfray** and **L. Rothstein**: The stereoisomers of quinite (1, 4, cyclohexanediol).—**Mlle. Marthe Montagne**: New researches relating to the action of organo-magnesium compounds on some fatty dialkylamides.—**C. Gaudefroy**: An apparatus for measuring the true angle of the optic axes.—**Ch. Mauguin**: The study of micas by means of the X-rays.—**J. Repelin**: The Aquitaine basin at the Helvetian epoch: the continental formations.—**Louis Besson**: The visibility and amount of dust in the air of Paris. For the same season of the year, at the same time of day, and with the same humidity, the visibility in 1919–26 was clearly less than during 1896–1903. It is calculated that the number of smoke or dust particles has increased in the air of Paris about 50 per cent. in twenty-five years.—**A. Maige**: The phenomena of fatigue of the plastids during amylogenesis.—**Pierre Gavaudan**: The presence of the oil-bearing system in the organs of multiplication of the Jungermanniaceæ.—**Albert Guillaume**: The variations in the alkaloid content in the lupin under the influence of feeding.—**H. Colin** and **R. Franquet**: A new plant containing maltose, *Schizopepon Fargesii*. This plant, more commonly known under the erroneous name of *Actinostemma paniculatum*, has tubercles from which maltose has been extracted.—**Pierre Dangeard**: The release of free iodine in marine algæ. The emission of free iodine by Fucus is not dependent on the plants being crushed, since paper containing starch can be turned blue without actual contact. It is proved that the emission of free iodine by certain varieties of Fucus and Laminaria takes place during their normal life.—**G. Athanassopoulos**: The limited numbers of young eels ascending the rivers in the eastern part of the Mediterranean. The fact that young eels are not found in the Black Sea, or in the rivers flowing into it, has been attributed to the sulphurous nature of the sea-floor preventing breeding. The author shows that the number of eels diminishes as the distance east from the Straits of Gibraltar increases. He regards the young eels as entering the Mediterranean Sea through the Straits of Gibraltar, the number diminishing progressively owing to the ascent by the fish of the rivers nearer Spain.—**E. F. Terroine** and **R. Bonnet**: The influence of the amount of glycæmia on the magnitude of the exchanges and the problems of specific dynamic action of excessive food supply.—**Jules Amar**: The laws of physical education.—**E. Rothlin** and **Th. Oliaro**: The biological estimation of the quantities of cardio-active glucosides fixed by the frog's heart.—**Georges Bourguignon**: The transcerebral excitation of the pyramidal system in man. Measurements of normal and pathological chronaxy.—**Henry** and **Edouard Lassalle**: A new theoretical expression of the limiting intensities as a function of the duration of the stimuli.—**Mlle. Goldsmith**: The evolution of a tropism.—**E. Brumpt**: The rôle of the viviparous American fish *Gambusia Holbrooki* in the struggle against paludism in Corsica. Biological methods based on the marked predilection of certain fish for the larvæ of mosquitoes have the advantage of low cost and of not interfering with the habits of the population of regions infested with fever. The efficacy of the American fish *Gambusia Holbrooki* in reducing the number of mosquito larvæ has been proved by experiments in Corsica.—**C. Dawydoff**: The reversibility of the process of development. The extreme phases of the reduction of Nemertes.—**N. Bezssonoff**: The immediate physiological action of a vitamin. A marked change in the bromine absorption figure of the urine after administration of vitamin C can be proved after 48 hours.—**Mlle. Suzanne Guery**: A new method of auscultation called differential binaural auscultation and apparatus for permitting its realisation.—**R. Cambier** and **F. Marcy**: The composition of the air of Paris streets.

BRUSSELS.

Royal Academy of Belgium, Oct. 8.—**Ad. Mineur**: The Hamiltonian equations. A proof independent of the calculus of variations.—**A. Demoulin**: The point correspondence between two surfaces by parallelism of the tangent planes, and on the infinitely small deformation.—**Victor Willem**: Observations on the locomotion of Actinia.—**Louis van den Berghe**: Experiments on the cardiac origin of the inspiratory reflex in fishes.—**G. Erdtman**: Vestiges of the recent quaternary history of Belgian forests. Conclusions based in pollen statistics from the peat deposits in the Hautes-Fagnes and Ardennes. The predominating trees are classified for five periods, starting about 7500 B.C.—**L. Rosenfeld**: The five dimension universe and undulatory mechanics.

Nov. 5.—**Th. de Donder**: The relativistic and quantic problem of *n* bodies.—**Th. de Donder**: The relativistic problem of *n* bodies to the first approximation.—**E. de Wildeman**: The morphology of the male flowers in the genus Scleria (Cyperaceæ).—**Lucien Godeaux**: The regular involutions of order three belonging to an irregular surface.—**Serge Avsitidysky**: Note relating to the work of M. M. Barzin and A. Errera, "Sur la logique de M. Brouwer."—**Marcel Homès**: The evolution of the vacuome in the course of the differentiation of the tissues in *Drosera intermedia*.

Dec. 3.—**Paul Stroobant**: (1) Observations of the transit of Mercury on Nov. 10, 1927, made at the Royal Observatory of Belgium at Uccle. (2) Observations on the same, made at the Astronomical Institute of the University of Brussels.—**Th. de Donder**: The equation of quantification of molecules comprising *n* electrified particles.—**P. Bruylants** and **A. Castille**: The butenoic amides.—**R. Ferrier**: The theory of the Amperian.—**Seligmann**: An account of the third general meeting of the International Geodesic and Geophysical Union.—**Paul Ledoux**: The histological characters of the cylinder axis in *Entandrophragma Leplæi* and *Entandrophragma roburoides* (Meliaceæ from the Belgian Congo).—**L. Godeaux**: The asymptotic lines of a surface and ruled space.—**Mlle. L. de Brouckère**: The adsorption of ferric chloride by crystallised barium sulphate.—**P. Swings**: The change of magnification in the aplanatic telescope.

Dec. 15.—**Th. de Donder**: The invariant form of linear partial differential equations of any order.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 14, No. 1, January).—**Oscar Knefler Rice**: (1) The quantum theory of quasi-unimolecular gas reactions. (2) The theory of the decomposition of azomethane. The considerations of the earlier paper are applied to this reaction, which is unimolecular at high pressures; they give results in fair accord with experiment. It is concluded that activation is by collision and that the chance of reaction of an activated molecule depends on the energy in about the way to be expected if the energy is localised in a particular place in the molecule.—**John R. Bates** and **Donald H. Andrews**: Fundamental frequencies, interatomic forces and molecular properties. There appears to be some relationship between (*a*) fundamental frequency and force of binding, and (*b*) heats of linkage, boiling points, and directive influence in non-polar molecules.—**Worth H. Rodebush** and **John C. Michalek**: The effect of intensive drying on the vapour pressure and vapour density of ammonium chloride.—**C. Dale Beers**: Some effects of dietary insufficiency in the ciliate *Didinium nasutum*. Didiniums fed on excessive quantities of normal Paramoecia remained healthy; those fed on Paramoecia which had been starved for a week died off after showing decrease in fission rate, loss of ability to encyst, inability to ingest food, decrease in size, monstrosities due to incomplete fission, etc. (qualitative insufficiency). Didiniums on nine Paramoecia daily rapidly encysted (quantitative insufficiency).—**Edwin B. Wilson**: Mendelian inheritance with assortive mating. A mathematical discussion.—**Chas. W. Metz**: Genetic evidence of a selective segregation of chromosomes in a second species of Sciara (Diptera). During the first spermatocyte division of Sciara, the maternal chromosomes separate from the paternal chromosomes without synapsis, and one group is thrown out. In *S. similans*, as in *S. coprophila*, the paternal haploid group is thrown out and the males transmit only the maternal chromosome. Probably all the paired chromosomes in Sciara undergo this segregation.—**George H. Shull**: (1) The 'outside-in' Œnothera flower, a new morphological type produced by the interaction of two recessive Mendelian factors. The characteristic feature of this flower is the rhythmic repetition of calyx, corolla, and androecium. It appears to be a double recessive, *brevistylis sup-plena*, in which these characters are complementary. (2) Linkage with crossing-over between *rubricalyx* buds and old-gold flower colour in Œnothera. The linkage observed is contrary to previous results. The explanation found is that old-gold flower colour is a compound character produced by the interaction of a dominant, *S*, the normal allele of the *sulphurea* factor, *s*, and a recessive, *v*, the *vetaurea* or old-gold factor.—**H. Hopf**: A new proof of the Lefschetz formula on invariant points.—**H. P. Robertson**: Note on projective co-ordinates.—**Oswald Veblen**: Projective tensors and connections. An introductory account is given of a system of differential invariants the algebraic theory of which is closely analogous to that of ordinary affine tensors, though the analytical theory is quite distinct from classical tensor analysis. It may have physical applications.—**Jared Kirtland Morse**: The molecular structures of methane. Scale models of diamond, graphite, and ethane using a cube structure for carbon have already been discussed. The model for ethane has more positions available for hydrogen than can be occupied, and it is suggested that, in ethane gas, molecular collisions may lead to the displacement of hydrogen from one position to another, giving rise to 'dynamic isomers.' Similar 'dynamic isomers' are possible with methane, some of which, since they have different moments of inertia, can be predicted from measurements of band spectra.—**Bergen Davis** and **Harris Purks**: Additional lines in the *K*-series of molybdenum and the natural breadth of spectral lines. The resolving power of the double X-ray spectrometer has been increased by turning the second crystal to increase the angular reflection. The new lines are regarded as 'spark' lines arising from multiple ionisation of the atom rather than 'fine structure.' The natural breadth of a spectral line is calculated as 0·00012 A.; the measurements made here seem to suggest a narrower line. If this is so, the radiation cannot come from a damped oscillating electron.—**J. H. Van Vleck**: The correspondence principle in the statistical interpretation of quantum mechanics.—**Carl Barus**: Experiments with modified mucronate electrodes. It was previously recorded that anode and cathode behave alike; this is incorrect.—**Leonard B. Loeb** and **L. DuSault**: The mobilities of gaseous ions in $H_2S - H_2$ mixtures. The corrected absolute velocities of the ions in carefully purified hydrogen sulphide are 0·69 and 0·71 cm./sec. per volt/cm. for the negative and positive ions respectively. It was found that the electrons do not attach themselves readily to hydrogen sulphide molecules. Work with mixtures of hydrogen sulphide and hydrogen showed, first, that in very pure hydrogen the electrons remain permanently free, and secondly, that a trace of hydrogen sulphide reduces both the positive and negative mobilities below that computed from Blanc's law, thus indicating clustering.

Official Publications Received.

BRITISH.

Proceedings of the Royal Irish Academy. Vol. 38, Section B, No. 1: On some Doubtful Species of the African Section of the Sempervivum Group. By Dr. R. Lloyd Praeger. Pp. 24. 6d. The Beck Pathological Microscope. Pp. 78. (London: R. and J. Beck, Ltd.)

Diary of Societies.

SATURDAY, May 5.

Royal Sanitary Institute (at Guildhall, Preston), at 10 a.m.—Prof. F. E. Wynne and others: Discussion on The Present Position of the Milk Supply.

Royal Society of Medicine (Otology Section) (Annual General Meeting), at 10.30 a.m.—J. P. Stuart: The Histo-pathology of Mastoiditis.—Dr R. Graham Brown: Case of Spherical Bulging of the Floor of the Third Ventricle, Secondary to Internal Hydrocephalus and Simulating a Pituitary Tumour.

Institution of Municipal and County Engineers (North-Eastern District Meeting) (at Thornaby-on-Tees).

British Mycological Society (at Cheshunt).—Phytopathological Meeting.

MONDAY, May 7.

Cambridge Philosophical Society (in Cavendish Laboratory, Cambridge), at 4.30.—Dr. A. A. Robb: On the Connexion of a Certain Identity with the Extension of Conical Order to n Dimensions.—J. Taylor: On the Action of the Geiger α-particle Counter.—J. Taylor and W. Taylor: The High Frequency Electric Discharge at Low Pressures.—E. J. Williams: Some Applications and Implications of Duane's Quantum Theory of Diffraction.—E. B. Moullin and A. D. Browne: On the Periods of a Free-free Bar Immersed in Water.—*To be communicated by title only*:—H. Lob: Note on Kuhne's Theorem.—J. M. Whittaker: The Electron in a Gravitational Field.

Royal Society of Edinburgh, at 4.30.—G. S. Carter: The Work of an Expedition to Paraguay and Brazil, 1926–27 (Address).—G. S. Carter and L. C. Beadle: Fauna of the Swamps of the Paraguayan Chaco in Relation to its Environment. I. Physico-Chemical Nature of the Environment.—E. Meyrick: Micro-Lepidoptera from the Chaco in Paraguay.—H. W. Parker: Some Reptiles and Amphibians from the Paraguayan Chaco.—R. Gurney: Some Branchiopoda from Paraguay.—J. Stephenson: The Oligochaeta from Paraguay.—D. A. Allan: Geology of the Highland Border from Tayside to Noranside.—F. Walker and J. Irving: Igneous Intrusions between St. Andrews and Loch Leven.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Pastor R. Saillens: Protestantism and Rationalism in France.

Royal Institution of Great Britain, at 5.—General Meeting.

Society of Engineers (at Geological Society), at 6.—J. N. H. Duke: Technical Education in Relation to Industrial Development in India.

North Staffordshire Institute of Mining Engineers (in North Staffordshire Technical College, Stoke-on-Trent), at 6.—A. Marshall: 'Whitewash' and its Application to Underground Roadways.—*Paper open for discussion*:—Description of the Bullhurst Coal Seam, and the method of working same at the Rookery Colliery of the Bignall Hill Colliery Co., Ltd., having regard to its Liability to Spontaneous Combustion, by J. Cowell.

Society of Chemical Industry (London Section) (at Chemical Society), at 8.

Surveyors' Institution (at Institution of Mechanical Engineers), at 8.—Discussion: The Report of the Royal Commission on Land Drainage in England and Wales.

Royal Geographical Society (at Æolian Hall), at 8.30.—Lt.-Col. L. N. F. I. King and Capt. E. H. M. Clifford: The Jubaland Boundary.

Royal Society of Medicine (Social Evening), at 9.15.—P. B. Tustin: Milk—from Cow to Consumer.

TUESDAY, May 8.

Institution of Petroleum Technologists (at Royal Society of Arts), at 5.30.—H. S. Rowell and D. Finlayson: Experiments in Viscometry.

Institute of Marine Engineers, at 6.30.—A. T. Ridout: Non-chemical Method for the Prevention of Scale Accumulation in Boilers, Diesel-jackets, and Water Circulating Systems in general.

Royal Photographic Society of Great Britain (Scientific and Technical Group), at 7.—E. A. Bierman and others: Discussion (with demonstration) on the Control of Gradation in Bromide Prints by Development.—H. E. Tomkins: Lunar Photography with a 24-inch Cassegrain Reflector.

Quekett Microscopical Club, at 7.30.—Dr. E. J. Salisbury: Stomata.

Institute of Metals (at Institution of Mechanical Engineers), at 8.—Prof. C. H. Desch: The Chemical Properties of Crystals (May Lecture)

Royal Anthropological Institute, at 8.30.—E. Torday: Dualism in Western Bantu Religious and Social Organisation.

WEDNESDAY, May 9.

Royal Society of Medicine (Surgery: Sub-Section of Proctology) (Annual General Meeting), at 4.45.—At 5.—Sir William de Courcy Wheeler (Surgery), Dr. G. Hodgson (Radiology), Dr. C. Dukes (Pathology), and others: Discussion on The Early Diagnosis of Carcinoma of the Rectum and Colon.

Geological Society of London, at 5.30.—W. B. R. King: The Geology of the District around Meifod (Montgomeryshire).—H. Dewey: Exhibition of a Palæolithic Flint-implement found in Gravel on the Dover House Estate, Putney Heath.

Royal Society of Arts, at 8.—Capt. R. W. Lane: The Sterilisation of Milk.

Eugenics Society (at Royal Society), at 8.30.—Dr. N. East and Prof. Van Loon: Crime and Heredity.

THURSDAY, May 10.

Royal Society, at 4.—Election of Fellows.—At 4.30.—Prof. I. P. Pavlov: Some Problems of the Physiology of the Cerebral Hemisphere (Croonian Lecture).

London Mathematical Society (at Royal Astronomical Society), at 5.—Prof. W. E. H. Berwick: Some Recent Advances in the Theory of Equations (Lecture)

Chemical Society (at Royal Institution), at 5.30.—Sir James Walker: Arrhenius Memorial Lecture.

Royal Aeronautical Society (at Royal Society of Arts), at 6.30.—B. N. Wallis: Design and Construction of Modern Rigid Airships.

Royal Photographic Society of Great Britain (Colour Group, Informal Meeting), at 7.—Major P. Bull: A Pocket Apparatus for Three-Colour Photography.—C. H. Clarke: A New Departure in Exposure Meters.

Institution of Automobile Engineers (Derby Graduates) (at Cavendish Café, Derby), at 7.30.—C. Mercy: Free Wheel Devices.

Optical Society (at Imperial College of Science), at 7.30.

Oil and Colour Chemists' Association (Annual General Meeting) (at 30 Russell Square, W.C.1).—H. Hepworth: Nitrocellulose Lacquers.

FRIDAY, May 11.

Royal Astronomical Society, at 5

Physical Society (at Imperial College of Science), at 5.—Dr. E. G. Richardson: The Amplitude of Sound Waves in Resonators.—R. E. Clay: The Focus of a Gas-filled X-ray Tube.—Demonstration of an Electric Harmonic Analyser, by Dr. R. T. Coe.

Malacological Society of London (at Linnean Society), at 6.

Junior Institution of Engineers, at 7.30.—A. T. Henly: Notes on the Drying of Industrial Products.

Society of Chemical Industry (Chemical Engineering Group) (Annual General Meeting) (at Chemical Society), at 8.—F. H. Carr: Some Chemical Engineering Aspects of the Fine Chemical Industry.

Royal Institution of Great Britain, at 9.—Prof. Doris L. Mackinnon: Life's Unsuspected Partnerships.

SATURDAY, May 12.

Royal Society of Medicine (Balneology and Climatology Section) (at Bath).

Institution of Municipal and County Engineers (South-Western District Meeting) (at Totnes).

PUBLIC LECTURES.

SATURDAY, May 5.

Arts School, Cambridge, at 3.—Sir George Newman: Linacre's Influence on English Medicine (Linacre Lecture).

MONDAY, May 7.

University College, at 5.—Dr. G. E. Coghill: Anatomy and the Problem of Behaviour (Succeeding Lectures on May 8 and 10.)

TUESDAY, May 8.

The University, Birmingham, at 5.30.—Prof. Fichter: Electrochemistry. (Succeeding Lectures on May 10, 11, 14, 15, 17, and 18.)

WEDNESDAY, May 9.

Medical School, Leeds, at 3.30.—Prof. G. G. Turner: Cancer of the Rectum.

THURSDAY, May 10.

Institute of Pathology and Research, St. Mary's Hospital, at 5.—Prof. E. C. Dodds: The Ovarian Hormone.

Imperial Institute, at 5.30.—Dr. J. M. Rendall: The Empire.

King's College, at 5.30.—Prof. J. O. Thomson: Problems of Ancient Geography.

FRIDAY, May 11.

University College, at 5.30.—Sir Samuel Hoare: The Value of Aviation to the British Empire.

CONFERENCES.

May 10 and 11 (at Bath).

Rheumatic Diseases.—President: Sir George Newman. Presidents of Sessions: Social Aspects, Lord Dawson of Penn; Causation, Sir Humphry Rolleston, Bart.; Treatment, Sir E. Farquhar Buzzard.

May 11 to 15.

Chemical Industry Conference (organised by Society of Chemical Industry in connexion with its London Section, Chemical Engineering Group, and Institution of Chemical Engineers).

Friday, May 11 (at Les Gobelins Restaurant, 1 Heddon Street, W.1), at 8.30.—F. H. Carr: Some Chemical Engineering Aspects of the Fine Chemical Industry.

Saturday, May 12.—Visit to Rothamsted Agricultural Experiment Station.

Monday, May 14 (at Institution of Civil Engineers), at 10.30 a.m.—Sir Arthur Duckham: The Fuel Industries and the Work of the Chemical Engineer.—Prof. G. T. Morgan: The Chemical Study of Low Temperature Tar.

At 2.30.—Sir Alexander Houston: Water Purification.—J. H. Coste: The Pollution of Tidal and Non-Tidal Streams.

May 15 (at Institution of Civil Engineers), at 10.30 a.m.—Sir Alfred Mond, Bt.: Scientific Research as applied to Industry.—Sir John Russell: The Part played by British Workers in the Application of Fixed Nitrogen to the Soil.

At 2.30.—Lt.-Col. G. P. Pollitt: Developments in the Heavy Chemical Industry.

SATURDAY, MAY 12, 1928.

The Technical Expert in the Civil Service.

IN his presidential address, given on April 17, on the occasion of the annual meeting of the Institution of Professional Civil Servants, Sir Richard Redmayne dealt briefly with the work of the Institution, the annual report of which for the past year supplies an impressive review of the whole field of national activities. He made, at the same time, some interesting remarks on the present position of the technical expert in the Civil Service.

In the annual report in question, the Institution, it is stated, has long held the view that an adequate solution of the problems affecting the employment of specialist officers in the Civil Service will only be arrived at as the result of an independent public inquiry. The reason given for this view is that although the increase in the numbers and in the importance of the work of the professional, scientific, and technical classes has been very considerable in recent years, nevertheless the public departments are still entirely controlled by 'administrators,' who not only constitute a close caste, but also have been unable satisfactorily to adapt themselves to the changed conditions which have come into existence in the activities of the public service. The chief problem relating to the technical expert in the Civil Service is essentially one of status, and it is recognised that its solution is unquestionably an undertaking of the first magnitude.

Realising that, in order effectively to attain its objectives, the membership of the Institution should be thoroughly representative of the professional, scientific, and technical groups in the several government departments, one of the chief aims of its council has been, almost from the earliest days of the inception of the Institution, to persuade the numerous associations which have come into existence in government departments for the protection of the interests of the specialist officers since the termination of the War, to link up with the main body of their colleagues organised in the Institution. Sir Richard Redmayne was able to announce that the policy of the council in this matter had in recent years met with marked success ; he further indicated that the membership of the Institution, which at the end of 1925 numbered 3000, would within a few months exceed 5000.

The technical expert must, Sir Richard urged, be recognised as indispensable for the carrying on of the complex task of government in the modern

State, and be afforded full and free opportunity for rising to the highest offices the public service could offer. He emphasised the fact that the position of the technical expert in the Civil Service is at the present time far from being a satisfactory one. The subordination of the technical experts now threatened in the Scottish Boards by the Reorganisation of Offices (Scotland) Bill affords an example of the need for a proper reconsideration of the functions and status of the technical expert in relation to the administration.

The objectives of the Institution of Professional Civil Servants have, needless to say, a wider importance than that of merely serving the purely personal interests of its members; they aim, in fact, also at the attainment of true economy and increased efficiency in the public service. It is common knowledge that the present organisation of government departments and their procedure promote neither of these two very desirable ends; indeed, in some respects, they militate against the attainment of them. What is wanted to-day is the complete modernisation of government departments with the view of bringing about such changes that the affairs of the public service may be conducted on the model of a well-managed business.

The claim for an improvement in the status of the technical expert is really intimately bound up with the subject of a root and branch reorganisation of the government departments, for the issue raised thereby ultimately resolves itself into a question of making a better use than is the case at present of the knowledge and abilities of the specialist officers in the employment of the State. This can alone result by introducing radical changes in the present hierarchical system of the Civil Service and in the methods now adopted in dealing with scientific and technical work in government departments. The method in vogue at present, whereby scientific and professional matters are discussed in writing, sometimes at inordinate length, between non-technical and technical officers, in practice too often creates a situation in which technical officers are called upon to afford instruction in some branch or another of technology to non-technical officers by a process somewhat akin to that of the much-advertised 'correspondence course.' On the face of it, such a method of conducting business cannot, and in fact does not, conduce to the attainment of either economy or efficiency; apart from the delays caused in arriving at a decision on the matters under discussion, owing to the time consumed in carrying on the correspondence, it will be evident that a larger number of non-technical and also technical officers must be employed by the State under these conditions than would be the case if a rational organisation existed in government departments. The spheres of responsibility of the administrative and technical branches should be so clearly laid down as to ensure in practice that the chief technical officer of a department should personally be solely responsible for the soundness of all technical projects and schemes prepared in his branch and submitted by him for the approval of the minister, as well as for the correctness of the advice on technical matters tendered by him.

The necessity for the modernisation of the organisation and the procedure of government departments is not a matter which rests on the views of those alone who are advocating the cause of the professional and technical groups in the public service. It is also made strikingly apparent in the reports issued during the past twenty years by numerous parliamentary and other official committees which have been called upon to investigate certain matters connected with some of the governmental activities, and, further, by the public speeches of ex-ministers delivered in recent years. These reports and speeches have made the public familiar with some of the unsatisfactory features connected with governmental enterprises of a technical nature; and, in particular cases, a need for a complete reorganisation of them has been stated in express terms.

The immediate question, then, is how to find an expeditious means for remedying a situation which unquestionably is prejudicial to the public interest. The members of the specialist groups in the Civil Service have very properly decided to act strictly on constitutional lines; this does not, of course, mean that they intend to fall into that state of pathetic contentment which is so disturbing to the mind of the ardent reformer. On the contrary, the majority constituting these groups have already organised themselves into regularly constituted associations and are gradually bringing about improvements in their separate organisations, and eventually, no doubt, the whole of the specialist officers in the Civil Service will be effectively organised, and ranged also under the banner of a central service institution. However, in view of the fact that government departments are controlled on traditional lines by a ruling caste whose inertia is proverbial, it seems improbable that the steps necessary for the modernisation of the public services and for securing a status for the scientific and technical experts in the employment in the State compatible with the real needs of the situation will be set on foot by a movement for reform inaugurated within the public service.

The Institution of Professional Civil Servants has, it is true, played a considerable part in securing benefits on behalf of the professional and technical groups, owing to the large share it has taken in the work of the National Whitley Council; and it certainly has no intention of relaxing its efforts in this direction. However, the procedure of referring matters to the Industrial Court is cumbersome and dilatory. Moreover, the functions of the Industrial Court are strictly limited; it is not empowered to deal with the question of the modernisation of government departments, which is fundamental if the public services are to be placed on a sound footing. Indeed, even as regards matters now falling within the powers of the Industrial Court, the Institution of Professional Civil Servants is so far from satisfied with the existing arrangements that it has set up a special committee with the view of securing improvements of the arbitration and Whitley machinery. Further, it is certainly not in the interest of the State that improvements in the status of an important body of its officers should be won piecemeal and by slow degrees. A reform obtained in such a manner must in the long run prove costly to the nation.

The measures which have been taken by the specialist officers for bringing about the reforms so necessary in the organisation of government departments, and in their methods of conducting business, deserve the full support of the public; it seems to be a matter in which the leading professional and technical institutions can well take an initial step. These institutions now show a considerable interest in questions affecting the occupations covered by their members, and some of them have already intervened on behalf of the professional group in the Civil Service by making suitable representations to the Prime Minister on matters dealt with in the Report of the Anderson Committee (Report of Committee on Pay, etc., of State Servants, 1923. H.M.S.O. 6*d*. net). The prestige which these institutions enjoy, not only among professional men, but also in the eyes of the public generally, renders them very suitable bodies for taking up the cause of the specialist officers in the public service; moreover, in doing so, they would be performing a task of immense benefit to the nation. The first step would seem to be the preparation by them jointly of a memorandum dealing with the whole subject of the status of the professional and technical officers; having taken this step, they could appropriately press for the appointment of a Royal Commission to inquire into the subject and to recommend remedial measures.

The Artificial Silk Industry.

(1) *The Manufacture of Artificial Silk: with Special Reference to the Viscose Process.* By E. Wheeler. (Monographs on Applied Chemistry, Vol. 1.) Pp. xv + 150 + 27 plates. (London: Chapman and Hall, Ltd., 1928.) 12*s*. 6*d*. net.

(2) *The Rayon Industry.* By Moïs H. Avram. Pp. xxi + 622. (New York: D. Van Nostrand Co.; London, Bombay and Sydney: Constable and Co., Ltd., 1927.) 42*s*. net.

(3) *Acetate Silk and its Dyes.* By Chas. E. Mullin. Pp. 473. (London: Constable and Co., Ltd., 1928.) 26*s*. net.

ARTIFICIAL silk, despite its name, has not assumed the place of the product of the silkworm in the textile industries, for the visible output of natural silk is increasing, although much less rapidly than that of artificial silk, which now exceeds it in annual amount. It appears, therefore, that the new fibre has found a place of its own, unless in so far as it may have dispossessed the other natural fibres, and its designation by some other name would have conveniences; but the word 'rayon,' invented and adopted in the United States, has not found favour in Great Britain, though the Drapers' Chamber of Trade recently decided to recommend the adoption of the word instead of the misleading term 'art silk.' Such a replacement of the natural fibres by artificial silk cannot yet have gone very far, as the amount produced during 1928 is not expected to exceed two per cent. of the total amount produced of all the natural fibres.

The rate of increase in the production of the new material, exemplified by the 99,500 metric tons produced in 1926 being twice the amount produced in 1923, continues, however, to be high; and the future possibilities of the new industry must appear to be great when it is considered that, apart from the more purely scientific researches which may have a bearing on the industry, systematic technical investigations are in progress with the object of producing a fibre more suitable for use in clothing; the employment of other derivatives of cellulose than those now used may become practicable, or even the manufacture of artificial fibres from other than a cellulose base. Meanwhile, the processes that hold the field are the viscose, the cuprammonium, and the nitro-cellulose processes, which yield fibres composed of regenerated cellulose, and the acetate process which yields fibres composed of acetyl cellulose.

(1) The object of Mr. Wheeler's monograph is "to present a description of the essential chemical and engineering details" of these processes "and of the properties and uses of artificial silk," with special reference to the viscose process, which is used for the production of about 90 per cent. of the world's output. As sources of cellulose, only cotton waste or linters and wood come into consideration at present; bleached sulphite wood pulp with a specified content of α-cellulose, prepared from spruce, fir, or hemlock, is commonly used for the manufacture of viscose, but the dearer cotton has the advantage of yielding a stronger artificial fibre; for the other processes cotton is generally employed, although wood pulp has been found to be suitable for the cuprammonium and acetate processes.

The viscose process depends upon the coagulation of an alkaline solution of cellulose xanthate by causing it to emerge from fine jets into a solution containing acids and salts, the composite thread formed from numerous filaments being afterwards desulphurised and otherwise prepared; the xanthate is made by the interaction of carbon disulphide and cellulose which has been impregnated with sodium hydroxide. Each of the numerous stages of the manufacture is carefully controlled; but the success of the viscose process is due in great measure to the ingenious mechanical arrangements, especially those employed for the spinning or conversion of the viscose into filaments. Mr. Wheeler accordingly, in his very clear and concise account of the normal process as carried out to-day in many factories, devotes considerable attention to the details of these arrangements; the text, supplemented by flow sheets, is freely illustrated by plates and diagrams, and reference is made to the patents and technical literature for further details and descriptions of alternative methods.

The other processes at present operated industrially are described equally skilfully, but more shortly. Of these the cuprammonium process, in which cellulose dissolved in an ammoniacal solution of copper hydroxide is regenerated in the form of filaments by passage into acid or alkaline solutions, is showing renewed vitality, although the proportion of artificial silk produced in this way is small; the nitro-cellulose process, which is the oldest, is on the wane; and the acetate process, which is referred to further below, is becoming increasingly important. Reference is also made to other methods proposed for the manufacture of artificial fibres, of which that depending on the production of cellulose ethers, now being developed on a large scale, is the most promising. The properties of artificial silk, both general and in relation to dyeing, its uses, besides other topics, are adequately discussed relatively to the scale of the book, which is a well-arranged and well-written outline of the subjects.

(2) The financial aspects of the industry are prominent in "The Rayon Industry," which appears to be intended mainly to inform the "groups of financial interests" who may be proposing to undertake the manufacture of artificial silk in the United States, although there is a list of the other numerous classes of readers for whom the book is designed. About one-quarter of the book of 600 pages is devoted to the history, finance, and economics of the industry, which are described with enthusiasm, tempered with warnings against unconsidered enterprises; forty pages are given to the natural textile fibres; thirty to the purification of water; fifty to yarn tables, and tables of weights and measures and such like; but only fifteen to dyeing. Useful features are the lists of patents and the bibliography of textiles generally, which together occupy about eighty pages. The actual processes of manufacture of artificial silk, described in a manner easily followed, occupy about one-quarter of the book; suggestions are made as to the plant required by an intending producer. Although the viscose process naturally occupies the chief place, the nitro-cellulose and cuprammonium processes are also described in some detail, but the discussion of the acetate process is somewhat meagre.

(3) Even in Mr. Mullin's conscientious and exhaustive work on "Acetate Silk and its Dyes," few details are given of the manufacture of this type of artificial silk, as "very little outside of the patent literature has been published." The preparation of cellulose acetate, and its properties, are, indeed, discussed at some length, but the book is essentially one on dyeing. As an ester of cellulose, acetate-silk is distinguished from the artificial silks composed of regenerated cellulose by special characteristics which at first hindered its dyeing. This book records the history of the development of suitable processes and describes the methods now employed, with copious citations of authorities. It will be of value to the dyer as a text-book and work of reference.

Modern Spectroscopy.

Handbuch der Experimentalphysik. Herausgegeben von W. Wien und F. Harms. Band 21: *Anregung der Spektren, spektroskopische Apparate*, von Georg Joos und Ernst v. Angerer; *Starkeffekt*, von Johannes Stark. Pp. xiii+562. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1927.) 49 gold marks.

ALL those engaged in research in physical optics, and spectroscopists in particular, must feel deeply indebted for the publication of this volume. Although some of its contents were available already in other publications (such as Kayser's "Handbuch" and Baly's "Spectroscopy"), it was often only in a much more diffuse form, and the more important part has only been published hitherto in a vast number of papers in the different journals.

Notwithstanding that the title of the work is experimental physics, there is an admirable account of the theory of the origin of spectra by Georg Joos, which even contains a brief summary of and many allusions to the results of the new wave mechanics. For the most part, however, this account deals with the theory of spectra in terms of the Rutherford-Bohr atom model and the old quantum mechanics modified to account for the complex spectra. There is, for example, a good, though rather too condensed, account of the 'doublet problem,' the first great difficulty of the older theory, and the development of the situation is carried on to include atoms with several electrons and the solution by the assignment of an intrinsic moment to each electron of one-half of a unit of $h/2\pi$.

This section of the book forms an admirable introduction to such a book as Hund's "Linienspektren."

The excitation of spectra is fully discussed, including the methods of electron impact (and the determination of ionising and resonance potentials), absorption spectra, subordinate series absorption, resonance and fluorescence, and finally collisions of the second kind, and brief mention is made of sensitised fluorescence and photo-chemical reactions. The only similar account in English known to the reviewer is Foote and Mohler's "Origin of Spectra," and this is by now necessarily incomplete and omits much of the recent important work.

In the discussion of the widths of spectral lines we think that, though this is essentially a book for specialists, for the benefit of students perhaps, the point might have been made that strictly monochromatic absorption and emission is impossible since it involves zero probability for the recapture or radiation by atoms.

There follows a very useful account of the different sources of light available for spectroscopic experiments.

The second part of the book, by E. von Angerer, is an account of the apparatus and methods of spectroscopy. In the discussion of prism spectrographs the great practical importance of a straight line focal curve for the camera objective is rightly emphasised, and a most useful account of several actual systems given. The treatment of grating spectrographs is equally comprehensive, and includes good practical instructions for cleaning gratings. We should like to have seen mention made of Newall's method of the 'diffractional index' for setting the slits of spectroscopes (*Mon. Not. R.A.S.*, **65**, 610; 1904); its value lying in the possibility of exactly reproducing of a setting. We welcome the account of the illumination in spectrographs and would have liked more on this topic. The problem of the use of a spectroscope in conjunction with an astronomical telescope is not discussed.

There follows a chapter in which are collected together accounts of the various interference spectroscopes, and their combinations with other instruments, and also of crossed interferometers.

The account of the determination of wave-lengths includes a valuable summary of the work on primary standards, but the actual method of finding wave-lengths by means of a standard comparison spectrum (of iron, say) is not explicit, in so far as the method of choosing standard lines for the calibration curve and correction curve of wave-lengths from Burns's table (in *Lick Observatory Bulletin No. 247*) and St. John's report to the I.A.U. (1923) is not given.

The chapter on photometry, and in particular photographic photometry, is opportune, and well up-to-date. The time has come when all tables of wave-lengths should also contain accurate measurements of intensity. It is astonishing how well some observers have been able to convert themselves into photometers, but the old system of eye estimates of intensity demanded a very considerable knowledge from the user of it, if he were not also its maker, if any results were to be deduced from it. Anderson's method (*Astro. Jour.*, **59**, 76; 1924) of obtaining an intensity scale is very much better, and we would have liked to have seen its use urged in this book, as being very little more trouble than crude eye estimates, but of course whenever the extra labour can be afforded (and we grant that it is considerable), a scale independent of wave-length is desirable.

The third part of the book is an account of the theory and experimental investigation of the Stark effect by the one most qualified to give it, namely, J. Stark himself, and the reviewer can only remark that comment on it by him is superfluous.

The book abounds throughout with references to the literature of the subject, which are very complete and are brought so well up-to-date that the only supplement needed should be recent numbers of *Science Abstracts*. The printing and illustrations are all that could be desired.

J. A. C.

Academic Mycology.

The Structure and Development of the Fungi. By Dame H. C. I. Gwynne-Vaughan and B. Barnes. Pp. xvi + 384. (Cambridge: At the University Press, 1927.) 15*s*. net.

THE increasing recognition of the significance of the fungi in agriculture and industry makes the publication of a treatise on this group of plants an event of notable importance. This is the more manifest when it is realised that, since the translation of De Bary's great work on the fungi in 1886, there has appeared no book in English which covers the subject as does the present volume, or which has been suitable as a mycological text-book for advanced students of botany. Further, during this period only one book—Gaumann's "Vergleichende Morphologie der Pilze," published in 1926—has appeared on the continent of Europe. The present volume by Prof. Gwynne-Vaughan and Mr. Barnes partially occupies, therefore, a niche which has been empty for some considerable time.

The authors have kept strictly to their title, which is "The Structure and Development of the Fungi," and have not attempted to consider wider issues such as the physiology, ecology, and general biological relationships of the group. This is, perhaps, a little unfortunate, for readers will gain little conception of the part played by these organisms in Nature, of their vast importance as disease-causing agents in agriculture, forestry, etc., or of the dependence of many great industries upon fermentative processes brought about by them.

The book is thus in no sense a general treatise on the fungi, but it is a well-written and readable account of their reproductive structures and processes. Accepted as such it is a notable success and is assured of a cordial welcome.

Beginning with the more primitive forms in each of the three great classes of fungi, and working through to the more advanced types, the authors present a clear picture of the present state of our knowledge. The systematic arrangement they have adopted is more simple than that of many continental mycologists, but with the increasing recognition of the entirely artificial basis of much, at least, of our fungal systematics and phylogenetic schematisation, simple diagrammatic arrangements have at present almost everything in their favour. The book contains a useful chapter on mycological technique and a bibliography that will be found of value by students desirous of consulting original sources. Two hundred and eighty-five illustrations, many of them original, add greatly to the value of the book, which is excellently produced and commendably free from misprints and errors. A certain amount of loose wording here and there which might give rise to ambiguity can easily be amended in the several editions into which the volume is sure to run.

W. B. B.

Our Bookshelf.

Electro-Farming: or the Application of Electricity to Agriculture. By R. Borlase Matthews. Pp. xvii + 357. (London: Ernest Benn, Ltd., 1928.) 25*s*. net.

The introduction of mechanical power to the farming industry has proceeded more slowly than in other industries. Apart from the natural conservatism of the agriculturist, the main reason for this is the diffuse and spasmodic power requirements on the farm. In other industries, the processes are localised in a factory and are not subject to the constant change of plans that the weather conditions impose on the farmer. Nevertheless, steam power for cultivations, and the internal combustion engine for cultivations, haulage, and general work in the farm buildings, have all found a place in agriculture and the use of power is now rapidly extending.

The latest claimant is electric power, and the author of this book, who is a well-known pioneer in the subject, has produced a thoroughly up-to-date review of the position. The characteristic of electric power that most commends it to agriculture is the extreme simplicity of the motor as compared with other prime movers. For all work that can be done by fixed or portable engines the electric motor will no doubt seriously rival all other forms of power, immediately an adequate supply of electricity becomes available in rural areas. The weak point is its use for work on the land, which absorbs by far the greater proportion of the total power used in agriculture. Flexible cables must be provided between the moving machine and the fixed distribution lines, together with some auxiliary form of power (or a heavy and expensive battery) for movement about the farm. Although several ingenious systems are in use on the Continent for reducing to a minimum the inevitable inconvenience of the flexible cables, the British farmer will need much persuasion before he adopts the system.

Electric stimulation of plant growth is discussed more optimistically than the present position of scientific investigation in this intricate subject really warrants, and the same is true, although to a lesser degree, of the chapters dealing with light treatment of plants and animals. A full account is given of the undoubted improvement that electricity could provide in the amenities of the farm homesteads and the rural areas generally.

Although the object of the book is to pave the way for electro-farming, perhaps its chief immediate value is that it directs attention to the numerous ways in which the forms of power at present available could be applied with advantage on the farm.

The Year-Book of the Scientific and Learned Societies of Great Britain and Ireland: a Record of the Work done in Science, Literature, and Art during the Session 1926–27 by numerous Societies and Government Institutions. Compiled from Official Sources. Forty-fourth Annual Issue. Pp. vii+416. (London: Charles Griffin and Co., Ltd., 1928.) 18*s*. net.

IT is with much pleasure that we welcome once more this useful annual; the publishers deserve our sincere thanks for the labour and expense they devote to it. Moreover, they realise that a reference book must be distinctively and strongly bound; lightly bound reference volumes, which fall to pieces after a few weeks of use, are most irritating.

An important part of the volume is the note on the title-page—"Compiled from Official Sources." It shows that the information provided can be depended upon, and our thanks should also go to the officials of societies, many of them busy men serving in an honorary capacity, who take the time and trouble to make it available. As regards the contents of the book, it is sufficient to say that the various societies are classified according to subject, and under each one is given its address, officers, meetings, publications, and so on. Local photographic and medical societies are dealt with briefly at the ends of the appropriate groups. Particularly valuable are the reports from the Government institutions. There is a good index.

The penalty of providing useful information is that it invites suggestions for improvements. We still lament the omission of most of the industrial research associations, an omission that is doubly strange in view of the increased attention that is given to research in the industries themselves and among the public. We also think that the Viking Society and the Spelæological Society would be more appropriately grouped under archæology than under biology, and that the Sociological Society and the Eugenics Society would come better under biology, which includes anthropology, than under psychology.

The Circle and the Cross: a Study in Continuity. By A. Hadrian Allcroft. In 2 volumes. Vol. 1: *The Circle*. Pp. x+370+4 plates. (London: Macmillan and Co., Ltd., 1927.) 12*s*. 6*d*. net.

MR. ALLCROFT'S interesting book is devoted to the thesis that the sacred pagan symbol, the circle, surviving from prehistoric into Christian times, can be detected not only in occasional circular churchyards, but also in the modern word *church* itself. Beginning with the round barrow as the first expression of the sacred circle, Mr. Allcroft traces the evolution of the holy sepulchral ring, and maintains that this acquired additional importance from its frequent use as a moot. It is as moots, indeed, that he would explain the stone circles of Great Britain, and he couples with this interpretation the assurance that they are in reality of much later date than is commonly supposed; in fact, he seems to think most of them were built so late as the fourth century B.C., if not later still.

On this point the verdict will assuredly be that Mr. Allcroft's case is not proven, but his survey of the stone circles and earthen 'amphitheatres' in Great Britain is none the less an important and thorough piece of work. Moreover, he cannot be accused of too narrow an outlook, for he has chapters on the Achæan and Latin moots, and on the Danish *ting*; and he gives, furthermore, an interesting account of the Nordic peoples, about whom he holds views that are often in opposition to orthodox theory.

Especially interesting are Mr. Allcroft's remarks on the difficult subject of the Picts; but it should be observed that as a guide to the course of the Celtic invasions of these islands, his book must be read with considerable caution. However, he may reasonably claim the indulgence due to those engaged in pioneer work—for such is the nature of his book—and this is no less than his due. Indeed, it would be churlish to deny that he has given us a learned and entertaining work.

Lehrbuch der Geophysik. Herausgegeben von Prof. Dr. B. Gutenberg. Lieferung 4. Pp. 609-796. (Berlin: Gebrüder Borntraeger, 1927.) 11·40 gold marks.

PART 4 of Gutenberg's "Lehrbuch" deals mainly with atmospheric phenomena. A section on the structure of the atmosphere, by Prof. L. Weickmann, gives a very thorough account of existing theories of its composition, the distribution of temperature and density with height, and the propagation of sound. Atmospheric optics is then treated in considerable detail by Prof. F. Linke and Prof. A. Wegener (who was not included in the list of collaborators as originally announced). Atmospheric electricity is discussed by Prof. H. Benndorf.

Letters to the Editor.

Two Kinds of Martensite.

MARTENSITE is a structure characteristic of quenched steels and consists of an aggregate of very minute needle-shaped crystals. It is a solid solution of carbon in α-iron and is very hard. During tempering at a gradually increasing temperature, the precipitation of the carbon from the solid solution in the form of cementite takes place in two steps at about 170° and 270°, as shown in Fig. 1 by the two stepped changes in the electric resistance–temperature curve, or by similar abnormality in the magnetisation–temperature curve, etc. Since the precipitation or the decomposition of martensite takes place in two steps, it is necessary to distinguish two kinds of martensite, α and β, the former being less stable, and hence more easily attacked by acid, than the latter. By X-ray analysis, Westgren and others have found that the martensite has a body-centred cubic lattice, carbon atoms being present within the interspace of the lattice.

Recently it has been found that beside the body-centred cubic martensite, a body-centred tetragonal martensite with an axial ratio $c/a = 1{\cdot}03 \sim 1{\cdot}06$ is contained in quenched steels. We have found by X-ray analysis that the former martensite, which is more stable than the latter and is to be identified with β martensite, is found in the inner portion of a quenched specimen; while the latter martensite, which is to be identified with α martensite, is always found in the surface layer of the specimen. The existence of the two kinds of martensite being thus far confirmed, the mechanism of their formation may be considered.

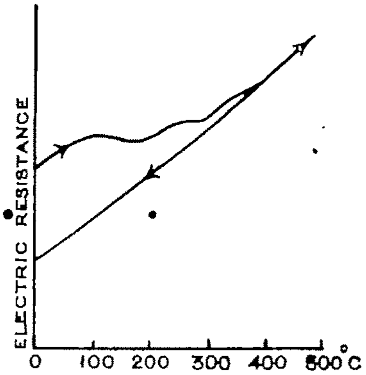

FIG. 1.—Resistance–temperature curve.

Since a face-centred cubic lattice may be considered a body-centred tetragonal one with an axial ratio $c/a = \sqrt{2}$ and also a body-centred cubic lattice as a body-centred tetragonal lattice with an axial ratio $c/a = 1$, the transformation from austenite to martensite takes place very probably in the order :

$$\text{Tetragonal lattice } (c/a = \sqrt{2}) \longrightarrow \text{tetragonal lattice } (c/a = 1{\cdot}06) \longrightarrow \text{tetragonal lattice } (c/a = 1),$$

or austenite $\longrightarrow$ α martensite $\longrightarrow$ β martensite.

Thus the mechanism of the formation of these martensites from austenite is very simple ; the tetragonal lattice ($c/a = \sqrt{2}$) is first to be compressed uniformly in the direction of the c-axis and at the same time uniformly expanded in the perpendicular direction. α martensite is obtained when the axial ratio of the tetragonal changes from $\sqrt{2}$ to 1·06, and β martensite when the ratio changes farther to 1.

In the outer layer of a quenched steel, where the cooling is very rapid, the first change, austenite $\longrightarrow$ α martensite, is partially arrested, and the second change, α martensite $\longrightarrow$ β martensite, is completely hindered, so that the outer layer must contain α martensite mixed with a small quantity of retained austenite ; while in the inner portion, where the cooling is less rapid, the first and the second change will take place almost completely, so that the inner portion must contain almost pure β martensite. These conclusions agree satisfactorily with the results of our experiments.[1]

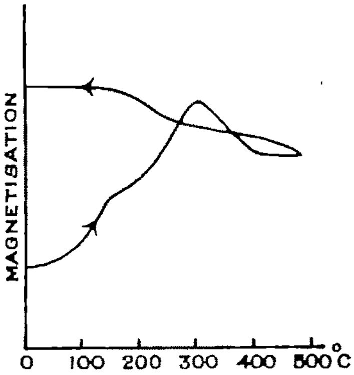

FIG. 2.—Magnetisation–temperature curve.

As regards the properties of α and β martensites, the following may be said with certainty :

Specific volume (V) :

$$V_{\text{au.}} < V_{\alpha\text{ mart.}} < V_{\beta\text{ mart.}}$$

Magnetisability (I) :

$$I_{\text{au.}} < I_{\alpha\text{ mart.}} < I_{\beta\text{ mart.}}$$

Specific electric resistance (R) :

$$R_{\alpha\text{ mart.}} < R_{\beta\text{ mart.}} < R_{\text{au}}$$

Hardness (H) :

$$H_{\text{au}} < H_{\alpha\text{ mart.}} < H_{\beta\text{ mart.}}$$

The following remark regarding the stepped change in Fig. 1 is very important. According to our view, the first step at about 170° is not due to the precipitation or the decomposition of the martensite, as it is usually believed to be, but to the transformation of α martensite to β martensite. Of course it is to be assumed that the decomposition of β martensite begins to take place far below 100°, its ratio being at first very small and rapidly increasing with the rise of temperature. In other words, the first step in Fig. 1 is not an abrupt change in the rate of decomposition of the martensite, but is due to the transformation of α martensite to β martensite, the rate of decomposition being assumed to increase steadily. The abrupt change in different physical properties in the vicinity of 170° agrees in its direction with what is to be expected from the inequality relationships given above.

Directional Wireless and Marine Navigation: the Rotating-Loop Beacon.

In a previous contribution to Nature (vol. 120, p. 774, Nov. 26, 1927) under the title "Directional Wireless as an Aid to Navigation," a survey was given of the present position of the application of wireless signalling methods to the navigation of ships and aircraft. Towards the end of that article brief mention was made of the rotating-loop method of directional transmission, with the intimation that the application of the method to marine navigation was then under investigation. As these experiments have now given results which make it possible to state that the method will prove of great importance in the future application of directional wireless to marine working, it is considered to be desirable to complete the above survey by summarising briefly the main conclusions arrived at.

The rotating beacon system of directional transmission has been developed to a high degree in Great Britain by the Royal Air Force, as providing a method of navigating aircraft without the necessity of carrying additional and elaborate apparatus in the machine itself. The transmitter employs a vertical frame coil which rotates at a uniform speed about a vertical axis, and which is supplied with radio-frequency oscillations from a suitable valve. The radiation in any direction varies as the cosine of the angle between the direction and the plane of the coil, and thus the signal intensity at a fixed receiving point varies from a maximum when the plane of the coil is in the direction of the receiver to a minimum or zero when the coil is perpendicular to this direction. Bearings are obtained on this transmitter by observing the time at which the signal minimum occurs after the transmission of a characteristic signal, which is sent when the plane of the coil is perpendicular to the geographical meridian. From a knowledge of the time of rotation of the coil, usually sixty seconds, the bearing of the receiver from the transmitter can be calculated. The bearing so obtained can be checked for every 180° rotation of the coil, that is, at half-minute intervals. Since the accuracy of observation is directly dependent upon the speed of rotation it is necessary that this shall be maintained very uniform. A combination of a tuning fork and phonic motor has been found to provide a simple and efficient means of speed control giving an accuracy superior to that required in the practical use of the beacon. Since the timing is but an intermediate process in obtaining a bearing, it is possible for the observer to use a stop-watch or chronograph provided with a dial marked in the form of a compass card, with both degrees and points of the compass. By starting such a watch on the North signal and observing the position of the index hand at the occurrence of the signal minimum, the bearing can be read straight off the dial.

Using such a type of rotating beacon in a series of experiments carried out in ships, it was found that for clear open-sea ranges up to 50 or 60 miles the observed wireless bearings agreed within an extreme limit of 5° with bearings estimated by other navigational methods, and in about 70 per cent. of the cases the agreement was within 2°. In subsequent experiments it was shown that for ships at anchor at distances of 90 to 100 miles, the wireless bearings observed in the day-time agreed to within 4° with the bearings calculated from the ships' positions. At distances exceeding 60 miles, however, wireless bearings from the rotating beacon were found to be subject to night effects similar to those experienced in wireless direction-finding. The errors resulting from these effects were not found to be very serious until the range of transmission exceeded 90 miles over sea, beyond which the errors of individual bearings amounted to 21°. Even in these circumstances, however, a moderately accurate bearing could be obtained by taking the average of a series of consecutive readings over a period of ten to fifteen minutes. The minimum range at which night errors were encountered was considerably reduced when the transmission was entirely or partly over land.

It will be evident from these results that the rotating beacon gives bearings comparable in accuracy with those obtainable with an ordinary direction-finder. This conclusion has been verified in the course of the investigation by some special experiments in which a direct comparison was made between the bearings observed on the rotating beacon and those obtainable with a direction-finder used on board the ship in the ordinary manner. When used in fixed positions on land, the direction-finder gives a somewhat superior accuracy, as it is not easy to obtain bearings on the rotating beacon to a better accuracy than two degrees; whereas a good land D.F. station should give bearings reliable to one degree. When wireless bearings are taken on board a ship at sea, however, the case is somewhat different. The D.F. bearing is taken relative to the ship's head, and its accuracy depends upon the steadiness of the ship and also upon the accuracy with which the direction of the ship's head is given by the compass reading at any desired instant. The bearing obtained by the rotating beacon is entirely free from this limitation, and its accuracy is practically the same whether the ship is at sea (in motion or at anchor) or in dock. Furthermore, no correction or compensation is necessary corresponding to the quadrantal error associated with the ship direction-finder. The limitation of range of accurate bearings due to night effect has been shown, both theoretically and experimentally, to affect both systems to the same degree.

From a scientific point of view, it thus appears that while there is little to choose in direction-finding between the rotating-loop transmitter and the rotating-loop receiver, the former may have a slight advantage for navigation purposes. It must remain for the mariner himself to become familiar with the operation and performance of each system and determine the sphere of their application as scientific aids to modern navigation. R. L. Smith-Rose.

National Physical Laboratory,

Devices for Increasing Accuracy in Weighing.

When high precision in weighing is essential, a considerable improvement is effected by constructing a rider which is supported on a point instead of resting on the beam by contact at two or more places as in the ordinary pattern. In order that the graduated beam scale may carry such a rider, the former must be of reasonable thickness.

This method of construction eliminates the uncertainty regarding the position of the beam at which the weight of the rider is applied. With certain precautions a reading to less than 0·1 mgm. can be made, and slight readjustments of the rider to give an exact balance, if required, can be carried out much more easily than with the standard rider.

Whilst it is true that few chemical balances as ordinarily used will enable weight determinations to be made to an accuracy greater than 0·1 mgm., the sensitiveness of the balance is in many cases actually such that it will allow of this if certain precautions are taken. The inconsistency that is noticeable when working to the limit of sensitiveness is due to the lateral shift of the whole beam to left or right each time the beam is released from its fixed supports. This of course gives a perceptible shift in the zero when observing swings on the fixed scale at the base of the main pillar.

If small differences in weight (of the order of a few milligrams) are being observed, where it is possible to obtain equilibrium by altering the position of the rider *without* raising the beam knife edge, this error does not arise, and a method of reading the exact position of the rider is at once of value. Where, however, it is necessary to raise the beam, accuracy can be obtained by making several observations of the zero of swings, between each of which the beam is raised and lowered again, and the mean of the zero positions taken. In this case a knowledge of the sensitiveness of the balance is of course essential for calculating the required difference in weight.

The rider in question can be constructed by using two pieces of clean nickel-chromium wire, one of which is bent as in Fig. 1*a*. One end of the other piece is wound round the horizontal part of the first, starting at the centre and leaving a small downward projection which acts as the *point support* of the rider. After a few turns, the wire is bent round to form a loop which is finished off by winding the free end towards the centre of the horizontal portion. Adjustment of the weight is made by cutting from the legs. The finished rider appears as in Fig. 1*b*.

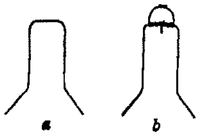

FIG. 1.

To avoid parallax in reading the exact position of the rider, a paper scale of the same dimensions as that of the rider scale can be pasted on to the glass front or back of the balance case, so that the eye reading the position of the rider may be placed at right angles to the beam at the point where the rider is situated.

Similarly, a suitable paper scale attached lower down, to the front glass of the balance case, enables accurate readings of the swings to be made even though the beam pointer be some distance in front of the scale at the base of the pillar.

Another device which has been found useful is a glass tube inserted through the side of the balance case and resting on the base. The tube is turned up underneath the left balance pan, and a rubber bulb is attached to the end of the glass tube outside the balance case. A slight pressure on the rubber bulb causes a puff of air on the under side of the pan, and this enables the beam to be set swinging to any desired degree, and the amplitude can be increased or diminished with ease.

Light-scattering at Critical Opalescence.

MESSRS. Ornstein and Zernike have published in a series of articles, notably one in *Phys. Zeits.* (27, 76; 1926), a theory of light-scattering, correcting that of Einstein, with the idea of accounting for the experimental fact that the scattered intensity at the critical opalescence of a pure substance or a binary mixture is not infinitely great. Their formula refers to the scattering at 90° of the incident beam. One can easily generalise it, for a direction of which the angle with the incident beam is θ. One therefore finds for Lord Rayleigh's ratio, and in their notations:

$$i=\frac{4\pi^2\mu^2\left(\frac{\partial\mu}{\partial v}\right)^2}{\lambda^4}\cdot\frac{\frac{RT}{N}\cdot v}{-\frac{\partial p}{\partial v}+\frac{8\pi^2}{3}\frac{RT}{v^2}\left(\frac{\epsilon\mu\sin^2\theta/2}{\lambda}\right)^2}. \quad (1)$$

$-\partial p/\partial v$ vanishes at the critical point. For a binary mixture, $-\partial p/\partial v$ must be replaced by another term, which also vanishes at the critical point of complete miscibility. It is known that Messrs. Ornstein and Zernike have deduced from their theory that the opalescence ought to be in $1/\lambda^2$ instead of $1/\lambda^4$ for the ordinary scattering; that is, during the passage through the opalescence, the scattered light ought to be seen less blue. We were unable to verify that law in the literature, but we deduce from the formula (1) other consequences, capable of experimental proof:

(1) By integration of the scattered light in all directions at the point of critical opalescence, formula (1) gives an infinite absorption coefficient.

(2) If one observes in two directions θ and $180° - \theta$ the same part of the beam, the ratio of the brightnesses would be according to (1) $1/tg^2\theta/2$, that is to say, 7 or 8 for θ near 40° (instead of 1 as in the theory of ordinary scattering).

(3) If we are not quite at the critical point, $-\partial p/\partial v$ does not vanish, and, if the incident beam is white, the scattered light in the direction θ (between 0 and 90°) ought to be bluer than that scattered in the direction $180° - \theta$.

We have tried to check experimentally these last two consequences, comparing by means of a simple optical apparatus the light scattered in two directions θ and $\pi - \theta$, symmetrical in respect to the beam. We ascertained that the brightnesses were the same on both sides, as well as the tint of the light, and that only so long as the observations were really made on a uniform phase of opalescence, before the precipitation of the 'critical fog,' which is, of course, no longer opalescence. Observations were made principally on a water-phenol mixture. The necessary optical adjustments were previously made with a solution of fluorescein in an identical container.

We made no measurement of the whitening of the critical opalescence; we had the impression it exists, but that it results more from the disappearance of Purkinje's effect than from an inherent cause.

It would therefore be a fault in the very ingenious theory of Messrs. Ornstein and Zernike which prevents them from getting the best out of their new principle: the influence of the cohesion forces on the fluctuations in density. We think we can see that fault when they *admit* a proportionality between the quantity $1 - F$ to $-\partial p/\partial v$ (see paper cited above), which means, they suppose that the classical theory of fluctuations in density is valid for big volumes, but not for small ones, and, specially, the mean square of the fluctuations might become infinite in a big volume and not in a small one: that is not at all certain.

The Velocity Coefficient for Bimolecular Reactions in Solution.

IN a paper of the above title, in the January *Journal of the Chemical Society*, Norrish and Smith have attempted to find a relation between second-order velocity coefficients for reactions between organic molecules in solution and the temperature coefficients of the reaction rates. As is well known, Hinshelwood has found that for second order gas reactions the rate of reaction can be found by multiplying the number of collisions between reactant molecules by a term $e^{-E/RT}$, where E is the experimentally determined energy of activation. Such an expression might arise from any of several mechanisms of activation and reaction. Norrish and Smith have now found that when it is attempted to calculate reaction rates in this same way for reactions in solution, the calculated rates are too large, and that a probability factor, P, must be introduced, which represents the chance of reaction at a collision involving activated molecules. The values found for P in a few reactions range from 4×10^{-11} to $4 \cdot 92 \times 10^{-5}$. The explanation which they offer for these very small values of P is that simple binary collisions seldom occur, and that a third molecule will often remove a portion of the energy and thus cause deactivation.

It seems to me that the effect of the third molecule should be activational in some cases, perhaps as often as it is deactivational, and that in any case the explanation of the small values found for P does not lie entirely in the frequency of ternary collisions. There are two other reasons, which were not suggested by Norrish and Smith, which would lead to small values of P, and to a great range of variation in these values. The first of these is the solvation of the reactant molecules, which should be expected to shield them from each other, reducing the chance of reaction upon collision by a factor which does not appear to be predictable. This effect should have a temperature coefficient, and there is thus the possibility that in some cases the value of E calculated from the overall temperature coefficient of the reaction will be too large; the calculated value of P would then be too large also, since the exponential term would be too small. An effect such as this is thus capable of accounting for large variations in the value of P.

The other reason why P should be small in all the reactions considered is to be found in the complexity of the reactant molecules. One of the reactions, for example, is between nitrobenzyl chloride and trimethyl amine. It is surely to be expected that a very special orientation at collision is a necessary condition for reaction in such a case; in the bimolecular gas reactions, which involve quite simple molecules, such as nitrous oxide, the orientation is of course of much less importance, but for these complex organic molecules a contribution to P of the order of 10^{-6} from this factor would not seem to be unreasonable.

There thus seems to be ample reason for expecting P to be small for reactions of the type studied by Norrish and Smith, and for it to vary markedly from one reaction to another, and even with change of solvent for the same reaction. There appears, however, to be slight chance of deriving even rough theoretical values. Indeed, the simple kinetic theory expression for the number of collisions is of doubtful validity in condensed systems.

Clot Bey and the Cairo School of Medicine.

MY attention has been directed to two paragraphs in the News and Views columns of NATURE of Jan. 14 concerning the centenary celebration of the School of Medicine, Cairo, and the International Congress of Tropical Medicine and Hygiene. It is stated in those paragraphs that "The story goes that one afternoon the Viceroy Mohammed Ali was driving through the streets of Cairo on the way to Shubra Palace when he ordered his coachman to stop, and summoning a well-dressed Frenchman who was walking along the streets, informed the stranger that he wanted him to create a Medical School in Cairo. . . . Clot Bey, in spite of his ignorance of medicine, was an able man, who accomplished the task thus entrusted to him with conspicuous success, which was recognised later by the conferring of the M.D. degree on him by the University of Paris."

The facts are that Dr. Clot, who was already a qualified French medical man, was called in 1825 to come to Egypt to organise the Medical Service of the Egyptian Army. He was followed by 154 European medical officers and apothecaries. It was only in 1827, that is, two years after his arrival in Egypt, that he started the Medical School. There is at the School of Medicine most of the literature of the time bearing out the authenticity of these facts. Dr. F. M. Sandwith, in a paper on the history of Kasr-el-Aini Hospital, A.D. 1466–1901, that appeared in the records of the Egyptian Government School of Medicine in 1901, mentions the details of the foundation of the School and gives many references on the subject.

In view of these facts, I can scarcely imagine that there could be any authentic source for the romantic account of the foundation of the Cairo Medical School referred to above.

M. KHALIL.

Faculty of Medicine, Cairo.

I AM sorry that Prof. Khalil has demolished the romantic tradition of Clot Bey, which for many years I had firmly believed to be the true story of the founding of the Cairo School of Medicine. In extenuation of my lapse in giving a new and wider circulation to this myth, I should explain that the brief statement referred to summarised my recollection of an elaborate and very circumstantial story given me years ago, when the late Dr. Sandwith was writing his history, by men who seemed to speak with intimate knowledge and authority. I am willing to admit that the British members of the staff of the Cairo School of Medicine in those days included several raconteurs of quite exceptional inventiveness, but I never had any reason to assume that this narrative was not true. The whole point of the story, as I heard it, was to emphasise the argument that the high efficiency of a medical school such as Clot Bey had created in Cairo was due to his administrative ability and judgment in selecting the right men for his staff.

THE WRITER OF THE NOTES.

The Correction of Astigmatism.

EVEN the more scientific members of the optical profession scarcely seem to be aware of their debt to mathematics for the discovery of the modern method of adjusting spectacle-lenses to suit astigmatic eyes. It is generally known that the first person to use cylindrical lenses for this purpose was Sir George Airy. During his tenure of the Lucasian professorship at Cambridge (1826–28), he had a pair of cylindrical lenses ground which corrected his own eye-sight. But we owe the complete general theory to a later Lucasian professor, Sir George Stokes (1849–1903), who was the first to prove mathematically that *any* eye (whether long-sighted or short-sighted) can be corrected for astigmatism (as well as these other defects) by using a lens which has one face spherical and the other cylindrical.[1]

To explain the importance (on the practical side) of Stokes's theorem, a few simple calculations may be added: an adequate outfit for an oculist may be taken to consist of 100 lenses (60 spherical and 40 cylindrical, the other faces being plane, in each case), combined with instruments to measure the angle of rotation (of the second lens) round the line of sight. It is not very easy to give an exact estimate of the accuracy of the angles measured in practice; it would seem to vary from about 1° with high powers (5 to 7 diopters[1]) to about 5° with low powers (½ to ¼ diopter). As an *average*, we may perhaps assume that the apparatus admits of about 80 to 100 distinctive positions for the cylindrical lens; then the oculist has at his disposal the equivalent of

---

[1] For more details, any of the more advanced books, for example, Herman's "Geometrical Optics," ch. x. art. 174, may be consulted.

$$60 \times 40 \times 80 = 192{,}000$$

or

$$60 \times 40 \times 100 = 240{,}000$$

separate astigmatic lenses. In round figures, we may take the outfit as providing 200,000 lenses: and plainly, if each lens had to be ground separately, the cost of such an equipment would be prohibitive. Even at 1*s.* each, the cost would be of the order of £10,000; the actual cost of 100 lenses (at the same rate) would be £5, and we may perhaps add £5 to £10 to represent the cost of the instruments for measuring the angles of rotation. Further, the labour involved in choosing the lens best suited to a given eye would be increased very considerably; and much care would be required in storing the lenses, so as to be readily accessible when testing a patient's eyesight.

It was stated recently that more than a million pairs of astigmatic lenses are prescribed in Great Britain every year: but (without the discovery made by Stokes) it is doubtful if even a thousand pairs of eyes could be tested in the same time.

T. J. I'A BROMWICH.

Cambridge, April 7.

Science and Nature.

RETURNING last week from attending an International Moral Education Conference at the Paris Sorbonne, where the ambiguity of philosophical and scientific terms in current use was considered as being a serious bar to true international understanding, it was with especial pleasure that I read Dr. J. E. Turner's letter in NATURE of April 21. We did not, on this occasion, at the Sorbonne deal specifically with the word Nature, although we might well have done so in view of its notorious ambiguity. Dogmatism and ambiguity are generally contrasted, but they are nevertheless often allied.

May I direct readers' attention to John Stuart Mill's essay on Nature, which was published after his death. In this essay Mill contends that it would be difficult to find a word that is responsible for "more bad morality and bad law." He points out that a critical examination of all the confused uses to which this word has been put, reveals two main definitions:

1. That held by the early Greek and Roman philosophers, who enjoined, as a fundamental principle, that we should "follow Nature"; implying by Nature the entire system of things, including not only the blind physical and biological forces acting spontaneously, but also all human intelligence, belief, perception, understanding, and action. Mill argues that an injunction to follow Nature, thus comprehensively expressed, is obviously superfluous, seeing that no one could in any circumstances by any possibility do otherwise. He says, however, that to endeavour to understand Nature in that sense is another and indeed quite profitable task.

2. The popular definition, *Nature* considered as opposed to *art*: That is to say, *Nature* signifying the spontaneous course of blind physical and biological forces acting presumably in complete independence of human intelligence. Mill then argues that to follow this kind of Nature is clearly immoral, in that all the noblest human endeavours throughout the ages have invariably been directed towards stemming and counteracting its ruthless depredations. Mill makes this proposition clear by means of a large number of cogent and striking illustrations.

We must conclude, therefore, that Nature is often employed euphemistically as an evasive term, either to cover our ignorance or to express some passing feeling or predilection misconceived as a fundamental principle. When, more than fifty years ago, I was one of his devoted students, the great Thomas Huxley was wont to remind us that words and phrases were instruments of thought, not substitutes for clear thinking.

The Buoyancy of Whales.

IN letters recently published in NATURE (Mar. 17, p. 421; May 5, p. 710) Mr. R. W. Gray records the interesting fact that whales dying 'at a depth' invariably sink, while those (of certain species) which die at the surface always remain floating. He suggests that the failure to rise after death may be due to the escape of air from the lungs, and in his second letter he attributes this to the water-pressure, which at a certain depth becomes sufficient to overcome the resistance of the valves of the blow-holes.

It does not seem probable that these statements are based on actual observation of the escape of air, and I think the explanation should not be accepted unless Mr. Gray can bring forward definite evidence that his suggestion is correct. He has informed us that a Greenland Whale barely floats after death at the surface, and it follows that its specific gravity does not differ greatly from that of sea-water. At considerable depths, whether the animal be dead or alive, the volume of its thorax must be appreciably reduced by the pressure of the water. The diminution of size involves an alteration of the specific gravity, which might well become greater than that of the water, in which case the dead whale would remain at the bottom. The fact that the carcase may rise to the surface later, after gases of decomposition have generated in the tissues, does not seem to preclude this suggestion.

The statement (p. 710) that when a whale wishes to sink it compresses its lungs is also open to criticism. I think it descends by swimming downwards, and it seems unnecessary to assume that it must deliberately alter the size of its thorax before it can leave the surface.

In another issue (April 14, p. 576) Mr. T. H. Taylor suggests that the filling of the lungs of whales may be due to the elastic recoil of the thoracic wall and not to a muscular effort. Is this not also improbable? The diaphragm is highly developed in the Cetacea, and definite evidence is surely required before it can be concluded that its function is not the same in these and other mammals. The extent of its projection into the cavity of the thorax (in the dolphins at least) should make it specially efficient in enlarging the chest by its contraction. The ribs of a large whale are, moreover, so heavy and massive that it is difficult to imagine an elastic recoil of sufficient force to expand the cavity of the thorax fully. There is no difficulty in supposing that the movement of the ribs during the act of inspiration is due to muscular action, as in other mammals.

[1] The diopter is the power of a lens the focal length of which is 1 metre: thus, when the centimetre is the unit of length, the diopter is represented by $\frac{1}{100}$.

An Optical Paradox.

THE paradox propounded by Mr. T. Smith in NATURE of Feb. 25 lays emphasis upon an important aspect of physical measurement and demands explanation. The considerations recorded in NATURE of April 7, in the letters of Dr. Campbell and Mr. Smith, leave the question unsettled, and I venture to give an explanation which would appear to be less forced and touches principally the process of reasoning.

The solution to the paradox seems to lie in a critical regard for the nature of the identity which is implied by equality. The sense datum upon which the experiment ultimately depends is the direct perception of relative dissimilarity of the contributory sensations. In the absence of perceptible dissimilarity the derived judgment is arrived at, stating the equality of the two stimuli. At each successive observation the observer perceives the same appearance, and in effect asserts the absence of the sensation of what can be referred to as contrast. (Proceeding otherwise he might, as in other methods of photometry, estimate and compare degrees of contrast.)

Now it is elementary knowledge that in any calculus of reasoning a relation of equality subsists between given entities by virtue of the identity under certain conditions of certain essential properties stated in the definition of the equality. In the present case the statement of equality proceeds from the inferred identical similarity of the contributory sensations, this step in arriving at the final judgment of the observer being legitimate if it be premised that insensible increments in stimulus do not affect sensation. This would be granted unless it were proposed to modify arbitrarily the connotation of terms.

Although, however, the equality may be regarded as established by this means, it should be noted that no relation between the properties not involved in the identity is established. The step made in concluding that, physically regarded, such properties as, for example, the candle power are the same is thus not rigorously supported by the observational data, and in extending the relation to these properties in order to render their physical measurement possible a logical *non sequitur* is incurred. This is the fallacy which gives rise to the paradox.

J. W. PERRY.

London, N.W.1.

Lucretius's Anticipation of Mendelism.

IN his review of the new edition of Munro's translation of Lucretius, in NATURE for April 14, Prof. D'Arcy Thompson refers to the many scientific 'anticipations' that are to be found in that wonderful poem, which has fossilised, so to speak, some fragments of the lost world of ancient wisdom. I have never seen any mention made of a passage in the "De Rerum Natura" in which the three fundamental postulates of Mendelism are laid down as the rules of heredity, and I think it deserves to have attention directed to it.

The passage is in Book 4, ll. 1210 *et seq.*, and in the 1898 Cambridge edition of Munro's translation it runs as follows:

"Sometimes the children may spring up like their grandfathers and often resemble the forms of their grandfathers' fathers, because *the parents often keep concealed in their bodies many atoms mixed in different ways*, which, *first proceeding from the original stock one father hands down to the next father*, and then *from these Venus produces forms after a manifold chance*, and repeats not only the features but the voices and hair of their forefathers."

The three italicised passages enunciate (seriatim)

(*a*) The principle of recessive (and by implication, of course, of dominant) characters.

(*b*) The constitution of the organism out of combinations of immutable unit characters.

(*c*) The chance recombination of these in mating.

Stellar Radiation and the Nature of the Universe.

THE difference between theory and practice is admirably illustrated by our solid, three-dimensional brain-minds theorising about fourth and other dimensions of space and 'matter,' and yet visualising a cyclic universe the radiations of which are related only to the superficies of matter! It seems that most of us are still unable to form actual conceptions of the *depths* of space as a condition different from the depth of a three-dimensional form of physical matter in space. Tyndall believed that the sum of Nature's energy is constant, and that "the utmost man can do in the pursuit of physical truth or in the applications of physical knowledge is to shift the constituents of the never-varying total . . . *the flux of power is eternally the same*." Tyndall surely did not imply by this that "just as much matter is created as destroyed" (NATURE, April 28, p. 674). He seems to distinguish the constituents from the *flux* of power with which, say, a sixth-dimensional mind might be quite happy without our physical constituents.

We are in equal darkness regarding both the origin and destiny of radiation, stellar or otherwise. From what interiors of space or matter come the 'flux of power' or the rays investigated by physicists? Into what 'depths' do they disappear by transmutation, electro-magnetic exchange, quantum action, or by 'actions' unknown on this planet?

April 28.

Prices of Periodical Scientific Publications.

THE letters of Dr. Baini Prashad and Mr. Wilfrid Bonser in NATURE (Mar. 31 and April 7) directing attention to the prices of certain German scientific periodicals, particularly those published by the firm of Julius Springer, Berlin, are very timely; for to many libraries the question whether they can afford to continue to purchase such periodicals must be a serious one. The Library Committee of this University has had the matter under consideration more than once in the course of the last year or two; for in view of the high cost of several of these periodicals, taken by the Library, the Committee has not infrequently been compelled to forego the purchase of important biological works. One is naturally reluctant to discontinue subscribing to periodicals of long standing and established reputation, but for many libraries and institutions with limited funds at their disposal for the purchase of biological books, this would seem to be the only way out of the difficulty. It is to be hoped that the present high charges for the journals in question will be speedily reduced.

Conversion in Science.[1]

By Prof. G. Elliot Smith, F.R.S.

On Nov. 13, 1859, eleven days before the publication of "The Origin of Species," Darwin wrote: "If I can convert Huxley, I shall be content."

Before his work was published Darwin fully realised the difficulties of the task he was undertaking in trying to convince his fellows of the reality of evolution. Hence he was anxious to secure the help of Hooker, Lyell, and Huxley. When we recall the obstacles that throughout the ages have ever hindered the advancement of learning, and in particular the efforts of isolated pioneers to obtain recognition for views that ran counter to strongly entrenched traditions, we can appreciate Darwin's good fortune in securing the sympathetic consideration of three such exceptional men as Sir Joseph Hooker, Sir Charles Lyell, and Thomas Henry Huxley. Different as they were in temperament and mental attitude, each of them in his own department was endowed, not only with wide and exact knowledge, but also with rare powers of clear insight and sound judgment. If he could convert Lyell, Hooker, and Huxley, Darwin knew that the future could take care of itself.

There never was any doubt about Hooker's attitude: for he had been so intimately associated with Darwin in the building up of the argument that they may be said to have kept step in the advance. But Lyell and Huxley had yet to be won over. If Lyell did not give his active support to the great scheme until the battle was won—largely as the result of Huxley's persistent championship—it must not be forgotten that his book, "The Principles of Geology," was, as Huxley expressed it, "the chief agent in smoothing the road for Darwin."

> "It brings home to any reader of ordinary intelligence a great principle and a great fact—the principle that the past must be explained by the present, unless good cause can be shown to the contrary; and the fact that so far as our knowledge of the past history of life on our globe goes, no such cause can be shown."

Huxley finished reading the proof of the "Origin" two days before the book was published, and on the following day Darwin received his verdict in these words: "I think you have demonstrated a true cause for the production of species, and have thrown the *onus probandi*, that species did not arise in the way you suppose, on your adversaries."

It is difficult for us at the present time to appreciate Huxley's reluctance to accept the fact of evolution. For once the morphological similarities of nearly related animals were appreciated, and the essential identities in ontogeny were admitted, what explanation was possible other than the recognition of a common origin? The idea of evolution was of course familiar to him, and had been the subject of repeated discussions with Herbert Spencer and others.

In his essay on "The Reception of 'The Origin of Species'" Huxley has given a characteristically frank account of his own conversion. While he "had long done with the Pentateuchal cosmogony," even the persistence and the dialectic skill of Herbert Spencer were impotent to persuade him to admit the reality of evolution. He justifies his stubborn refusal, not because the unconvincing arguments of Lamarck and the author of "Vestiges of Creation" antagonised him, for, as Dr. Chalmers Mitchell clearly showed in his Huxley Memorial Lecture a year ago, Huxley had a peculiarly keen sense of logic and cogency, but because "the evidence in favour of transmutation was wholly insufficient, and no suggestion respecting its causes had been made which was in any way adequate to explain the phenomena." He did not accept the hypothesis of natural selection as the adequate explanation: but Darwin's insistence on the facts revealed by selective breeding of domestic animals and plants convinced Huxley of the possibility of finding natural factors to establish the fact of transmutation. No longer did he harbour any doubt as to the reality of evolution. To quote his own words:

> "I imagine that most of those of my contemporaries who thought seriously about the matter were very much in my own state of mind—inclined to say to both Mosaists and Evolutionists, 'A plague on both your houses!' and disposed to turn aside from an interminable and apparently fruitless discussion, to labour in the fertile fields of ascertainable fact. And I may therefore suppose that the publication of the Darwin and Wallace paper in 1858, and still more that of the 'Origin' in 1859, had the effect upon them of the flash of light which, to a man who has lost himself on a dark night, suddenly reveals a road which, whether it takes him straight home or not, certainly goes his way. That which we were looking for, and could not find, was a hypothesis respecting the origin of known organic forms which assumed the operation of no causes but such as could be proved to be actually at work. We wanted not to pin our faith to that or any other speculation, but to get hold of clear and definite conceptions which could be brought face to face with facts and have their validity tested. The 'Origin' provided us with the working hypothesis we sought. Moreover, it did the immense service of freeing us for ever from the dilemma—Refuse to accept the creation hypothesis, and what have you to propose that can be accepted by any cautious reasoner? In 1857 I had no answer ready, and I do not think that anyone else had. A year later we reproached ourselves with dullness for being perplexed with such an inquiry. My reflection, when I first made myself master of the central idea of the 'Origin,' was 'How extremely stupid not to have thought of that!' I suppose that Columbus' companions said much the same when he made the egg stand on end. The facts of variability, of the struggle for existence, of adaptation to conditions, were notorious enough; but none of us had suspected that the road to the heart of the species problem lay through them, until Darwin and Wallace dispelled the darkness, and the beaconfire of the 'Origin' guided the benighted."

This illuminating confession is the clearest and most searching analysis we have of the factors that play a part in the process of conversion in science. Huxley was a man of rare insight and courage: he had at his command all the information that was necessary to convince him, not only of the reality of evolution, but also of the fact that man could not be left out of the scope of the process of transmutation once he accepted it. Yet he held back. He needed a working hypothesis to convince him of the possibility that transmutation might be effected by some natural process.

---

[1] From the Huxley Memorial Lecture, delivered at the Royal College of Science, South Kensington, on May 4.

Huxley's great service to learning was not simply the fact that once he was convinced of the truth of evolution he devoted himself to the task of converting the world of educated men and women, but that he concentrated attention upon the problem of man's status. By so doing he effected perhaps the greatest revolution that has ever been effected in the attitude of mankind to knowledge in general, for all learning is inevitably centred upon man and his relationship to the Universe.

It is the human aspect of the problem that I specially want to study in this lecture.

It is one thing to convert men of exceptional insight and understanding such as Hooker, Huxley, and Lyell, but quite a different matter to convince men of average ability. Darwin complained that he "found the most extraordinary difficulty in making even able men understand at what he was driving" (letter to W. B. Carpenter, 1859). In particular was he distressed by the unfair and ignorant criticisms of opponents who failed to understand his theory. In December 1860 he was forced to admit: "I can pretty plainly see that if my view is ever to be generally accepted, it will be by young men growing up and replacing the old workers, and then young ones finding that they can group the facts and search out the new lines of investigation better on the notion of descent than on that of creation." This is true of all learning that is coming for the first time under the influence of the scientific discipline. Its hope is in youth and the coming generation rather than in men already involved in the shackles of conventional views, who, as Anatole France expressed it, "are no longer curious."

This is a true picture of what usually happens in any progressive movement. The number of men competent to understand a new generalisation and apply it in practice is lamentably small. As Darwin confessed, we have to look at young men, who are free from traditional obsessions and are ready to embark on new adventures that seem hazardous to their elders. Before their views become set in a rigid mould men would welcome hypotheses that provide satisfying explanations of the growing knowledge and provocative ideas to stimulate new inquiries.

The two great obstacles that stand in the way of the acceptance of a new interpretation of evidence are exemplified in the cases of Lyell and Huxley. The former was hampered by tradition, the force of which it took eight years to overcome. Huxley was no longer under the influence of such restraints against clear thinking. His only reason for hesitancy was the fact that he could not imagine how evolution could be effected by known natural agencies. Hence when Darwin put forward a hypothesis to supply what was lacking, Huxley's conversion was, as he himself has explained, instantaneous.

Huxley has discussed with characteristic clearness and decision the much-misunderstood function of working hypotheses in science. I make no excuse for quoting him once more on a subject so directly relevant to my present argument.

In the preface to the English edition of Haeckel's book on "Freedom in Science and Teaching" (1879) he wrote:

> "No profound acquaintance with the history of science is needed to produce the conviction that the advancement of natural knowledge has been effected by the successive or concurrent efforts of men whose minds are characterised by tendencies so opposite that they are forced into conflict with one another. The one intellect is imaginative and synthetic; its chief aim is to arrive at a broad and coherent conception of the relations of phenomena; the other is positive, critical, analytic, and sets the highest value upon the exact determination and statement of the phenomena themselves.
>
> "Every science has been largely indebted to bold, nay, even to wild, hypotheses, for the power of ordering and grasping the endless details of natural fact which they confer; for the moral stimulus which arises out of the desire to confirm or to confute them; and last, but not least, for the suggestion of paths of fruitful inquiry, which, without them, would never have been followed. From the days of Columbus and Kepler to those of Oken, Lamarck, and Boucher de Perthes, Saul, who, seeking his father's asses, found a kingdom, is the prototype of many a renowned discoverer who has lighted upon verities while following illusions which, had they deluded lesser men, might possibly have been considered more or less asinine.
>
> "Nor have I, for one, anything but cordial assent to give to his declaration, that the modern development of science is essentially due to the constant encroachment of experiment and observation on the domain of hypothetical dogma; and that the most difficult, as well as the most important, object of every honest worker is 'sich entsubjectiviren' to get rid of his preconceived notions, and to keep his hypotheses well in hand, as the good servants and bad masters that they are."

Assuming the rôle of champion of evolution, Huxley boldly attacked the most contentious issue and made "Man's Place in Nature" the cardinal issue of the conflict. The particular field that Lyell avoided, Huxley selected as his chosen battle-ground. In putting man into the centre of the picture Huxley was doing again, though in a vastly different way, what the French humanitarians did in the eighteenth century. Rousseau wrote in 1754: "The most useful and least advanced of all human knowledge seems to me to be that of man himself." However paradoxical this statement may seem, there can be no question of its truth. The question of man's origin and history, and the interpretation of human nature and behaviour, are problems that vitally affect and interest every human being. The essential subject matter of ethnology necessarily comes within the knowledge of every human being. Each individual is aware of his own thoughts and actions, and is vitally interested in the behaviour of his fellow men and women. Everyone therefore knows from his own experience the essential truth concerning the great problems concerning which scholars have been wrangling for two centuries. Why then, it will be asked, is there any difference of opinion when everybody knows the truth? The answer to this query is provided by the history of the last two centuries, for to-day the truth is still obscured by the survival of the old conflict between the followers of Descartes and those who adopted the discipline of Newton.

In the remote past, all inquiries, whether astronomical or chemical, botanical or zoological, mathematical or physical, were essentially anthropocentric. In most early speculations what man was striving after was not knowledge, but the means of safeguarding his own life and prosperity. After the demolition of astrology, when this crude type of anthropocentrism was superseded, the attainment of the strict discipline of the scientific method was determined by the extent by which men could eliminate human emotions from their inquiries.

Huxley's achievement differed profoundly from the early revolutions in thought. While the latter aimed at subordinating the forces of Nature for man's benefit, Huxley's object was to assign man to his true place in Nature, and to discover his origin as a part of the natural processes. But his interest was not restricted to the biological aspects of the problem. He boldly plunged into the discussion of the cultural aspects of anthropology and, although he quoted the familiar phrase that had been handed down from the Cartesian scholiasts of the eighteenth century, he refused to accept the theory of "the similarity of the working of the human mind" as an adequate explanation of anything more than the simplest of inventions. Writing in the same year (1865) Mr. (afterwards Sir Edward) Tylor spoke with equal emphasis in favour of diffusion as the only possible interpretation of the facts; but in 1871 a subtle change was taking place in his opinions. Then he was admitting in the preface of his "Primitive Culture" the fact of his indebtedness to Adolf Bastian. While criticising in the most scathing terms, and with a wealth of forcible illustrations, his contempt for those who had pretended to ignore the historical method and the principles of diffusion of culture, Tylor himself was drifting towards the very views he was denouncing. He was developing his theory of animism (that there was an innate tendency in mankind to attribute life and soul to inanimate objects around them), and this enunciation of a 'natural law' brought about a sudden lapse into the Cartesian error, from which ethnology is still suffering.

It is a thousand pities that, when Tylor thus abandoned the Newtonian discipline, Huxley did not continue to insist upon the true principle of ethnology which he defined so clearly in 1865. But he was too fully occupied with biology to have time for ethnology, which he left to Tylor.

I have already referred to the important part played by Lyell's principle of continuity in geology in preparing the way for the acceptance of biological evolution. Yet a century before Lyell's time, essentially the same principle of continuity had been confidently applied to human affairs by Turgot, in words described by the late Lord Morley,[1] as "among the most pregnant, as they were among the most original, in the history of literature, and reveal in an outline, standing clear against the light, a thought which revolutionised old methods of viewing and describing the course of human affairs, and contained the germs of a new and most fruitful philosophy of society." The tragedy is that the true philosophy of society enunciated by Turgot in 1750 did not revolutionise old methods of viewing and describing the course of human affairs. In spite of Lord Morley's appreciation, as just as it is eloquent, of the greatness of Turgot's achievement, men failed to apply his teaching for the salvation of humanistic studies. It is, in fact, the most urgent need of ethnology at the present time that this long-delayed reform should begin. Turgot contrasted the operation of the laws of Nature with the behaviour of mankind.

> "The phenomena of nature, subjected as they are to constant laws, are enclosed in a circle of revolutions that remain the same for ever! . . . The succession of men, on the contrary, offers from age to age a spectacle of continual variations. Reason, freedom, the passions, are incessantly producing new events. *All epochs are fastened together by a sequence of causes and effects, linking the condition of the world to all the conditions that have gone before it.* The gradually multiplied signs of speech and writing, giving men an instrument for making sure of the continued possession of their ideas, as well as of imparting them to others, have formed out of the knowledge of each individual a common treasure, which generation transmits to generation, as an inheritance constantly augmented by the discoveries of each age; and the human race, observed from its first beginning, seems in the eyes of the philosopher to be one vast whole, which, like each individual in it, has its infancy and its growth." (Lord Morley's Translation.)

This is a clear and definite statement of the principles of diffusion of culture, for the recognition of which some of us are still fighting to-day, more than one hundred and seventy years after Turgot.

Two centuries ago Fontenelle, the enthusiastic disciple of Descartes, was expounding the facts of human society in terms of his master's idea of "natural laws," and was pouring scorn on the historical method and the principle of continuity. In Scotland, where Cartesian philosophy retained a hold long after it had been replaced by the Newtonian discipline in England, and even in France, the ethnological teaching of Fontenelle survived the criticism of Turgot, and in 1777 was given a concrete form by Dr. William Robertson, Principal of the University of Edinburgh, in his "History of America." He maintained that the ancient civilisation of America was of independent origin; and in support of his speculation he referred to "such a resemblance in their manners and customs as necessarily arises from a similarity of their condition," a form of phraseology which, after nearly a century of half-hearted lip service, suddenly acquired the force of a dogma, when, having been revived by Adolf Bastian in 1860, it was adopted in 1871 by Sir Edward Tylor. Thus modern ethnology was brought under the influence of Cartesian philosophy.

---

[1] Lord Morley, in his article on Turgot in "Biographical Studies."

Since Newton rescued astronomy and physics from the stranglehold of Descartes' method, every branch of science in its turn has been emancipated. Ethnology alone remains in the bonds of such superstition. For more than a century, it is true, men continued to render lip service to Turgot's recognition of the fundamental factors underlying human institutions, without, however, applying them with full understanding and consistency. Under the influence of Lyell's revival of the idea in reference to geology, Tylor in 1871 reaffirmed the fundamental importance of the principle of continuity and the historical method as the essential factors in the interpretation of the facts of ethnology. Thus in the first edition of "Primitive Culture" he wrote :

> "The notion of the continuity of civilization is no barren philosophic principle, but is at once made practical by the consideration that they who wish to understand their own lives ought to know the stages through which their opinions and habits have become what they are (p. 17). History, taken as our guide in explaining the different stages of civilization, offers a theory based on actual experience. This is a development-theory, in which both advance and relapse have their acknowledged places. But so far as history is to be our criterion, progression is primary and degradation secondary ; culture must be gained before it can be lost. Moreover, in striking a balance between the effects of forward and backward movement in civilization, it must be borne in mind how powerfully the diffusion of culture acts in preserving the results of progress from the attacks of degeneration. A progressive movement in culture spreads, and becomes independent of the fate of its originators" (p. 34).

Just as Huxley and Darwin in 1860 had to expose the fallacy that evolution did not necessarily imply progress, so Tylor had to explain, as Turgot had already done in 1750, that there is in man no innate impulse to compel him to embark on what we call progress. Yet this very error is the fallacy underlying present-day speculation. By a strange irony this reaffirmation of the sound principles that should find expression in all humanistic inquiries occurs in a book that was reviving the appeal to 'constant laws,' against which Turgot protested. For by claiming that mankind as a whole display an innate tendency to develop animistic beliefs Tylor was inventing a 'law of Nature' for which there is no evidence. While referring to this flagrant defiance of the principle of continuity, one is tempted to quote Tylor's own warning. For the learned author of "Primitive Culture" himself discusses (vol. 1, pp. 378 and 379) with characteristic frankness the curious phenomenon that ethnologists enunciating certain views often cite evidence stultifying their own opinions. After giving specific illustrations of this neglect of logical consistency he makes this interesting comment : "Such cases show how deceptive are judgments to which breadth and generality are given by the use of wide words in narrow senses."

The late Sir Edward Tylor thus missed the great opportunity of giving full expression to the principles enunciated by Turgot. He was deflected from his purpose by his enthusiasm for the theory of animism—a lapse into the methods of Cartesian scholasticism that was fatal to a consistent exposition of the Newtonian method which Turgot had introduced into the study of mankind. If Tylor had not indulged in the speculation in animism that led him to accept the revival of this type of scholasticism by Bastian, he might have revolutionised the whole range of humanitarian studies, and have achieved in ampler measure what Lecky claimed for the great teachers of the seventeenth century, "destroying the old prejudices, dispelling illusions, rearranging the various parts of our knowledge, and altering the whole scope and character of our sympathies."

Air Conditioning in Industry.

By N. E. JACKSON.

AIR conditioning, as the term implies, is the treatment of air necessary to give certain conditions of heating, cooling, moistening, or drying of air contained in a given space. It may be more exactly defined as the application of scientific principles and engineering practice for the obtaining of specified and predetermined physical effects upon materials, human beings, or the atmospheric conditions in buildings, by treatment with air the temperature, humidity, and purity of which is definitely controlled. This treatment must, however, only be regarded as a means of securing a certain objective, either physiological effects on human beings, or physical effects on materials.

The general properties of air are well known. It should, however, be clearly understood that air is capable of very extensive treatment, such as heating and cooling, humidifying and dehumidifying. Its avidity for moisture is considerable ; the higher its temperature, the more water vapour it is capable of absorbing. Thus at a temperature of 45° F., one cubic foot of air when saturated holds in suspension 3·44 grains of moisture. At 100° F., one cubic foot of saturated air holds 19·98 grains of moisture in suspension.

Air conditioning is resorted to in a great many important industries which require special atmospheric conditions for the carrying out of some of the many processes involved. A few of its applications are enumerated below.

ARTIFICIAL SILK.

In this more recent and highly specialised branch of the textile field, correct atmospheric conditions are absolutely essential. Fairly high humidities coupled with moderately high dry-bulb temperatures are required in the spinning rooms, otherwise crystallisation of the filament is likely to occur. In the reeling rooms, similar conditions must be maintained to avoid breakage of the yarn, whilst the sorting rooms must certainly be conditioned to ensure the silk maintains its correct moisture content, 11 per cent. of its weight being the maximum permitted.

DRYERS.

Dryers, generally constructed on the tunnel principle, are used in many trades, both with the object of speeding up production and ensuring uniformity of product.

In the brickmaking industry dryers are very essential, and when it is realised that a 10 lb. brick may contain from ¾ to 1¼ lb. of initial moisture, it is seen that for maximum output something more than natural drying by wind and sun is necessary. The time taken to dry bricks on the shed floor is 50 per cent. longer than with a modern tunnel dryer, and the cost of shed floor drying twice as great as with the modern apparatus; so in this trade the advantages of progressive drying are very obvious.

In timber drying by artificial means greater production (that is, more rapid seasoning) and a more uniform product are obtained. In progressive drying by hot air, the wet or 'green' material enters the dryer at the opposite end to the hottest air, so that the material is dried out gradually. If the reverse process is followed (as might be thought advisable on first consideration), the hotter air has a tendency to dry only the surface of the material, leaving the interior still wet.

The table following gives some of the more important articles in everyday use and their respective drying temperatures and length of time required for efficient drying.

TABLE I.

DRYING CONDITIONS.

Material.	Temp. (Degrees F.).	Drying Period
Leather and hides	90°	2 to 6 days
Starch and salt	180°–200°	12 hours
Dried fruits	140°–180°	6 hours
Tobacco	85°–200°	..
Soap	100°	2 days
Wood (average timber)	105°	..
Rags	180°	18 hours
Pottery	120°	..
Bricks	150°–200°	30 to 60 hours
Cereals	180°	..
Beans and rice	140°–150°	..
Sugar (cane)	150°–200°	20 to 30 minutes
Coffee	160°–180°	24 hours
Glue	70°–90°	2 to 4 days
Paper	140°–150°	..
Rubber	80°–90°	1 to 2 weeks
Wool	105°	..

It will be noticed that in no case does the temperature at which drying is carried out exceed 200° F., whilst the drying periods vary enormously with the different products dealt with.

FOOD STUFFS.

Cool air is very essential for rapidly cooling pastry in order to prevent the contents of pies, and so on, from soaking into the pastry and spoiling its appearance, therefore making it unmarketable. In the fermenting department of a brewery a ventilating and cooling plant is very necessary, a large volume of cooled air being required to disperse rapidly the carbon dioxide given off from the vats, and to keep the temperature in this department below 66° F. to prevent the yeast going bad. Again, in the manufacture of chocolates with fancy fillings, after these have been coated with hot liquid chocolate they are placed on trays, and cleaned and purified air is blown over the trays. The air must be cooled in warm weather, the temperature in the coating department not being allowed to exceed 65° F., or a damaged and therefore unsaleable product results.

There are numerous other processes in food preparation that can only be properly carried out by the provision of air-conditioning equipment, generally automatically controlled to ensure exact temperature and humidity requirements.

HEATING AND VENTILATING BUILDINGS.

Many buildings are nowadays heated by the delivery of previously warmed air through a system of ductwork to the various rooms, the advantage being that rooms are heated and at the same time ventilated, instead of depending upon the opening of windows for ventilation, and on individual radiators or steam or hot-water pipes for the heating. The ideal system of heating by warm air is one which incorporates the previous moistening of the air, thus raising its relative humidity and preventing the parching effect of heated air, which, if not properly humidified, causes excessive evaporation of moisture from the skin of the individual.

Certain temperature and humidity conditions have been advocated by the medical profession as being most suitable for human requirements. Generally, in Great Britain, a room should be heated to a temperature between 55° F. and 65° F., the relative humidity ranging between 50 per cent. and 63 per cent. It is only by the maintenance of temperatures and humidities within the given range that ideal healthy conditions prevail in rooms occupied by human beings. By providing correct artificial atmospheres, the working efficiency of occupants of offices, etc., is considerably increased, there is less absence due to illness, and a great minimising of the tendency to respiratory and catarrhal diseases, so prevalent in overcrowded cities and manufacturing towns. In hospitals there is far less risk of contagion where there is a plentiful supply of fresh air at a suitable temperature.

No. 3054 MAY 12, 1928

Research on the Control of Aeroplanes.[1]

By Prof. B. MELVILL JONES.

AN essential factor in the control of anything, whether it be a motor-car, a ship, or an aeroplane, is some means of applying the necessary force in the desired direction. The car requires its steering wheel, the ship its rudder. But this is not the only factor which decides the character of the control, whether quick or slow, difficult or easy. Other factors inherent in the craft to be controlled have to be considered. One such factor is inertia. A motor-car has very little inertia compared with the forces which can be exerted through the road wheels; consequently, it responds at once to a movement of the steering wheel, and the turning stops immediately the wheel is centralised. A ship has great inertia compared with the force exerted by the rudder; consequently the rudder must be applied some time before an appreciable turn is started, and reversed *against* the movement long before the ship has swung to its new course. The character of the control of a ship is thus entirely different from that of a car, on account of this factor of inertia, which has nothing to do with the controls themselves.

Another factor is the stability or instability of the motion when the controls are not moved. A stable motion is one which, if slightly disturbed, will settle back into its original form; an unstable motion is one which, after a slight disturbance, will depart further and further from the original form. In a modern car, the pivots about which the wheels turn in steering are arranged like the casters of a chair, so that the wheels have a slight tendency to turn to the side towards which the car is trying to slip. If the car moves round a curve, the centrifugal force makes it try to slip outwards, and the wheels, left to themselves, turn outwards and straighten the path. Such a car is stable and easy to drive straight; if the wheels had the opposite tendency, it would be unstable, and the driver would have continually to be correcting tendencies to swerve to one side or the other. An unstable car is not impossible to control, and may even, by practice, come to be controlled by unconscious reflex action, with no more fatigue than is felt in walking, but experience has shown that it is better to make it stable. It should not, however, be too stable, for then it will be heavy to steer round corners at high speeds, when the centrifugal force is large, and it will try to run down hill, so that, when travelling on the side of the camber of the road, it will have continually to be held out of the ditch.

The motor-car thus illustrates some important points which are common to the control of any kind of craft: although the control of an unstable craft may not be impossible, stability is on the whole desirable, but too great stability may introduce other undesirable qualities and may be as bad or worse than instability. A condition which might be described as benevolent neutrality is generally sought.

Again, a craft may be stable, in the sense that it tends to return when disturbed from a straight path, but it may overshoot on the other side farther than the original deviation, so that an oscillation of increasing magnitude may arise. Such an increasing oscillation is said to contain a negative damping term. Conversely, an oscillation which tends to decrease is said to contain a positive damping term. An example of a negatively damped oscillation occurs when a yacht's dinghy, loaded by the bows, is towed by a short rope. As the tow rope is shortened the dingy starts to yaw from side to side with increasing violence and may ultimately be swamped.

A negatively damped oscillation is difficult to control; an inexpert hand on the controls generally makes it worse. It is even possible to convert a truly stable motion into an increasing oscillation by inexpert use of the controls; this is generally due to lag, or the time interval between the impulse to control and the muscular response.

Long before successful man-carrying aeroplanes were developed, a division of opinion on matters of control was apparent. One side, which contained on the whole the practical men who tried to fly themselves, was mainly concerned with providing control organs and acquiring the skill to use them.

---

[1] Discourse delivered at the Royal Institution on Friday, Feb. 10.

The other side, which contained mainly the theorists and the constructors of uncontrolled models, were mainly concerned with the stability of the uncontrolled craft. This division of opinion continued well into the War, and traces of it are still present. A short historical sketch of this controversy may serve to make the present situation more clear, and the sketch can be used to illustrate certain important points in the control problem.

The great problem before the protagonists of the control school was to remain alive long enough to achieve sufficient practice and to perfect their apparatus. Their difficulty was greater than they could guess. Nature laid a trap for them, the full cunning of which we are only just beginning to realise. To understand this trap we must look a little into the matter. The first essential of steady flight is that the air shall exert a lift on the wings equal to the weight of the aeroplane. This lift depends upon speed through the air and upon the incidence, or angle, at which the wings strike the air. A typical relationship is shown in Fig. 1. If, in this example, the aeroplane weighs 2000 lb., it cannot be supported at speeds less than 50 m.p.h. At high speeds support can be obtained at a small incidence, but if the speed drops slowly towards 50 m.p.h., a point is reached at which the incidence will have to increase rapidly, and just above 50 m.p.h. flight will be possible at two alternative incidences, one considerably larger than the other. The minimum possible speed is called the stalling speed; the critical incidence, at which the minimum speed is just possible, is called the stalling incidence, and an aeroplane flying above this incidence is said to be stalled. So long as the speed is considerably greater than the stalling speed, the achievement of stability and control is relatively easy, but as the speed falls and the stalling angle is approached, changes occur in the air-flow about the wings which, unless special precautions are taken, render the aeroplane violently unstable and simultaneously destroy the power of control.

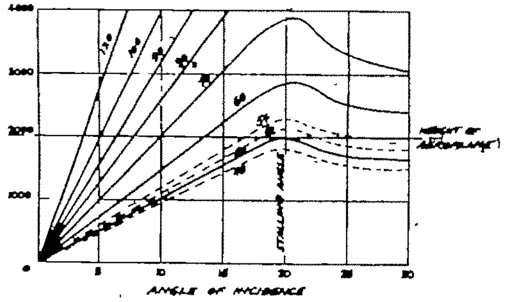

FIG. 1.—The aerodynamic lift, at different speeds and wing incidences, of an aeroplane which stalls at 50 miles per hour. (Numbers on curves show speed in miles per hour.)

Now the nature of the trap is perceived. The early pioneers perhaps succeeded, with the help of the wind, in taking off at a speed greater than the stalling speed, which for their machines was very low. Possibly they carried out many flights without stalling and, delighted with the ease of control, were emboldened, on some favourable day, to glide to a considerable height above the ground. Sooner or later they were bound to stall and, if high up at the time, to kill themselves; for the motions following a stall are peculiarly violent, and liable to lead to heavy impact with the ground.

Herein lay the wisdom of the Wrights, the greatest exponents of the control school of thought. Warned by the experience of others, they suspected some such trap, and never in all their early work allowed themselves to get more than a few feet from the ground. They must have experienced the stall or the approach to the stall, for they discovered what is now known to be the simplest, though not the only counter to it—a powerful rudder. That was the turning-point in aeronautics, when the Wrights managed to get trained in control without being trapped and killed by the stall. After this, increased engine power and experience enabled the stall to be avoided more easily, and deaths from this cause became relatively less frequent, though it has still remained the principal cause of fatal accidents up to the present time. Early progress, however, lay all in the improvement of normal flight, and the study of the stalled condition was not taken up seriously until after the War.

The Wrights achieved their success with an aeroplane which was definitely unstable in several ways, counteracting the effects of this instability by acquired skill. Early design naturally followed this lead, and stability came to be regarded by many of the pioneer flyers as of no practical interest and indeed as a kind of bogy, invented by scientists for their own glorification. After a few important but not fundamental changes from the form in which the Wrights created them, control organs crystallised by about 1911 into a form typified by the BE 2 Aeroplane, produced in the Government Factory at Farnborough, under the guidance of Geoffrey de Havilland. Since that time the method of control, except for the introduction of balancing devices to lighten the pilot's effort on large aeroplanes, has scarcely altered, and the interest in the story shifts to the side of stability.

In 1896, Langley had worked out the general principles of stability sufficiently to make a model, driven by a small steam engine. This model was so stable and well balanced that it flew a distance of more than three-quarters of a mile.

About the same time, Lanchester, working with smaller gliding models, succeeded in unravelling the complicated factors which influence the stability of an aeroplane in normal flight (below the stalling angle), and his results, which he collected in a volume published in 1908, contained in essence most of the principles of practical importance which we employ to-day in the calculation of stability.

About 1911 two interesting things happened. Capt. Dunne made and flew successfully his remarkable tailless aeroplane with swept-back wings, which was undoubtedly extremely stable, probably far too stable for comfortable flying; and Prof. Bryan published a book in which he showed how calculations upon the stability of aeroplanes could be brought into line with conventional mathematics.

Dunne's line of development was not followed up, but we shall see something of the sort cropping up again towards the end of this lecture. Bryan's book was the foundation of modern methods of calculating stability

Bryan's idea was to measure the effects of simple disturbances, such as rolls or pitches, separately, and thus to obtain a number of characteristic quantities, or 'derivatives' as they are called, which could be used in the calculations of stability. He did not have the means to make the necessary measurements, but the scientists of the National Physical Laboratory, who were already in possession of wind tunnels, set to work to determine these quantities for small models and to make the necessary calculations along the lines which he had indicated. The experimental campaign so started has been in progress ever since.

The application of this systematic study of stability to man-carrying flying machines was first made in the Government Factory at Farnborough by Busk. He modified the unstable BE 2A into the stable BE 2C by relatively small changes in the position of the centre of gravity and in the area and arrangement of the fixed surfaces on the end of the tail. This was a distinct step forward, and much notice was taken of it in the Press, where the opinion was freely expressed, mainly by non-flyers, that the safety of flying was now assured. This view was wrong; the provision of stability alone is not sufficient for safety, as Busk and his fellow-workers well knew. Safety is mainly concerned with the taking off and landing of aeroplanes, when a rapid response to control is even more important than stability.

The opposing school of thought—lineal descendants of the pioneer flyers—were naturally aggravated by this widely advertised and erroneous view of the relation between safety and stability, and the breach between the two schools widened still further, culminating in two extreme examples, the very stable SE 5, produced in the Government Factory at Farnborough, and the very unstable Camel designed by Sopwith. These two machines, diametrically opposed in every feature relating to stability, shared between them the brunt of the single-seater fighting during the later stages of the War; opinion ran high concerning their relative merits and the lines of thought which they represented. Readers of that remarkable diary "War Birds" will find the view of the supporters of the SE 5 forcibly expressed, but I have heard the other side equally strongly maintained. These two machines marked the culminating point in the controversy to which reference has been made. Later development has been all towards compromise, slightly on the stable side of neutrality: benevolent neutrality as I have called it.

Though the experimental technique and the mathematical calculations necessary for a thorough study of control and stability are difficult and elaborate, the main results are simply and easily stated.

The pitching motions of an aeroplane depend upon what is called its weathercock stability. An aeroplane hung up in a wind so that it can rotate about a horizontal axis through its centre of gravity has weathercock stability if, like a weathercock, it desires to face the wind and returns to its original attitude on being disturbed. As with a weathercock, this kind of stability is increased either by moving the pivot—in this case the centre of gravity—forward, or by increasing the area of the tail.

A free flying aeroplane which has this form of stability will, if disturbed from steady flight, first rotate rapidly so as to restore the incidence to the equilibrium value and then execute a series of long slow pitching movements, similar to a ship travelling over ocean waves. The length of these waves from crest to crest is between ½ and 1 mile, and the time taken some 30 seconds. These movements are so slow that they have little influence on control.

The weathercock *unstable* aeroplane, if pivoted like a weathercock, would very quickly turn round and face backwards. If this happened in free flight it would be unflyable, except by a pilot with the skill of a juggler, but it does not happen. Suppose the aeroplane is flying freely and the nose is accidentally deflected upwards; being unstable it will throw up its nose still farther, but at the same time the increased incidence will cause it to leap upwards with great suddenness. The direction of motion is thus *rotated upwards* faster than the aeroplane itself, so that the first quick adjustment is a fall of the incidence to nearly its original value. Afterwards the upward tilt and upward trend of the path increase relatively slowly, until the aeroplane slows up and stalls. There is, however, ample time for the pilot to correct this subsequent motion, provided that his attention has not wandered. This is the reason why the Wrights and others were able to fly aeroplanes which were unstable fore and aft.

So long as the instability is not too great, the aeroplane, like the motor-car, can be controlled effectively whether it is stable or unstable. As in the motor-car, too great stability is definitely objectionable, partly because heavy forces are then required to execute rapid manœuvres and partly because heavy forces, or adjustments of some sort, are required to 'trim' the aeroplane for different speeds. For alterations in speed must be accompanied by changes in incidence, which in a very stable machine will require large control forces. A neutral aeroplane, on the other hand, if trimmed for one speed will be in trim for other speeds within a wide range. The problem here before the designer is so to adjust the centre of gravity and the tail areas as to produce a very slightly stable aeroplane.

The rolling and yawing motions of an aeroplane can also be simply described, though in detail they are very complicated.

When the aeroplane rolls the falling wing meets the air at a larger incidence than the rising wing and experiences a greater lift; a very large couple opposing the roll is thus generated. This is the predominating factor in the lateral control, for it prevents rapid rolling and gives the pilot time to observe what is happening and correct it. This is the reason why the Wrights could control an aeroplane which was laterally unstable.

If the aeroplane has a 'dihedral angle'—tips of the wings higher than the middles—side slip tends to raise the wing towards which the slip is occurring. If it has a large vertical fin on its tail, it will turn or yaw towards the slip. In normal flight the dihedral angle has a powerful stabilising influence, because if one wing falls below the other, side slip will occur towards that wing, and a couple will be generated raising the wing.

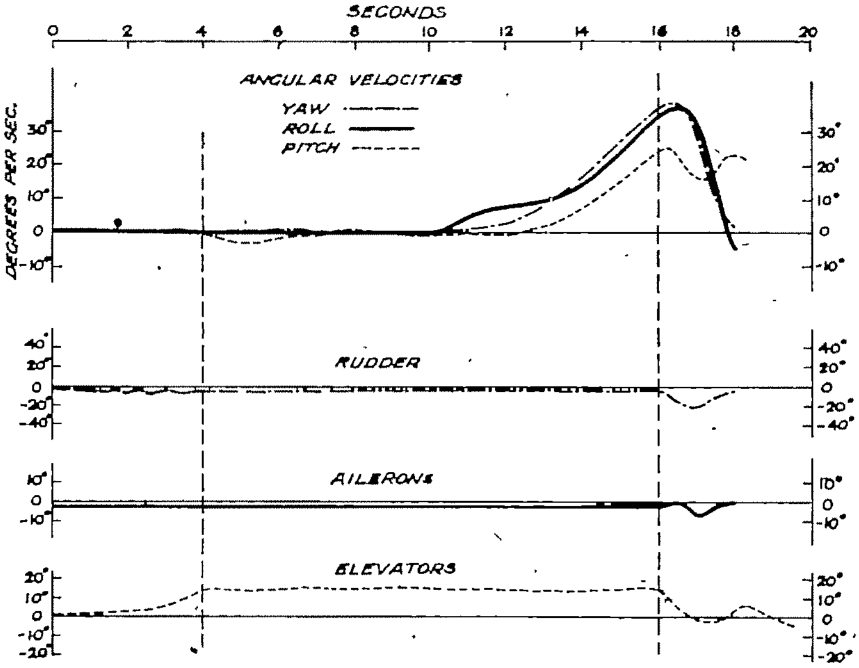

Fig. 2.—Controls fixed. The unstable rolling turn.

An aeroplane which has too large a vertical fin on its tail and too little dihedral angle will have what is called spiral instability; if slightly disturbed from straight flight, it will continue to roll and turn from its course, and ultimately descend in a spiral curve. This motion is, however, so slow in developing that it is of no importance so long as the pilot is in control, but like other forms of instability it is undesirable, particularly when long flights are contemplated.

Another motion possible to an uncontrolled aeroplane consists of a complicated rolling and yawing oscillation, generally of about six seconds period. This will become unstable and render the aeroplane practically unflyable if the vertical fin in the rear is too much reduced. Thus the exact proportions of these fin surfaces is a matter of great importance; if they are too small, the relatively quick oscillations will become unstable, with disastrous results; if they are too large, the slow spiral instability, which on the whole is undesirable, will occur. The problem is eased by giving a good dihedral angle, for this widens the limits permissible in fin size, without incurring either of these defects.

One other fact of interest has only lately come to light. If the dihedral angle is too small, the short period oscillation to which reference has been made may become of the type which is caused to increase by a control which contains a lag. As there is always some lag between the pilot's intention and his performance, this latent defect may cause trouble; even though it may not be so bad as actually to cause the oscillations to increase, it may lead to great difficulty in damping them down. In bumpy weather, therefore, the oscillations may be continuous from one air bump to the next, with disastrous results both on the strength of the pilot and the stomachs of the passengers. The improvement in the bad weather qualities of some of the later cross-channel aeroplanes is attributed partially to increased dihedral.

No more need be said now about control in normal flight. In what precedes an attempt has been made to explain why the provision of good control qualities is more a question of proportioning the aeroplane and adjusting its load properly than of devising new control organs.

This brings us to about the end of the War. More data have accumulated and measurements have been refined, but most of the foregoing statements might have been made then. The trap which killed the early pioneers still, however, continued to take its toll of life, though in a much lower proportion to the hours flown. Ample power had become available to allow the normal flying speed to be so much greater than the stalling speed that

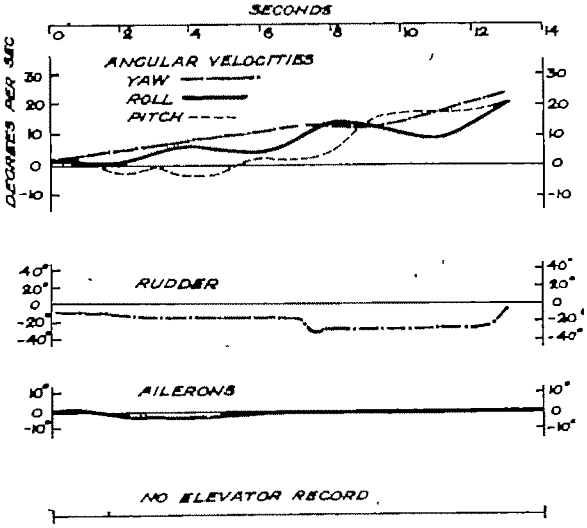

Fig 3.—Controls fixed. The increasing oscillation.

accidental stalling became rare, except when a pilot was deliberately flying slowly with the object of making a landing. When it did occur, however, the same consequences followed as with the early pioneers: but the danger was increased, because of the higher loading and consequent heavier impact of the later machines. Throughout the history of flying to the present day this has been, and still remains, the most frequent cause of fatal accidents.

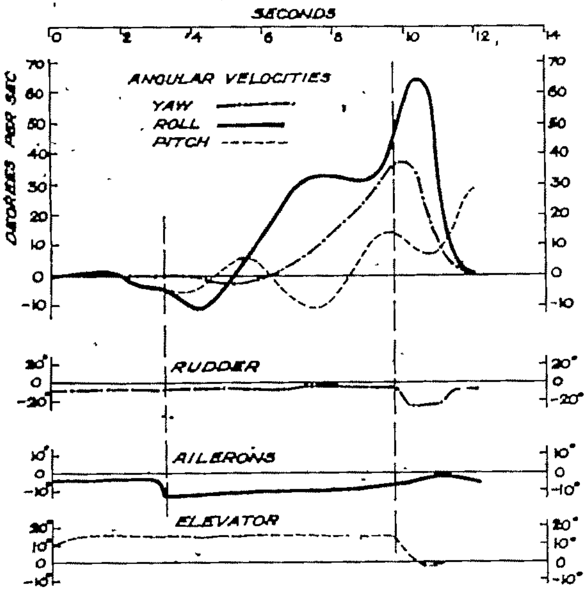

FIG. 4.—Failure of ailerons applied during steady flight. (Note apparent success at first.)

Shortly after the War, the British Research Committee for Aeronautics started a research campaign into the causes and cures of this trouble. The research was carried on in wind tunnels, by theoretical work, and in actual flight at heights sufficient to rob the stall of its danger, with the result that the principles underlying the matter are now understood and several ways of eliminating the danger are known.

One small part of this campaign of research is being carried on by the University Air Squadron at Cambridge. Our task is to endeavour to obtain precise experimental records[1] of the motions of stalled aeroplanes, both when left to themselves and when the pilot is trying to control them. The apparatus which we use was developed and constructed at the Government Research Establishment at Farnborough and lent to us for the purpose. It consists of a box containing three gyroscopes which are slightly deflected against a spring control when the aeroplane is turning. The deflexion of each gyroscope is proportional to the rate at which the aeroplane is turning about some particular axis, and they are arranged so that, between them, they measure the three rates of turn about three axes mutually at right angles. These three records are recorded continuously upon a moving photographic film. Three other instruments record independently the movements of the three controls—elevator, rudder, and aileron—and all these records are synchronised from a central clock, which records half-second intervals on all the films.

Figs. 2-9 show some graphs drawn from records selected from more than a hundred sets which we have obtained. These results, which will now be described, have all been predicted, at least in their general features, by calculations based on wind-tunnel observations of the forces acting upon models supported in various ways in the wind tunnels of the National Physical Laboratory and the Royal Aircraft Establishment. The wind-tunnel experiments and calculations were made long before precise records in free flight had been obtained, but for lecture purposes I shall reverse the chronological order of the events and describe the results first before explaining why they occur.

Fig. 2 shows a record of one such flight. The experiment began at the vertical line marked 4 seconds, when the elevator was pulled right back and the incidence of the wings (not shown in the figure) was between 19° and 20°. From that time the controls were held fixed until 16 seconds, when the experiment ended. This experiment began exceptionally favourably, with no rotation of any importance occurring. Straight flight continued undisturbed until 10 seconds, when some slight disturbance started the unstable motion characteristic of this aeroplane at this incidence. Increasing rates of rolling and yawing, both to starboard, were then recorded, which in six seconds had grown to some 30° per second. The aeroplane by this time had rolled through some 60° from the horizontal, and the pilot then stopped the motion by pushing forward his elevator and reducing the incidence of the wings below the stalling point.

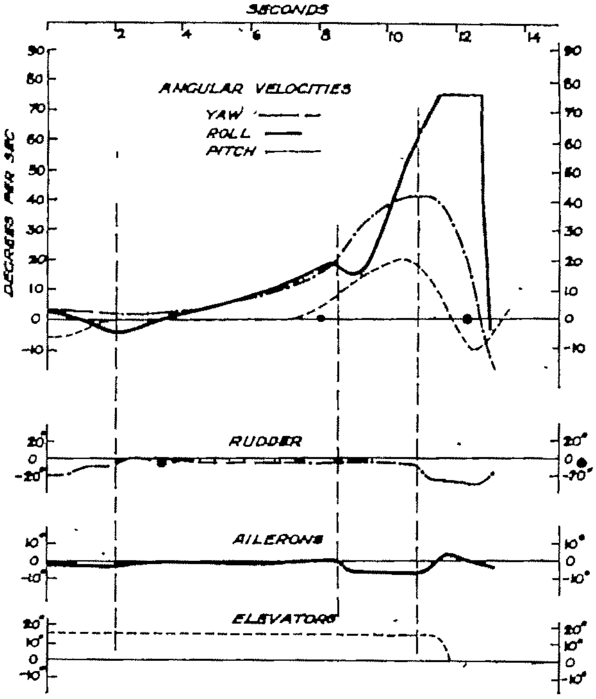

FIG. 5.—Failure of ailerons to check a rolling turn.

The rapid check to the roll which followed this last control movement should be noted. The reason why a rapid roll at a low incidence is impossible has already been explained.

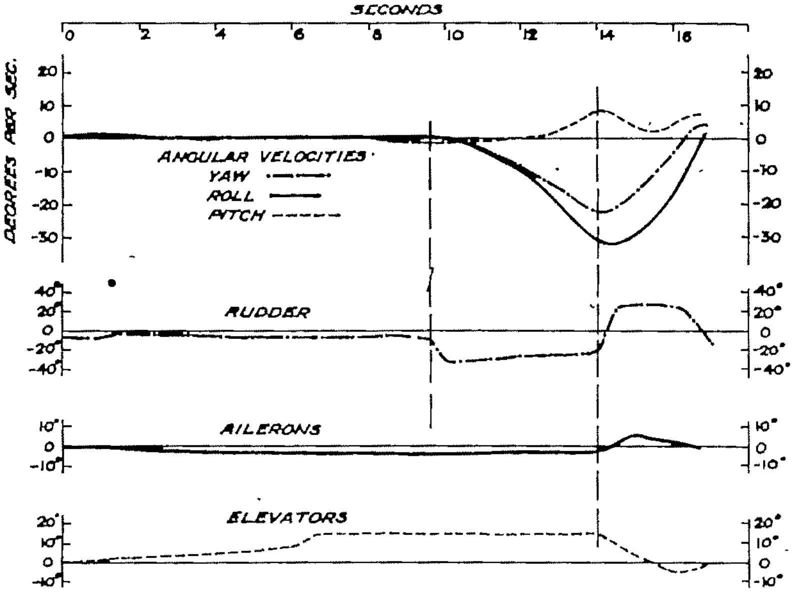

FIG. 6.—Effect of rudder applied during steady flight. (Note indirect influence on rolling.)

Superimposed on this unstable motion is a slight rolling oscillation; this feature of the movement is by some accident more clearly shown in Fig. 3, where the amplitude of the roll is seen to increase automatically.

This particular machine at this incidence shows, therefore, two distinct forms of instability, one technically known as a divergence, which approximately doubles itself in every second, and the other an oscillation with a tendency to increase.

Fig. 4 shows the effect of applying ailerons, in straight stalled flight, at about 20° incidence. For the first second after they are applied the aeroplane rolls in the direction to be expected, but almost immediately its direction of roll is reversed and it plunges wildly over on the opposite side.

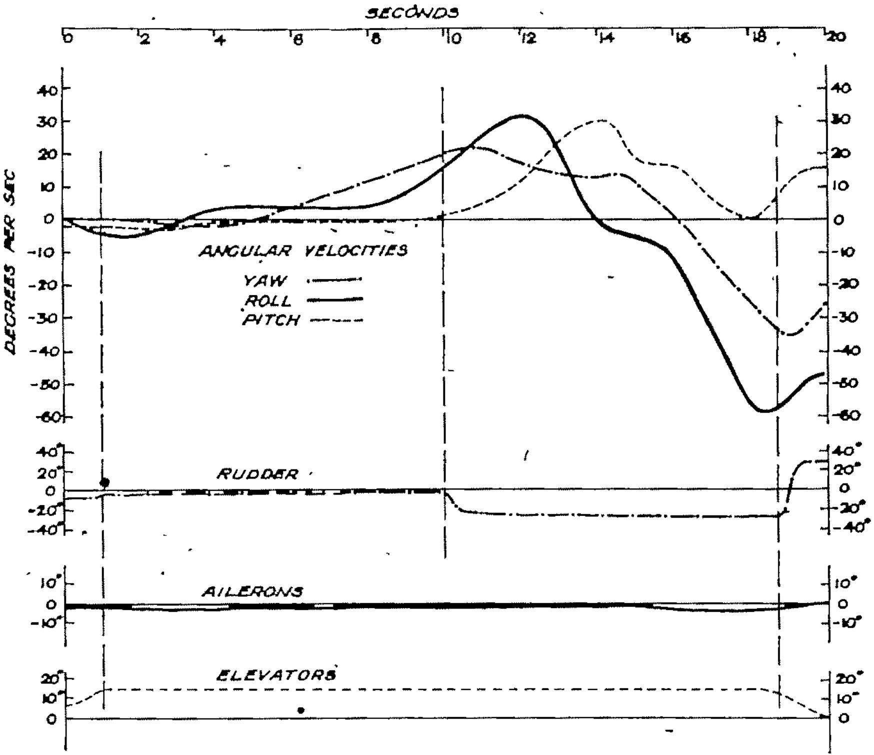

FIG. 7.—Rudder succeeds in checking a rolling turn. (Note delay in action.)

Fig. 5 shows that this failure of the ailerons is even more marked when they are used to check a roll which has already started.

Fig. 6 shows that the rudder, applied in straight flight, has the desired effect of turning the aeroplane, but that it also causes it to roll in the sense that the wing which is being pushed forward rises.

Fig. 7 shows that the rudder can be used to check a roll which has already started, if it is applied so as to reverse the turn which accompanied the roll (*i.e.* to push forward the falling wing tip). The delay in the action and the violence of the reversed roll which follows should be noted.

Fig. 8, however, shows that if applied too late the rudder may, in certain circumstances, fail to check this unstable motion, though for the first two seconds after it was applied it appeared to be going to succeed.

Fig. 9 shows the ultimate history of an attempt to control these unstable motions by means of the rudder alone; note the liability of the oscillation to increase despite the pilot's efforts to check it.

These results have been chosen because each shows some particular aspect of the matter clearly. In many of the other results obtained these various aspects are so mixed together that a practised eye is required to disentangle them.

The utter uselessness for any practical purpose of control with the above characteristics requires no emphasis.

As has been stated, these results can all be explained, in general terms, by mathematical analysis based on data obtained from wind tunnels, and though the analyses are intricate the broad explanation can be given simply.[2]

The primary cause of the trouble lies in the change, when the aeroplane stalls, of the effect of rolling upon the rolling couple. Instead of a large couple opposing the roll being generated, as in normal flight, a slight couple is generated in the sense to increase the roll. This is because (see Fig. 1 at 20° incidence and above) the increased incidence of the falling wing tip no longer increases the lift upon it, but slightly decreases it. There is thus nothing but the inertia of the aeroplane to prevent rapid rolling. The complicated effects of inertia, such as those we observed in relation to ships at the beginning of the lecture, are thus introduced, and the valuable factor of time for the pilot to think is absent.

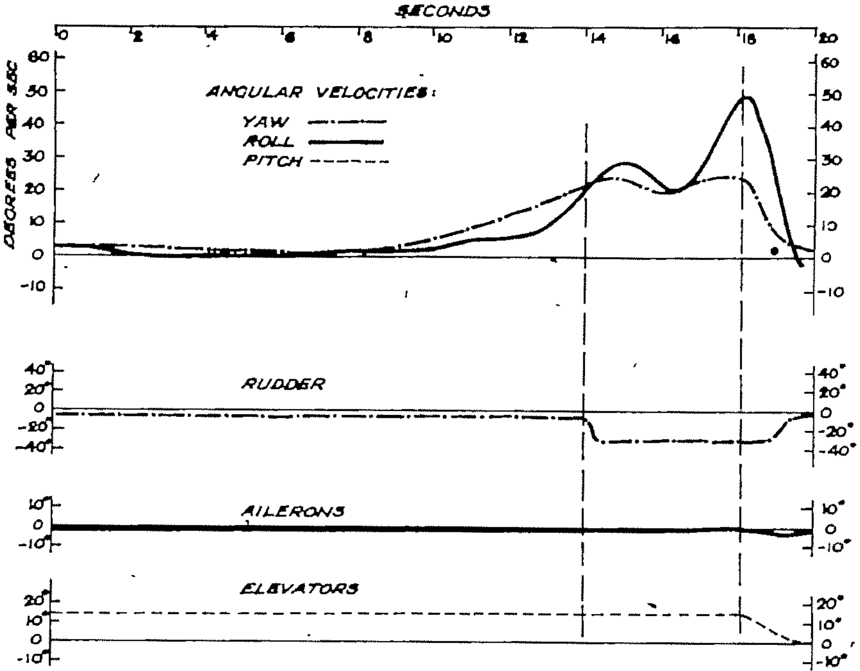

FIG. 8.—Rudder fails to check a rolling turn.

The instability of the motion is easily explained. When a stalled wing rolls there is not only a slight couple increasing the roll, but in addition a couple tending to retard the falling wing. This is because drag increases very rapidly with increase of incidence on a stalled wing. Now in stalled flight, even a small rate of yaw generates a large rolling couple depressing the retarded wing. This is partly because the advancing wing is travelling faster than the retarded wing and partly because of the side slip which follows the yaw. (It has been found that the rolling moment produced by side slip is, for some as yet unknown reason, very much greater on a stalled than on an unstalled wing.) Any slight disturbance in yaw therefore generates a rolling couple, and the resulting roll both tends to increase itself and to cause the rate of yaw to increase still further. Such a process is obviously cumulative.

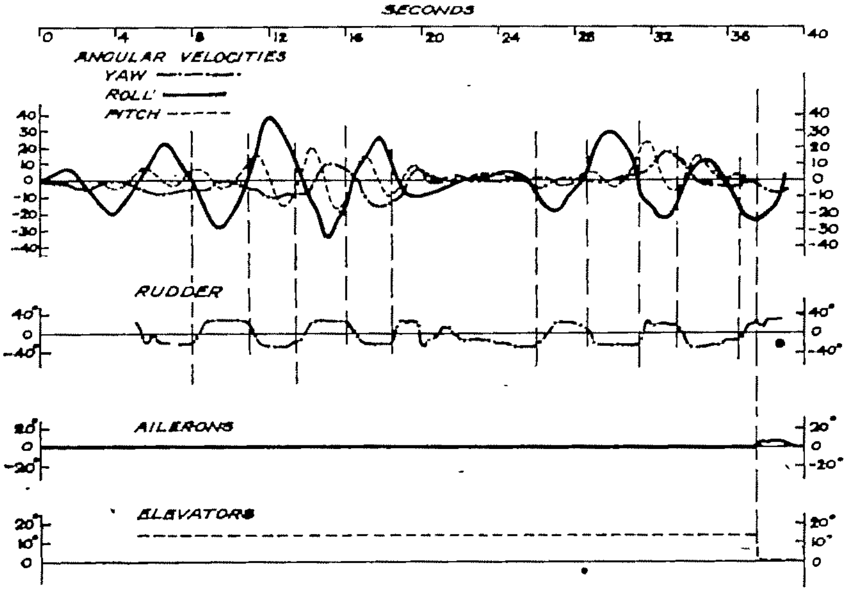

FIG. 9.—Attempt to control the roll by means of rudder alone.

The increasing oscillation can also be explained, but the explanation is too involved to be given in the time at my disposal.

The outstanding feature of the whole problem is, however, the great influence of yawing motions on rolling couples, and this should be borne in mind when the action of the controls is considered.

The characteristic feature of aileron control in stalled flight is that, whilst the rolling couple which they can exert is weak, they also exert a powerful yawing couple retarding the wing tip which they are trying to raise. This starts the aeroplane yawing, and a large rolling moment is soon indirectly generated by the yaw, which entirely swamps the direct action of the ailerons. The apparent success, in Figs. 4 and 5, of the ailerons, for the first second after their application, followed by complete failure, is thus explained.

---

[2] The explanations which follow will be more easily understood with the help of a model aeroplane which can be held in the hand and moved in the ways described. Failing a model aeroplane, a piece of card in the form of a T to represent wings and body should suffice.

The action of the rudder in causing the aeroplane to roll, so that the retarded wing falls, is now easily understood; the roll follows after yaw has been generated. The difficulty of using the rudder in a way which will not cause an increasing oscillation arises from the fact that its effect on roll is delayed until it has succeeded in generating a yaw. We saw in the beginning of the lecture that delay in the control of a motion which automatically tends to increase, is fatal.

To sum up. The motion is violently unstable in two ways. The ailerons are a positive source of danger, since they produce an effect which at first appears satisfactory but is ultimately the opposite of that expected. The rudder, though effective, provides a kind of control very difficult to use and, moreover, is often too weak even to prevent the first unstable plunge from continuing.

The continuous series of accidents resulting from accidental stalls near the ground are thus explained, for, though the motion can always be checked by thrusting the stick forward, and so diving to regain speed, this remedy is of no use when the ground is near. The pilot's reflex response when he finds himself suddenly rolling over and diving into the ground is to pull the stick back and to the side away from the roll. This, as we have seen, has disastrous results.

There are two lines along which a cure can be effected. One is to eliminate the instability and the other to improve the control. After what has been said above, there will be no difficulty in realising that the final solution will be along both lines.

The simplest way of improving the control was that originally used by the Wrights: to supply a powerful rudder. This prevents the worst consequences of stalling, but it does not, as we have seen, provide a satisfactory control. Moreover, it can only cause the aeroplane to roll after it has started it yawing, and this may be very undesirable if there happens to be a house or tree on the side towards which the yaw has to be made. An effective rudder, however, though not a sufficient cure, is a *necessary* factor in any complete cure.

Another solution is to provide some form of control at the wing tips, which will lift the wing powerfully and simultaneously push it forward, rather than push it backwards, as does the standard aileron. The yawing action of the aileron will thus indirectly reinforce the direct rolling action, instead of opposing it as at present. There are several ways of doing this; one is to provide a surface beyond the wing tips which, even when the main wings are stalled, will be inclined downwards so as to meet the air edgeways. This surface will not itself be stalled, and if its angle is controlled by the pilot it can be made to exert either an upward and forward or a downward and backward force, which is just what is required. Such surfaces will also prevent rapid rolling and eliminate the instability. This device is used in Hill's Pterodactyl, a tailless aeroplane which is said to be as stable and controllable when stalled as in normal flight.

A second method of achieving the same result is to place one of Handley Page's slots in front of the wing tips. If these slots are left permanently open they will delay the stall on the tips until long after it has occurred on the remainder of the wings; the characteristics of unstalled wings which prevent rapid rolling from occurring will thus be retained, and the tendency for rolling to cause yawing will be eliminated. Stalled flight then becomes very stable and easily controlled, though the rate of control is not rapid. If in addition the slots are interconnected with the ailerons, so as to close on the side to be depressed, but to remain open when the stick is central, the power of rapid control will be secured in addition to stability, for the closing of the slot will cause the wing tip to stall, with a consequent large loss of lift and increase of drag by comparison with the other tip on which the slot remains open. The large direct rolling moment generated in this way is thus reinforced by the indirect effect of the yawing moment resulting from the increased drag on the wing tip which it is desired to *depress*. This is the reverse of the action of normal ailerons, which exert an increased drag on the wing which it is desired to *raise*.

Unfortunately, the slots cannot be left open permanently, because the wings will then absorb too much power in normal flight; hence schemes have had to be devised to cause them to shut automatically, when the incidence falls below the stalling angle. Handley Page has devised one very successful method of doing this, of which accounts have been given in the daily Press. Another somewhat different method of doing the same thing has been devised by McKinnon Wood at Farnborough

Which of these methods will ultimately prevai is as yet uncertain, but that a complete cure in a practical form can be found is now beyond doubt and we can confidently look forward to a time when its principal danger having been eliminated, flying will be ready to take its place in the world's transport, on terms which, in respect of danger, wil compare not unfavourably with the older and more established methods.

PHOTOGRAPHIC INDUSTRIES.

The importance of air conditioning in this industry is very great. Absolutely pure, dirt-free air is required in the manufacture of film and sensitised papers, as the slightest atmospheric impurity is reflected in the developed photograph. The air filtration plants must be as nearly as possible 100 per cent. efficient. Temperature and humidity conditions are extremely important, especially the latter, owing to the danger of static electricity in winding and consequent risk of fire should the film become too dry. Again, in film studios, a dry pure atmosphere is required when 'shooting' pictures, otherwise the film is blurred.

PRINTING TRADES.

In newspaper printing, correct atmospheric conditions are essential to prevent breakage of the paper due to too much moisture in the pressroom, and also to keep the ink at the right temperature, and the rollers pliable. Too low a temperature causes these rollers to become hard. In colour printing, correct temperature and humidity are very necessary, or the colours do not remain distinct.

THEATRES, CINEMAS, ETC.

Here again air conditioning plays an important part. Discriminating playgoers will not patronise a theatre or cinema which is chilly in winter and insufferably close in summer. Absolute comfort can only be ensured by proper heating and ventilating equipment, coupled with some means of air purification, and air cooling in warm weather. This question of air cooling is very obvious when it is remembered that an adult at rest emits about 400 B.Th.U. per hour; therefore, in a cinema with seating accommodation for 2000 people, 800,000 B.Th.U are given off hourly from the occupants.

Summarising the above, it will be seen that air conditioning enters into many spheres of our industrial life, both for ensuring human comfort, and also uniformity of product and more rapid output of many manufactured articles. There is scarcely a single important industry that can dispense with air conditioning in some form or another. In this short article I have only chosen a few examples at random.

Table II. gives a few typical uses to which air conditioning may be put, together with air changes, temperatures, and humidities usually employed.

TABLE II.

Type of Building.	Air Changes per Hour.	Temp. (Degrees F).	Relative Humidities.
Offices . .	1 to 3	58°–62°	50 to 63 per cent.
Theatres .	2 ,, 4	60°	50 ,, 63 ,,
Hospitals .	2 ,, 8	60°–70°	50 ,, 63 ,,

AIR-CONDITIONING EQUIPMENT.

There is no standard air-conditioning plant that will universally perform all the above-mentioned requirements; each individual application must be carefully considered, the method of obtaining the desired results decided upon, and the equipment must then be designed and installed by an expert air-conditioning engineer, to suit the prevailing conditions.

Briefly, the principal components of an air-conditioning plant and its method of operation comprise:

(1) Some positive means of moving the air being dealt with. This is usually effected by fans, of either the centrifugal-cased or propeller type, direct-coupled to some prime mover, such as a steam or internal-combustion engine, or an electric motor, or belt-driven from any convenient source of power.

(2) There must be some means of distributing the air where it is wanted. This is usually effected by blowing the air through ducts, constructed either of bricks, concrete, wood, galvanised sheet steel, copper, or aluminium. The materials used for duct construction are entirely decided by the use to which they are put, and the type of building in which they may be installed.

(3) There will be some form of heater for raising the temperature of the air; this usually takes the form of a battery of plain or gilled tubes over which the air is passed, the tubes being fed with either live steam or exhaust steam from engines and turbines. Alternatively, if the battery is required for cooling the air, then brine or expanded ammonia gas must be pumped through the tubes.

(4) It may be necessary to filter the air; this may be effected by the dry, viscous, or wet filtration processes. In the dry method, the air is either drawn or forced through canvas bags, or metal-plate filters with rough cloth linings, to which the particles of dirt adhere, or sometimes for very special filtration a combination of canvas-bag filter and metal-plate filter may be used. In the viscous method, the filter consists of a metal frame containing coils of wire immersed in oil, the dust in the air being arrested by the film of oil. In the wet filtration method the air either passes through copper gauze screens, the screens being flooded by a continuous stream of water, or else it is cleaned in a proper air washer and humidifier.

(5) Air is humidified in several ways, all of which demand the intermixing of the air with a steam or water spray. The usual humidifier, which also acts as a wet filter and air washer, comprises a body casing of sheet metal, of either galvanised steel or copper. This casing is mounted on a settling tank containing water. The air enters one end of the humidifier, where it comes into intimate contact with a bank of water sprays or atomisers. These atomisers are supplied with

water under pressure from a centrifugal pump, the effect being that the air is thoroughly intermixed with a very fine cloud of water particles and is therefore washed and saturated. The air then strikes against zig-zag baffle plates or eliminators, which remove all its entrained moisture, and leaves the humidifier at a relative humidity of 100 per cent. and is 98 per cent. pure and clean.

The above brief description of the chief components of an air-conditioning plant is by no means complete, but it may serve to indicate what are the essentials of some installations used in industry.

The Royal Academy's Exhibition.

THE opening of the Royal Academy Exhibition at Burlington House is a seasonal event which interests most of us, even if we are not endowed with special artistic perceptions. In art, as in science, there is specialisation into particular spheres; and therefore great variety of effort, with the necessary limitations, must be displayed in the works exhibited by an Academy. As in science also, creative ideas cannot be expected to be conceived so frequently as commonplace performances.

In portraiture there are, at this year's exhibition, as usual, a good many 'personalities.' Somehow, we always regard these frequencies with vague detachment, schooling ourselves into approval or disapproval. Contrasts are inevitable, but perhaps complete antithesis is exemplified in Sir William Orpen's study of Mr. Lloyd George (290), and that of Mr. Stanley Baldwin, by Oswald Birley (434), the one distinctive enough, yet flamboyant, and the canvas full of accessories; the other of marked sobriety of treatment, wholly pleasing. So much for our rulers. But Orpen's Sir George Maxwell (193), a ruler in lesser measure, and a gift to him, in tribute of service, from the Chinese community of Malaya, is a great possession. George Harcourt has painted Dr. Cyril Norwood (237), almost full length, for Marlborough College, with accuracy, and the dignity befitting a distinguished schoolmaster. There is a suggestion of an academical robe, otherwise we have the philosophy of clothes in meticulous display, which upper forms will note. Sir Arthur Keith, by W. W. Ouless (100), disappoints us in aspects of intellectual virility; surely here was a sitter who could wear no mask. On the other hand, we might apprehend possible trials with Sir Gowland Hopkins, but his portrait by George Henry (243), for the Bio-Chemical Laboratory, Cambridge, is good, if of rather ruddy tone. However, man does not live by calories alone. Richard Jack gives us a capital example in his Prof. A. G. Perkin (382), scarlet and green much in evidence. The catalogue places him outside the humanities, and names him "Perkins." Sir Arthur S. Cope supplies a conscientious presentment of Dr. Alfred Palmer (374) for the University of Reading. George Harcourt's oil of Mr. Llewelyn B. Atkinson, lately president of the Institution of Electrical Engineers, we find disappointing, lacking reminiscence. Lavery paints Dr. Nicholas Murray Butler with subdued and faithful effect. The late Thomas Hardy (in three-quarter) looks straight out at one on a canvas by R. Grenville Eves (55). It should please the novelist's admirers. Many will approve also of Fiddes Watt's "George Summers, Huntsman, Duke of Buccleuch's Hounds" (448), excellent and arresting in characterisation. Other portraits of special interest include the Master of Sidney Sussex (W. W. Russell), Sir Herbert Warren (Glyn Philpot), and Lord Hewart (Lander), painted for University College, Oxford.

Among landscapes Ernest Parton's "A Morning on the Kennet" (129) is of high order; also La Thangue's "A Sussex Stream" (181), where we have brilliant water, and a boy with net and bottle. Farquharson's "November" (165), "Winter" (268), and "A Winter Evening" (394) are specially good of their kind, while W. T. Wood's "Winter at Burpham, Sussex" (331), should be seen. Slade's "Sussex Weald from the Devil's Dyke" (537) portrays that much-discussed expanse, formal but faithful.

Apart from the natural aspects of landscapes the botanist may give attention to the numerous examples of flower studies, in mixed bunches, or selected, which are hung. Merit varies; and ugly vases on chessboard patterns do not enhance effect. We like Hayward's "Lenten Hellebore" (44), depicted in a tankard-shaped receptacle, and Wood's "Drooping Roses" (48).

Quite a number of old barns and their interiors are here, which is all to the good. They well repay study, especially Steel's "Unthank Hall Barn, Derbyshire" (64). Many ancient barns are now marked for destruction under the transport march; and, going off at a tangent, we are much interested in A. J. Munning's presentations of horses, particularly his "Solario" (84).

The Architectural Room claims mostly the attention of those interested in the style and progressive ideals of designers. On the whole there is much of an encouraging character. We like Mr. A. N. Prentice's "New Public Library for Westminster City Council," in course of erection on the site of Sir Isaac Newton's old home, Orange Street, and in proximity to the offices of this journal. Sir Edwin Lutyens's "Ambassador's Entrance: British Embassy, Washington," buildings of low pitch, dignified and restful, make one feel that residence in such quarters would duly regulate the blood pressure of diplomacy. The "New Mercantile Bank, Singapore," by P. H. Keys and F. Dowdeswell, is stately and satisfying. Designs for various English engineering, chemical, and zoological laboratories may also be seen.

News and Views.

IN his Royal Institution discourse on "Research on the Control of Aeroplanes," which appears as a Supplement to this week's issue of NATURE, Prof. B. Melvill Jones gives a very lucid exposition of a problem that has long been a subject of controversy among aeronautical experts, young though the science be. Broadly speaking, the question at issue is, whether safety in flight should be achieved along the lines of construction for aerodynamic stability, or along the lines of pilot controllability. The theoretical experts have rather inclined to the former, the practical flying men always to the latter; and Prof. Jones, who has played the part both of pilot and theoretician, is well qualified to appraise both viewpoints. It is not difficult to appreciate the influences that have stirred the theoretical experts. Bryan's masterly exposition of the disturbed motion of an aeroplane regarded as a rigid body and his analysis of the conditions that make for stability caught the imaginations of the interested mathematicians, trained as they were in the Newtonian school of simplified abstractions from reality, and for a long period determined the direction of aeronautical research.

THE fact remained, however, that to the pilot the aeroplane was never even remotely a rigid body, for he himself, as part of it, was continually operating its controls and guiding it to his will. A highly stable aeroplane was rather a nuisance to him, for he did not wish to rely on a self-willed machine, but on himself. The mathematicians, recognising the fallibility of the pilot and consequently tending to ignore him as a control, wished to depend rather on the machine. In the last resort it was the multiplicity of accidents on landing, that is, at low speeds of flight, that stimulated a searching and critical analysis into the aerodynamics of flight under these conditions and into the natural and sometimes disastrous responses of the pilot himself to rolls and dives. As Prof. Jones shows in his lecture, these have served to illuminate the whole problem of stability and control, to expose their respective limitations and to indicate that the final solution must partake of both factors. Incidentally, Prof. Jones's lecture illustrates two other points. In the first place, it demonstrates the extent to which experimental finish has been procured in the study of an intricate scientific problem under conditions of operation infinitely more difficult than those normally attendant in a laboratory experiment; and in the second place, it has brought out that the aeroplane industry, principally in the person of Mr. Handley Page, has played no small part in the elucidation and solution of these scientific problems.

THE Society for the Preservation of the Fauna of the Empire has undertaken a great and important work, and the inroads which have been made in recent years upon the wild stock of many British colonies and dependencies show that it has entered the field none too soon. It is a commonplace that the spread of civilisation, with its breaking in of wild territory, felling of forests, and draining of marshes, uproots and decimates the aboriginal fauna, and it is as patent that destruction even more rapid may follow upon unrestrained slaughter in the name of sport or commercial ventures. Even where laws are made to restrain these activities within reasonable bounds, and in almost all parts of the British Empire such laws now exist, it is difficult without a prohibitively large staff of wardens to enforce the law. Consequently, in many regions, of land and sea, destruction moves ahead of the natural replenishment of the stock, towards the inevitable goal of extermination. The Society properly accepts the view that the progress of civilisation cannot be stayed, and that the legitimate interests of sport must be safeguarded. It wisely concentrates its efforts, therefore, upon the sheltering of a nucleus of the wild life of any region in great reserves or national parks. An excellent pamphlet on "The Passing of Wild Life" describes the Society's point of view, and insists upon the need of public support and of immediate action in the creating of reserves. Copies of the pamphlet may be had from the Secretary of the Society, c/o Zoological Society of London, Regent's Park, London.

SIR ROBERT HADFIELD, Bart., has been elected a foreign associate of the National Academy of Sciences of the United States of America. The announcement has a fitting complement in the award by the Iron and Steel Institute, referred to below, of the Bessemer Gold Medal to Mr. Charles Schwab, one of the leaders of the steel industry of the United States. Incidentally, it may be mentioned that the Bessemer Gold Medal was awarded to Sir Robert Hadfield so long ago as 1904. Sir Robert's latest honour brings him into distinguished company. The National Academy of Sciences held its first scientific meeting in 1864, and immediately took advantage of a by-law permitting the election at any one meeting of not more than ten foreign associates, by electing this number; the names included Faraday and Brewster. Since that time, the National Academy has grown steadily in importance and in numbers. The membership roll has now increased to more than two hundred, but the list of foreign associates is less than twenty. Sir Robert's election brings the number of British men of science on this roll of honour up to twelve; it includes the two living past-presidents and present president of the Royal Society. The last British worker to be elected was Sir Frank Dyson, Astronomer Royal (1926).

ON May 3, at the annual general meeting of the Iron and Steel Institute, the Bessemer Gold Medal was presented to Mr. Charles Schwab, president of the American Iron and Steel Institute and the president of the Bethlehem Steel Corporation. Mr. Schwab was born in Williamsburg, Blair County, Pa., on Feb. 18, 1862, and started his distinguished career in the Edgar Thomson Steelworks of the Carnegie Company by driving stakes at a dollar a day. By his own energy and ability he rose in seven years to be chief of the Engineering Department of the Carnegie Company. The great Homestead Steelworks plant, designed by him, and erected under his supervision, was arranged to be a practically continuous mill, so that the raw materials went in at one end and the finished products came out at the other. In 1896 he was made a member of the board of managers of the Carnegie Companies, and in the following year was elected as its president. The problem in the United States at that time was the manufacture of more steel, better steel, and more rapid production. In this, Mr. Schwab achieved the best practical results. Smaller concerns were combined until the Company attained an impregnable position in relation to raw materials, modern equipment, and skilful management. Further commercial development on economic lines was made possible by a fusion of interests between the larger companies, and the United States Steel Corporation came into being with Mr. Schwab as president. Mr. Schwab resigned this post after three years and obtained a controlling interest in the Bethlehem Steel Corporation, of which he is now chairman of the board of directors. The Bethlehem plant at that time was largely engaged in the manufacture of munitions. Under the control of Mr. Schwab it has become one of the best steel works in the world, and at the present time the manufacture of munitions takes up less than 5 per cent. of the productive capacity of the plant.

The annual May Lecture was delivered before the Institute of Metals in London on May 8 by Prof. C. H. Desch on "The Chemical Properties of Crystals." Prof. Desch discussed the various ways in which atoms may be held together in a crystal: by the simple exchange or sharing of electrons, or by residual forces. In rock salt the molecule has disappeared, but there are many substances built up of molecules in the solid as well as in the liquid state. In a few simple cases it has been found possible to calculate the forces of attraction in a particular face of a crystal, and in that way the differing chemical properties of different faces can be explained. Such differences account for the varying habit of crystals of the same substance grown under different conditions. When a metal is attacked by an acid, distinct 'etch-figures' are produced, and the shape of these must be intimately related to the internal structure of the metal crystals. The figures vary in the most curious way when the solvent is changed, as is shown by large single crystals of copper. The compounds of metals with one another have puzzled chemists, as they do not follow the ordinary rules of valency, and have many anomalous properties. The modern view of the constitution of the atom makes it possible to explain them, and the relations which have been found between the forces of cohesion and of chemical affinity make it likely that there is a gradual transition from the simplest solid compounds, such as salts, through intermetallic and other compounds, to solid solutions, which are regarded as mixtures. The chemical properties of crystals are most easily illustrated by substances which do not consist of closely packed atoms, but have an open structure, such as graphite. Looseness of structure is also important for diffusion in solids, on which many technical processes depend.

Dr. F. H. G. Van Loon, formerly professor of psychiatry and neurology in the Medical School of Batavia, read a paper on "Primitive Instinctive Reactions in Pathological and Normal Malay Life," at a meeting of the Eugenics Society held on May 4. Dr. Van Loon illustrated his paper by a kinematograph film of a case of latah, the curious Malay insanity in which the patient copies any movements made in front of her. The problem with which Dr. Van Loon dealt is of much wider interest. He has been studying mental differences in race, not through the well-known avenue of mental tests, but by means of the insane behaviour shown when the normal intelligence and control are thrown out of gear by disease. He compared amok and latah, for example, with manifestations of insanity such as those against which legislation has been enacted in England to allow a judge to prevent undue litigation by an insane person who is frequently bringing cases into court. Clearly there is a wide distinction between such 'reasoning' madness and a more primitive and animal-like reaction, for running amok corresponds very definitely to the behaviour of some animals acting under the instinct of extreme fear; the hallucinations which are the first symptoms of amok are such as to induce terror. He also showed that these primitive and animal-like instincts come out in the white races when acting as a group. Mob psychology brings the group down to the primitive instincts which are rarely observed in the white individual; and a European or American mob, when it 'sees red'—virtually goes mad—behaves with all the primitive and brutal barbarity shown in the insane patients of primitive races. The obvious conclusion is that fundamental differences of race are of a hereditary nature.

A well-attended meeting was held, by permission of the Royal Society of Medicine, at 1 Wimpole Street, on May 2, for the purpose of furthering a scheme for founding in Oxford a science museum of instruments and exhibits to illustrate the history of science and medicine. Sir Humphry Rolleston, in taking the chair, spoke of the new life given to the famous museum of Elias Ashmole at Oxford by the splendid gift of the Lewis Evans historical collection. After referring to the whole-hearted support given to the scheme by the late Sir William Osler, he invited Dr. R. T. Gunther, to whose energy and enthusiasm is due the fact that the project is assuming practical shape, to give an account of ways and means.

Dr. Gunther remarked that Ashmole's Museum, opened in 1683, is the oldest natural history museum in Great Britain. The building was originally devoted partly to the exhibition of specimens and partly to the meetings of the Oxford Philosophical Society. The ground floor was furnished as the oldest public chemical laboratory in the country. The upper floor has now been recovered as a museum, but the remainder should surely be restored to something more resembling its original purpose than its present use as a book store. The meeting was addressed by Dr. Knobel speaking for astronomy, Dr. Calman for zoology, Prof. Gibson for pharmacology, Sir G. Fordham for cartography, and Prof. Boycott for medicine. Three resolutions in favour of establishing such a museum in the Old Ashmolean building, which already houses the Lewis Evans Collection and valuable supplementary exhibits, were carried unanimously. A further resolution, "That this meeting approves the formation of a society of 'Friends of the Old Ashmolean' for the purposes of assisting in the restoration of the Old Ashmolean building as a public *Ashmolean Museum of the History of Science* (comparable to the *Ashmolean Museum of Art and Archæology*), and for providing by means of annual subscriptions an income for the purchase of desirable objects of scientific interest for the Lewis Evans Collection," proposed by Sir D'Arcy Power and seconded by Dr. F. A. Dixey, was also carried unanimously.

ON May 4 the annual Romanes Lecture was delivered at Oxford to a large assembly by Prof. D. M. S. Watson, on "Palæontology and the Origin of Man." Prof. Watson pointed out that the minor periods of geological time are determined by palæontological remains. The changes produced by evolution tend generally to greater efficiency in relation to the mode of life. But though the general course of succession in any given group is often beyond question, the actual line of descent remains frequently in doubt. Pithecanthropus had bony superciliary ridges and a very small brain; Piltdown man (Eoanthropus) had an ape-like lower jaw, but slight brow-ridges; the brain was still small. The Heidelberg jaw was man-like. Neanderthal man had strongly developed ridges, and so had the Rhodesian skull, though it differed in other respects. The course of human evolution is thus uncertain. Prof. Watson said that Dryopithecus is probably in the line of human ancestry, but evolution has doubtless proceeded on greatly divergent lines. Many of these have depended on mental development, that is, on the arrangement of molecules in the nervous system; and so have transcended the province of the palæontologist, whose business is only with the obvious morphological facts.

MR. ROLLO APPLEYARD gives a complete account, in the *Electrical Review* for April 27, of the Penzance cable station of the Western Union Telegraph Co. This is the first time that a full description has been published of a submarine cable station fully equipped with modern types of amplifying and repeating apparatus. It is of great interest at the present time in connexion with the competition between radio and cable companies. The main cables of the Western Union Telegraph Co. are divided into two groups, one ending in Valentia and the other at Penzance. The introduction of cables sheathed with permalloy has enormously increased the speed of working. Every cable in the Company's Atlantic system is a link in one of nine through routes. All the manual work of the cables is done at terminal stations such as London or Liverpool and New York or Boston. The whole of the intermediate relaying is now automatic. There is no possibility of accumulation of traffic anywhere except at the terminal stations. The introduction of through working has greatly increased the accuracy and speed of transmission. The limit of manual working used to be about 150 letters per minute. Now a loaded cable having four channels works normally at 1300 letters per minute with much higher accuracy. It is interesting to remember that progress in cable design began by reducing the electrostatic capacity. The loading of cables with induction coils was then suggested, and finally the discovery of permalloy made uniform loading possible. At the present moment the Company is experimenting with modified loading to see if duplex working, which would double the speed, is possible. Unfortunately, trans-Atlantic telephony by submarine cable is not yet in sight.

DR. W. R. BROWNE, assistant professor in the Department of Geology and Physical Geography of the University of Sydney, has been elected president of the Linnean Society of New South Wales.

THE George Darwin Lecture will be delivered by Mr. W. H. Wright, of the Lick Observatory, at the ordinary meeting of the Royal Astronomical Society on June 8. The subject of the lecture will be "The Photography of Planets."

SIR FRANK DYSON, Astronomer Royal, will deliver his presidential address to the Institute of Physics at 4.30 P.M. on May 15, taking as his subject "Physics in Astronomy." The address will be given in the rooms of the Institute at 1 Lowther Gardens, Exhibition Road, South Kensington, London, S.W.7.

THE following have been elected honorary members of the Institution of Civil Engineers: His Royal Highness The Duke of York, Sir Alexander B. W. Kennedy, the Right Hon. H. P. Macmillan (Lord Advocate of Scotland), Mr. Samuel Rea, (Pennsylvania, U.S.A.), Sir Ernest Rutherford, and the Right Hon. Lord Wemyss.

THE Linnean Gold Medal for 1928 has been awarded by the Linnean Society to Dr. Edmund Beecher Wilson, Da Costa professor of zoology in Columbia University, New York, and a distinguished worker in the fields of animal embryology and cytology. Prof. Wilson's early work dealt with descriptive embryology; in the 'nineties, he took a great part in founding the new science of experimental embryology, and many of his experiments, especially those on *Amphioxus*, *Nereis*, *Patella*, and *Dentalium*, remain classical. He is known to a world-wide circle as the author of that admirable text-book "The Cell in Development and Heredity." First published in 1896, a greatly enlarged third edition appeared in 1925 (reviewed in these columns on May 9, 1925,

p. 669). It is a model of what a text-book should be—encyclopædic, trustworthy, and judicial—and shows the hand of a master.

Prof. G. W. Ritchey will deliver the Thomas Young Oration to the Optical Society on Wednesday, May 16. The subject of his address will be "The Modern Reflecting Telescope." Prof. Ritchey will give an account of his experience in making and using the great telescopes of Yerkes and Mount Wilson Observatories, and of the new cellular mirrors. The meeting will be held at the Imperial College of Science and Technology, South Kensington, commencing at 7.30 p.m., and will be open to all who are interested in this subject. Tickets will not be required.

The Council of the Institution of Civil Engineers has made the following awards in respect of papers read and discussed at the ordinary meetings during the session 1927–28:—Telford Gold Medals to Dr. Oscar Faber (London) and Mr. G. L. Watson (Newark, New Jersey). Telford Premiums to Prof. John Goodman (Skipton); Mr. James Williamson (Wallington); Mr. R. M. Wynne-Edwards (Vancouver); and jointly to Mr. F. C. Vokes (Birmingham) and Mr. C. B. Townend (Birmingham).

The Rockefeller Medical Fellowships for the academic year 1928–29 will shortly be awarded by the Medical Research Council, and applications should be lodged with the Council not later than June 1, 1928. These Fellowships are provided from a fund with which the Medical Research Council has been entrusted by the Rockefeller Foundation. Fellowships are awarded by the Council, in accordance with the desire of the Foundation, to graduates who have had some training in research work in the primary sciences of medicine or in clinical medicine or surgery, and are likely to profit by a period of work at a university or other chosen centre in the United States before taking up positions for higher teaching or research in the British Isles. A Fellowship will have the value of not less than £350 a year for a single fellow, with extra allowance for a married fellow, payable monthly in advance. Travelling expenses and some other allowances will be made in addition. Full particulars and forms of application are obtainable from the Secretary, Medical Research Council, 15 York Buildings, Adelphi, London, W.C.2.

At the annual meeting of the members of the Royal Institution, held on May 1, the annual report of the committee of visitors for the year 1927, testifying to the continued prosperity and efficient management of the Institution, was read and adopted. The report of the Davy Faraday Research Laboratory committee was also read. The following were unanimously elected as officers for the ensuing year:—*President*, The Duke of Northumberland; *Treasurer*, Sir Arthur Keith; *Secretary*, Sir Robert Robertson. *Managers*, Lord Blanesburgh, Sir James Crichton-Browne, Dr. J. Mitchell Bruce, Mr. A. Carpmael, Prof. F. G. Donnan, Sir James Dundas-Grant, Viscount Falmouth, Sir Robert Hadfield, Mr. J. S. Highfield, Mr. W. E. L. Johnston, Sir Henry Lyons, Mr. C. H. Merz, Mr. S. W. A. Noble, Sir Richard Paget, and Dr. G. C. Simpson. *Visitors*, Prof. E. N. da C. Andrade, Mr. A. Glegg, Commdr. A. C. Goolden, Mr. W. Vaux Graham, Mr. K. R. Hay, Sir Lawrence Jones, Dr. V. W. Low, Mr. W. Macnab, Mr. E. S. Mond, Dr. W. A. Milligan, Dr. C. C. Paterson, Dr. E. H. Rayner, Mr. H. M. Ross, Mr. S. Skinner and Mr. W. J. Tennant.

A large earthquake was recorded at Kew Observatory on May 2 at 21 hr. 59 min. 42 sec. G.M.T. The epicentre is estimated to have been 1620 miles away and probably in the Grecian Archipelago. The intensity of the disturbance was about one-half of that produced by the earthquake which occurred in the same region on Mar. 31 and caused destruction at Smyrna.

A new enterprise on the part of the Ordnance Survey is announced in *Geography* (Spring 1918), which consists in the reproduction of one-inch maps of the country originally published 1801–1830. The series which the survey is prepared to reprint covers England south of a line through Chelmsford, St. Albans, Oxford, and Stroud, and certain other sheets, including the Humber, Lincolnshire, the Wash, Pembrokeshire, and the Gower area. In most cases four sheets cover a county. If the demand justifies the printing of an edition of 100 or more copies of each sheet, the price will be 5*s.* a sheet. These maps should prove valuable to students of geography and economic history.

It is announced in *Science* that Dr. Henry Augustus Pilsbry, chief of the Department of Mollusca at the Academy of Natural Sciences of Philadelphia, has been awarded the Academy's Joseph Leidy Memorial Award for 1928 "in recognition of his researches on the phylogeny of the terrestrial mollusca, in which field he is universally regarded as a leading authority, and for his work on the classification of the Cirripedia which constitutes the most notable contribution to the subject in recent years." The award consists of a bronze medal and honorarium, given once in three years for outstanding work in the natural sciences. It was founded in 1923, and its first recipient, in 1925, was Dr. H. S. Jennings, of the Johns Hopkins University.

Sir John Rose Bradford contributes to the May issue of the *Nineteenth Century and After* an article on William Harvey, in which he gives an interesting account of the discovery of the circulation of the blood, of the state of medical knowledge at the time, and of Harvey's connexion with the Royal College of Physicians, London. In the coming week, the Royal College of Physicians will celebrate the tercentenary of the appearance of Harvey's "Exercitatio Anatomica de Motu Cordis et Sanguinis," which was published at Frankfurt in the spring of 1628 when its author was fifty years of age (see also Nature, Mar. 31, p. 507).

The twenty-third International Congress of Americanists will be held in New York City during the week beginning Sept. 17 next. An organising committee has been formed, of which Dr. Franz Boas is chairman, and Mr. P. E. Goddard, of the American Museum of Natural History, is secretary. The Congress will be divided into six sections, dealing with the ethnology of America, the archæology of America, the origin, distribution, and ethnography of the American Indian, native languages, the discovery and early history of America, and finally, geographical and geological questions with special reference to human activities. The titles of papers and abstracts for submission to the Congress should be in the hands of the secretary not later than June 1.

In spite of the advances in medical knowledge and practice, maternal mortality has continued at a high level, and has shown little tendency to decline. The subject is engaging the concern of the Ministry of Health, and in a circular (No. 517) issued in 1924, the attention of local authorities was directed to the importance of providing facilities for assistance in the diagnosis of puerperal fever and puerperal pyrexia, and for the treatment of patients who are unable to secure adequate treatment for themselves. In a further circular (No. 888) recently issued, the Minister of Health again directs attention to these necessary services, and expresses the hope that in all areas all maternal deaths will be investigated by a competent and experienced medical officer.

Applications are invited for the following appointments, on or before the dates mentioned:—A Paterson research scholar in the Cardiographic Department of the London Hospital—The House Governor, London Hospital, E.1 (May 15). A professor of philosophy in the Egyptian University, Cairo—The Director, Egyptian Educational Office, 39 Victoria Street, S.W.1 (May 22). An assistant lecturer in zoology and geology in the University College, Southampton—The Registrar, University College, Southampton (May 28). Research chemists at research establishments of the Department of Scientific and Industrial Research—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (May 28). A student probationer (zoologist, botanist, or physiologist) at the Marine Biological Laboratory, Plymouth—The Director, Marine Biological Laboratory, Plymouth (May 30). The Grote chair of philosophy of mind and logic at University College, London—The Academic Registrar, University of London, South Kensington, S.W.7 (June 14). The Sir William Dunn chair of pathology at Guy's Hospital Medical School—The Academic Registrar, University of London, South Kensington, S.W.7 (June 15). A temporary reader in organic chemistry in the University of Dacca, East Bengal—The Registrar, University of Dacca, East Bengal (June 26). An assistant lecturer in chemistry at the Battersea Polytechnic—The Principal, Battersea Polytechnic, S.W.11.

Our Astronomical Column.

Bright Meteor from Halley's Comet.—On the morning of May 6, at 1 h. 40 m. G.M.T., a meteor quite equal to Jupiter was seen by two observers at Bristol, and the flight was recorded from 317° − 1° to 187° + 10°, which is equal to about 125 degrees. Such a lengthy course is very seldom recorded for a meteor of any kind. The path recorded shows the radiant was probably at 337° − 4° and from the position computed for meteors from Halley's comet (May 4). There is little doubt, therefore, that this small fireball was a particle from the famous Halley's comet. Though the full moon was shining strongly at the moment the object appeared, the latter presented a fine spectacle as it occupied five seconds in its transit and threw off a bright trail of sparks. As viewed at more southern stations and from the English Channel, the meteor must have been a very conspicuous object, and it is hoped that some additional observations of its path will come to hand. This shower, discovered by Tupman in 1869–70, is specially interesting from its association with Halley's comet.

Cometary Spectra.—Mr. N. T. Bobrovnikoff has recently published several papers on this subject (*Astro. Jour.*, October and December 1927; *Pop. Astr.*, January 1928). Halley's comet showed marked changes of type during the apparition; when near the sun reflected sunlight predominated; at distance 1·2 from the sun, the violet type of spectrum due to inherent light predominated. A sudden change happened on May 24; the bands of CN IV disappeared, those of C + H became much weaker, those of C IV somewhat weaker. Barnard at the same time noted a swelling up of the nucleus. A note is made of the tendency of the head of this comet to repeat its behaviour at successive returns; many of the drawings made by Bessel in 1835 resembled phases seen in 1910; bright jets from the nucleus were also drawn in 1682 and 1759.

The comet Pons-Winnecke last summer exhibited the violet type of spectrum, which could be traced as far into the ultra-violet as in the case of Altair, which was in the same region of the sky. The bright knots of the spectrum of the head indicated the following diameters: C + H, 5000 km.; CN IV, 3600 km.; C IV, 3000 km.; continuous spectrum, 2000 km. A change in the spectrum occurred between June 10 and 19, CN IV being first brighter, then fainter than C + H. This was one of the first comets to be examined spectroscopically, by C. Wolf in 1869; he noted the three bands of the Swan spectrum.

The Einstein Deflexion of Light in the Eclipse of September 1922.—*Lick Observ. Bull.*, No. 397, contains the full discussion, by Prof. W. W. Campbell and R. J. Trumpler, of the photographic investigation undertaken in West Australia. The diagram gives very convincing evidence of the closeness with which the observed deflexions of star-places agree with those calculated on Einstein's law. A discussion follows as to the possible effect of abnormal terrestrial refraction owing to the fall of temperature during totality; it is convincingly shown that the effect would be very small compared with the observed shift. It is also shown that Courvoisier's yearly refraction could not be traced and was apparently not present. It may be pointed out that as some people are still unconvinced by the evidence, the Einstein effect is to be further investigated at next year's eclipse in Sumatra by Dr. Jackson and Mr. Melotte.

Research Items.

Pit River Indian Tribes, California.—An attempt to reconstruct the culture and distribution of Indian tribes of north-eastern California, before the coming of the whites, in field work carried out in 1926, is made by Mr. F. B. Kniffen in vol. 23, No. 5, of the *University of California Publications in American Archæology and Ethnology*. The Achomawi and Atsugewi were oriented around the Pit River in a region with a certain general unity of climate and resource which contained a series of semi-isolated habitable tracts. There were certain unifying factors in a common culture and a largely common language which encouraged trade, exchange of food privileges, and unity against a common foe. Even within groups, however, political unity was generally circumstantial rather than natural. The population was roughly in the neighbourhood of 3000. The Indian has now been pushed back to the rocky edges of the valleys or works for the white rancher. They once claimed as their own a vast territory extending from Mount Shasta and Goose Lake to the Madeline Plains and Mount Lassen on the south, and from the Warner Range on the east to Montgomery Creek on the west; but it was especially along the Pit River that the centres of attraction were found. The valley areas offered an amazing variety of animal and vegetable food, the vegetable being capable of being either consumed immediately or stored for winter. The Indians recognised eleven groups, each composed of those living on a single site or on several nearby sites, nine of them being collectively termed Achomawi in anthropological literature, though they had no collective name for themselves. The two Atsugewi groups differed from the Achomawi in language and, while friendly with some, were at enmity with others. The four western groups of Achomawi and the Atsuge buried their dead, built round winter houses, used dug-out canoes, possessed the full Californian acorn technique, owned food-tracts privately or by families, but recognised no chieftainship over the group as a whole. The five eastern groups and the Aporige cremated their dead, built their winter houses over rectangular or oval excavations, had no canoes or acorn complex, and recognised a group chief, but no private ownership of food-bearing tracts of land.

Model Houses over Graves in Oceania.—In *Man* for April, Mr. Patrick Buxton describes a burial custom followed in Nanomea in the Ellice Group, now that the older customs have died out owing to the introduction of Christianity. Formerly it was the practice to bury the dead in houses in the village. Now that burials take place in a cemetery, a small house is erected over the grave. The body is buried in the ground and white coral is strewn over the grave. Above this a small house is erected, the largest observed being about 5 ft. high and having a ridge-pole about 6 ft. long. Nothing quite like this has been recorded from any other part of Polynesia, although the erection of huts in the burying ground and the strewing of black and white pebbles over the grave have been noted. Mr. Buxton also records two remarkable rock-cut basins of unknown use and date from Tanna, New Hebrides. They are cut in two large masses of rock—a very soft red tuff—which have been roughly squared and faced. In each has been cut a basin. In one case the basin is circular, about 26 in. in diameter and 6 in. deep, with two overflows and circular depressions around the margin. In the other, the basin is rectangular, and about 26 in. by 9 in. long and 6 in. or 7 in. deep. Each held water. No similar objects have been recorded by any other visitor to the island.

Plumage and Sexual Development.—On many of the mud-flats of British estuaries, as well as on the sandbanks of Holland, groups of waders remain during the summer months, while their kin have departed for the arctic regions, to which the breeding range is confined. These laggards are generally regarded as young and immature birds, and yet although in the majority the plumage indicates immaturity, in a very small percentage of cases, the full summer plumage is apparent. Dr. G. J. van Oort, in order to investigate the possibility of correlation between coloration of plumage and development of the gonads, collected a number of the delayed birds during the summer months, and now reports upon the Knot and Turnstone (*Tijdsch. Ned. dierk. Vereen.*, p. 25; 1928). In the twenty-two examples examined, he found that in both species the testes of the majority were inactive, and that in such birds the plumage varied greatly, but that all possessed some feathers of the adult summer plumage. On the other hand, in the few individuals in which the testes were active and many spermatocytes had been formed, the plumage is identical, or nearly so, with the normal adult summer plumage. Dr. van Oort reaches the conclusion that the full summer plumage cannot develop unless spermatogenesis has started and many spermatocytes have been formed.

Drawings of Indian Fish.—Dr. Sundra Lal Hora (*Jour. As. Soc. Bengal*, vol. 22, pp. 93-125; 1926) states that in the library of the Asiatic Society of Bengal there are bound volumes of zoological drawings made by Mackenzie, Buchanan-Hamilton, and Lord in the early part of the nineteenth century. The volume of the manuscript drawings of Mackenzie at present contains 2 plates of pencil sketches and 55 plates of coloured drawings, although originally there were 65 plates. Among the twenty-six illustrations of fishes in this volume there are two of a globe fish from St. Thomé River, near Madras. It is probable that the globe fish referred to belongs to the genus *Kanduka*, recently described from the Ganges delta. It would appear that the Society came in possession of these manuscripts in December 1822. There are four volumes of Buchanan-Hamilton's drawings. It is suggested that the originals found their way to the India House and are the same in the main as the set described by Günther in *Zoological Records* for 1869, and that the drawings in Bengal are only replicas. In the first volume there are 22 plates of fish illustrations, representing 51 species, and the rest of the plates are of mammals; the second and third volumes are drawings of birds made by Mr. Gibbons; and the fourth are those of fishes, representing 150 species. Lord's manuscripts are those of fishes in the collection of Sir Alexander Burnes. There are 47 illustrations; of these 35 are of whole animals, 9 outline sketches showing the fish from above, and 3 of special parts. In the 'forties, efforts were made to publish these drawings with the author's notes, but unfortunately the notes were lost and the publication was not completed.

The Fall Army Worm.—Among the insect fauna of North America the Fall Army Worm (*Laphygma frugiciperda*) is of especial interest, since it is one of the few insects that frequently disperse and breed throughout the greater part of the United States, only to perish at the end of the season. It is only in the warmer parts of Florida and Texas that this insect remains a permanent resident, and it redistributes itself elsewhere through annual migrations of the moths. A very complete account of its biology and control is given in the *Technical Bulletin*, No. 34 (Feb. 1928) of the U.S. Dept. of Agriculture, written by Mr. P. Luginbill, of the Bureau of Entomology. The caterpillars feed upon a wide range of plants, but are more especially addicted to various grasses, and they rank as a pest of the first order. Periods of cool weather and rainfall favour the spread and multiplication of this species, while these same conditions are known to be deleterious to the multiplication of its natural enemies—notably predaceous and parasitic insects. The abundance or scarcity of these enemies determines to a very large extent whether or not there will be an outbreak of the Fall Army Worm in a particular season: local outbreaks are often checked entirely by such natural agencies. In view of the importance of this aspect of the economy of the Army Worm, a very full and interesting account is given of the relationship between it and its parasites and hyperparasites.

VEGETATIVE PROPAGATION BY SEED.—In *Science*, vol. 62, No. 1733, Dr. Chas. F. Swingle directs attention to an account of four apple seedlings (variety, Transparent de Croncels) which have developed from unfertilised ovules of emasculated and bagged flowers to the bearing stage. The apparent identity of these plants with the seed-mother tree, together with the results of Kobel's cytological studies, seems to warrant the conclusion that under certain conditions (not yet defined), unfertilised ovules of this variety of apple may set viable seeds, genetically constituting true vegetative reproduction. These results differ from the somewhat similar observations of Frost, that in *Citrus* the stimulus proceeding from fertilisation seems necessary for the production of such 'asexual' seeds. The importance of apogamic seeds as a possible means of obtaining uniform clonal rootstocks should at once be apparent. Although under the conditions of his experiments Kobel was unable to get a sufficiently high percentage of these apogamic seeds to make them a factor in the production of uniform rootstocks, still his results point to the desirability of continuing and extending such experiments with as many different varieties of apple under as many different conditions as possible, in the expectation that the complex of varietal and environmental conditions necessary for vegetative propagation by apogamic seeds will be discovered. (See also "Zytologische Untersuchungen an Prunoideen u. Pomoideen," *Archiv Julius Klaus-Stiftung f. Vererb., Soz., u. Rassenhygiene*, vol. 3, No. 1, 1-84, 1927. Zürich.)

'FALLEN STARS' OF THE BENGHAZI STEPPE.—In a note published in the *Atti della Pontificia Accademia delle Scienze* for 1927, D. Vito Zanon describes small globules resembling drops of resin found in the steppe to the south of Benghazi. These globules are mostly orange-yellow or brownish-red, but occasionally white outside, and are so hard that the blow of a hammer is necessary to break them. The interior has the yellow colour of the finest amber and is shining and glassy, with a conchoidal or sub-vitreous fracture. It was at first thought that this material, the Arab name for which signifies 'fallen star,' consisted of amber, but chemical analysis indicates the presence of albumin and, in the inner portion, of lecithin. The obvious inference is that the spherules are eggs, presumably of a small reptile, which have been prevented by the high temperature of the soil from putrefying or undergoing other changes except drying and slight external deformation. A curious feature observed is the inclusion in the material of large numbers of both fresh-water and marine diatoms of many different forms. These were doubtless wind-borne, and were imprisoned when the egg-substance had been rendered so spongy by the action of surrounding moisture as to become permeable to atmospheric dust.

WEED KILLERS AND GARDEN PATHS.—Results of weed killer trials on garden paths, in which the effectiveness of a number of chemicals was compared with that of several proprietary weed killers, are described by A. Hill in the *Scottish Journal of Agriculture* (vol. 11, p. 203). Although common salt, washing soda, iron sulphate, sulphuric acid, carbolic acid, and sheep dip all gave disappointing results, copper sulphate applied as a fine powder at the rate of 1 lb. per 100 sq. ft. proved entirely successful, a plot treated twice in June 1924 remaining free from weeds up to November 1927. Weather conditions, however, were of the greatest importance, the best results being obtained if the path was treated on a sunny day after rain, and fine weather followed the application. If heavy rain followed the treatment, the effectiveness of the dressing was greatly reduced. Various types of proprietary weed killers also gave good results provided several applications were made, but they were less effective than the copper sulphate, and further, if they contained arsenic, caused a blackening of the paths. A non-poisonous weed killer (1 per cent. solution) in which sodium chlorate was the active constituent, also proved useful provided dry weather followed the application, but, as is apt to occur with some other weed killers, there was a tendency later for the path to become covered with moss. Iron sulphate was decidedly better than copper sulphate or caustic soda for eradicating moss, though the latter is recommended for removing green growth from concrete paths in shady positions. For this purpose the alkali is applied as a powder and allowed to absorb moisture from the air; the path is then swept with a stiff brush and finally well flushed with water.

WHALING RESEARCH.—On April 2, at the Æolian Hall, London, Prof. A. C. Hardy lectured before the Royal Geographical Society on the work of the R.R.S. *Discovery* in the dependencies of the Falkland Islands. Prof. Hardy outlined the objects and scope of the *Discovery* Expedition, details of which have already appeared in our columns. It is evident that both the shore party and the staffs of the *Discovery* and the *William Scoresby* have collected a vast amount of material, and a considerable period of time must elapse before the actual results of their research will be available. Prof. Hardy, however, was able to give the broad conclusions of the results of an intensive plankton and hydrographic survey of the whaling grounds round South Georgia that are of extreme interest. The euphausians, which form the bulk of the food of the whale in that locality, were found to be concentrated on the north-east side of South Georgia; on the west side of the island was a very rich zone of diatom plankton, which encircled the island on either side some distance from the shore. The island is placed at right angles to the westerly drift of water coming from Drake's Straits, and Prof. Hardy indicated how this current would set round either side of the island to meet some distance behind it, leaving an area of 'dead' water on the north-east side. This current, striking the shelving bottom on the west of the island, would cause upwelling of phosphate-rich water which could support a heavy crop of diatom life; these diatoms would be carried round either end of the island, and by eddies into the sheltered water where the euphausians occurred. This dead water would thus form a sheltered nursery for the euphausians. The theory suggested fits well with the results of the phosphate analyses obtained. Work is still continuing at the shore station and in the *William Scoresby*.

Collisions Between Electrons and Molecules.—A big advance towards solution of the difficult problem of the motion of an electron projected towards a neutral molecule has been made by Dr. I. Langmuir and Mr. H. A. Jones in a long series of experiments carried out in the Research Laboratory of the General Electric Company at Schenectady. The simplicity of the apparatus employed, which was essentially a cylindrical thermionic tube containing a trace of gas, with the grid replaced by a space charge of positive ions, and a pair of auxiliary electrodes inserted, was in marked contrast to the heavy analysis involved in the reduction of the observations. Their main results are collected into three tables in the March number of the *Physical Review*. The first (p. 399) is a list of ionisation and resonance potentials for the gases used (mercury, neon, argon, helium, hydrogen, nitrogen); it is remarkable that the resonance potential important for the discharge is not necessarily the lowest excitation potential of the gas. The second (p. 402) gives the free paths for inelastic collisions of electrons with speeds equivalent to a number of potentials between 30 volts and 100 volts; these prove to be very close to the values calculated on kinetic theory from the viscosities of the gases. The third (p. 403) includes both data on the probability of various types of collisions and the average deflexion of an electron when it excites or ionises a molecule, and the maximum number of ions that can be produced by an electron with a specified initial velocity. The paper contains in addition considerable information about the groups of electrons which are present in an ionised gas, and confirms earlier records of the existence of several sets, each with a Maxwellian distribution of velocities.

The Green Auroral Line.—The recent *Bulletin of the American Physical Society* (No. 3 of the current volume) includes an abstract of a paper by J. Kaplan, in which it is stated that the spectrum of the afterglow of nitrogen which has been mixed with a few per cent. of oxygen shows only two of the lines of the latter in the visible region. One appears to be the auroral line, and the other is in the red at 6655 A. The absence of other lines due to oxygen, which is accompanied by a strong development of the alpha bands of nitrogen, indicates that the two which are present are produced in some very simple way (*v.* also NATURE, May 5, p. 711). The actual mechanism which is effective in the upper atmosphere is discussed by Dr. G. Cario in the April issue of the *Journal of the Franklin Institute*. He criticises Prof. McLennan's views, and offers the suggestion that the action occurs in two stages, in the first of which ultra-violet solar radiation induces a photochemical dissociation of molecular oxygen into atoms in a normal singlet state, whilst in the second the atoms are excited to the upper level of the green line transition. Dr. Cario states that he has experiments in progress designed to test this hypothesis.

Silver Nitrate Concentration Cells in Acetonitrile and Benzonitrile.—The Nernst formula for concentration cells, which has been confirmed for aqueous solutions, is known to hold for several non-aqueous solutions such as silver nitrate in ethyl alcohol. In the *Journal of the Chemical Society* for February, F. K. V. Koch gives measurements of electromotive forces which show that at 0° C. and 25° C., silver nitrate concentration cells in acetonitrile and benzonitrile also support this formula. These solutions appear to conform to the solution laws almost as nearly as aqueous solutions.

Effect of Catalysts on the Combustion of Carbon Dioxide and Oxygen.—In the *Journal of the Chemical Society* for February, W. E. Garner and C. H. Johnson describe a very interesting apparatus, which they have used to investigate the rate of emission of radiation, the duration and extent of ionisation, and the speed of flame during the explosion of carbon monoxide and oxygen mixtures. Various substances were employed as catalysts, and it was found that those containing hydrogen decrease the infra-red emission, but increase the flame speed and ionisation. Very small quantities of water vapour have a large effect upon the amount of energy radiated. The ionisation persists for a much longer period in the absence of hydrogen-containing substances, but does not appear to be due to 'after-burning,' since the extinction of flame and steady radiation coincide. With dry gases it is also possible to distinguish a combustion phase responsible for the emission of infra-red energy, and a second phase characterised by ionisation and the emission of visible radiation. It suggested that this luminescence may be due to the slow recombination of ions. These effects are most marked with mixtures containing small quantities of carbon tetrachloride, but disappear in the presence of hydrogen.

'Sunviray' Ultra-violet Lamp.—This small arc lamp, made by Messrs. Ajax, Ltd., for home use, which was described in NATURE of April 21, p. 641, has been greatly improved in design by the substitution of a rotary switch in place of the knife switch of earlier models. This eliminates the risk of a shock from the exposed electrodes at that point. It is regretted that in the previous description the lamp was incorrectly described as the 'Uviray'—the correct name is as given above. The arc is between cored carbons and will run on either D.C. or A.C. without change of adjustment.

Movements of the Heaviside Layer.—Experiments with radio waves have proved fairly satisfactorily that there is a refracting and reflecting layer (Heaviside layer) in the upper atmosphere. Experiments carried out by the engineers of the Bell Telephone Laboratories, New York, have shown that the radio signals received at a distance of 50 miles indicate quite clearly interference between rays probably refracted by this layer and those which come directly along the surface of the earth. The time interval between the interfering waves enables us to find the length of the path of the indirect waves. A study of the experimental results by R. A. Heising appears in the *Bell Laboratories Record* for February. He concludes that at night the apparent height of the refracting region varies between 150 and 400 miles. Since ultra-violet light from the sun produces free electrons at altitudes so low as 16 miles, the apparent height of the refracting region is much lower by day than by night. He concludes that the refracting region does not remain in a fixed position but moves up and down. He has observed a rise of six miles per minute and a fall of twenty-five miles per minute. The rapid movement of the refracting region at night appears to be the cause of the rapid fading of those waves which travel well during the night time. If the refracting layer were fixed and the frequency of the waves from the transmitting station fixed also, fading would not occur. Any transmitting station operating with variable frequency will probably produce bad quality reception at the receiving station if there is more than one transmission path between the two. The greatest care, therefore should be taken when designing a broadcast station to prevent variation of the carrier frequency during the course of an audio wave.

The Nature of Manual Dexterity and its Relation to Vocational Testing.

By Prof. T. H. PEAR, J. N. LANGDON, and EDNA M. YATES.

RECENT research to discover suitable tests of manual dexterity has concentrated upon two kinds, the sample or 'trade' test, and the 'analytic' test. The first kind explains itself; the second attempts to analyse the candidate's manual dexterity into simpler and, if possible, unitary dexterities. It then separately examines his capacities for them.[1]

To the immediately practical mind the sample test has advantages so obvious that it would appear foolish to supplant it. But the defects of its virtues are many. Though it measures a candidate's ability in the actual occupation for which he is wanted, it leaves quite undetermined a beginner's *capacity* for learning such a job; and ability is often acquired only at the expense of time and money. Except, therefore, for low-grade dexterities, the sample test will be useless for selecting those persons who, though they are not yet proficient in a particular job, are specially fitted for it. Furthermore, the risk of spoiling tools or machinery, and the physical danger in allowing potential failures to undertake complicated sample tests, are obvious.

Of these defects, the failure of the sample tests to discover capacity, as distinct from ability, is of chief psychological interest. For though such a failure must obviously occur with high-grade, complex skills, it is not certain that a sample test of low-grade dexterity, comprising only a few simple movements, would not test capacity.

Dissatisfaction with the sample test has encouraged attempts to discover simple or unitary capacities underlying more complicated forms of dexterity. Generally speaking, testing the simple muscular dexterities in the analytic procedure is far from simple, and requires a trained psychologist. This necessity, however, is admitted in many quarters. In Germany especially the analytic test is much in favour.[2]

Yet there is little evidence concerning the important question, whether the 'simple' factors which, after an analysis of any instance of muscular dexterity, are chosen to be tested, really compose that dexterity. While it seems that in a highly complicated skill the whole performance is not the mere sum of its parts, this seems less certain of a low-grade skill, which appears to be merely the simultaneous or successive combination of simple movements. For what is actually known concerning the functional interrelationships of the simpler motor capacities suggests that they are not so intimate as was formerly supposed. Perrin,[3] Muscio,[4] and the present writers[5] have found very low correlations between simple motor performances. The manner in which they are 'tied together' is not certainly known.[6] As Prof. Edward L. Thorndike has pointed out from the result of experiments, "We see the possibility of a disciplinary effect[7] where superficial observation would have expected none, the difficulty of transfer in a case where speculative and verbal thinking would have assumed that it was easy, and, in general the ignorance that we suffer from, concerning the internal constituents of almost every act of learning."

Obviously, therefore, in searching for a test of *capacity* for manual dexterity (low-grade skill) it is necessary to examine, in the light of any procurable evidence, the relative claims of the sample and analytic tests.

EXPERIMENTAL TESTS USED.

The investigation described below was carried out with the support of the Industrial Fatigue Research Board in the psychological laboratory of the University of Manchester. It concerned a simple instance of manual dexterity closely resembling an actual process in the chain-assembling industry. Its main aim was to discover whether there is any transfer of training acquired in one kind of dexterity, to another in which there has been no such training.[8] It offers evidence, however, bearing upon the validity of the 'analytic' procedure in the vocational testing of manual dexterity.

A group of 28 subjects was trained intensively for eight days on an operation in which links were removed from and others replaced on spindles, the handling of which involved the rotation of a turntable. Improvement in general was more than fifty per cent. of the initial score. Before training was commenced, the performance of each subject was measured in various tests designed to show the presence or absence of transfer. These tests were selected in accordance with an observational and introspective analysis of the operation with the links and spindles described above. It will be seen from the following that many of them are simple tests of manual dexterity and may be of some interest in connexion with vocational selection.

(1) *Match insertion.*—The match-insertion board used in psychological testing was employed. Matches were taken one at a time from a standard position and inserted in the small holes, the score being the number of matches inserted in a two-minute period.

(2) *Placing matches in a box.*—Thirty matches were arranged in a row on the table, and were picked up one at a time and placed neatly in a match-box. The score was the time taken.

(3) *Placing rings on a rod.*—The subject took rings, one at a time, from a bowl, and slipped them over a rod. The score was the number dealt with in two minutes.

These three tests were performed with right and left hands separately.

(4) *Steadiness.*—The apparatus is described in Whipple's "Manual of Mental and Physical Tests," vol. 1, p. 152. It is the usual tracing board, with a slit bounded by converging metal strips. Along one edge is mounted a millimetre scale. The subject was instructed to draw the stylus along the slit without making contact with the sides. At the first contact the subject stopped and repeated the process. This was repeated eleven times. The score in each case was the distance traversed before contact, and the final score was the median of these eleven.

(5) *Steadiness.*—The metal plate pierced with holes of different diameters, as described in Whipple's "Manual," was employed. The subject had to hold the stylus in each hole in turn for 15 seconds. The total time before contact was made was recorded, and the score was the median of 7 trials.

(6) *Arm movement.*—The blindfolded subject was required to make a movement of the arm, the extent

of which was measured by apparatus which precluded all save a rotary movement. He was then instructed to make another movement of the same extent as before. The score was the coefficient of variation of ten such trials.

(7) *Moede's impulse meter.*—The subject holds a hammer in his right hand and is instructed to strike a specially devised anvil. The force of the blow is measured on a scale. (An illustration is given in the apparatus catalogue of E. Zimmermann, Leipzig.) He is then told to strike the anvil again with just the same force as before. He repeats this ten times in all. Here again the score was the coefficient of variation.

(8) A group test of intelligence, No. 33 in the National Institute of Industrial Psychology's series.

PROVISION OF ADEQUATE INCENTIVES.

It is a valid criticism of many experiments upon the acquirement of skill that one is uncertain if the motives urging the learners to try their best are adequate. Since many of the tasks are very simple and may become monotonous, boring, or irksome, the stimulus is lacking which a recognised test of intelligence naturally offers to university undergraduates or graduates, who are the usual volunteer 'subjects' for such experiments.[9] The Industrial Fatigue Research Board made it possible to supply a financial motive for adequate performance; the subjects, unemployed boys aged fifteen to eighteen years, from the local Labour Exchange, were employed full time. They were paid a minimum wage of 12*s.* per week plus a piece-rate depending upon daily performance. A similar piece-rate was paid for success in the 8 tests described. The work therefore was to them extremely important. They were under close observation all the time. It is thus perfectly certain, both from their behaviour and from their own account of the work, that the incentive to try hard was adequate.

The correlations obtained between each of the tests and the abilities in the operation with the links and spindles at the end of 8 days' training will now be given. In addition, the scores of the first, second, and third periods of ten minutes' practice, and also the mean score per period of the first day's training, were correlated with the mean score per period of the last day's training.

The table shows that the supposedly analytic tests show little correlation with the practised operation. The coefficients are all lower than that between rank in the second period of ten minutes' practice and rank in the mean performance on the final day of training. The coefficient derived from the second period of ten minutes' practice when correlated with the practised operation is identical with that from the first day's practice when correlated with the operation. It is higher than that derived from the first period of 10 minutes' practice when correlated with the final practised ability in the operation with the links and spindles.

CONCLUSION.

In this investigation, involving simple manual dexterity or low-level skill of a kind similar to that required in industry, the present experimental results do not support the hypothesis of a close relation between the simple performances in the analytic tests and the more complex performance involved in the practised operation itself. This agrees with the major result of the investigation reported elsewhere, that there is no evidence for transfer of training from the practised operation to performances in the 'simple' tests.

Results pointing in a similar direction but obtained upon a smaller number of subjects have been recently published by Dr. Hans Kellner.[10]

If such results are further confirmed by experiment they would justify the use, as a selective test for an occupation at a *low* level of skill, of a sample 'try out' in the operation itself. But this would have to be done only after an initial trial had been given to secure adaptation to the experimental conditions. Even here it must be emphasised that the correlation between the second (adapted) performance and the final (practised) ability is very low.

CORRELATION WITH ABILITY IN THE OPERATION WITH THE LINKS AND SPINDLES AT END OF 8 DAYS' PRACTICE.

Test.	Correlation coefficient.	Probable error.
First 10-min. period in the operation with links and spindles	0·43	0·11
Second 10-min. period in the operation with links and spindles	0·57	0·09
Third 10-min. period in the operation with links and spindles	0·52	0·10
Mean score of first day in the operation with links and spindles (sixteen 10-min. periods)	0·57	0·09
Match insertion. R. hand	0·24	0·13
Match insertion. L. hand	0·24	0·13
Placing matches in box. R. hand	0·46	0·11
Placing matches in box. L. hand	0·16	0·13
Placing rings on rod. R. hand	0·30	0·12
Placing rings on rod. L. hand	0·28	0·12
Steadiness (1)	0·34	0·12
Steadiness (2)	0·06	0·13
Impulse meter	0·23	0·13
Arm movement	0·22	0·13
Intelligence	0·21	0·13

Despite this fact, however, a 'try-out' on the operation appears to be fairly useful in diagnosis. For in the present investigation, after a preliminary trial for adaptation, it was found that of those boys who were in the upper half of the distribution in the 'try-out,' 86 per cent. were in the upper half of the distribution on the last day of training.

The investigation also throws light upon another common and natural view not supported by the present figures. This opinion is that in selection for a performance involving low-grade skill, an error in the choice of operatives would not be serious.

In the present investigation, at the conclusion of the 8 days' training, the difference between the best and the worst performance was 126 links per period. There were 16 such periods per day. Therefore, even in this short working-day, between the best and the worst performance there was an average difference of more than 2000 links. In other words, the practised ability of the worst worker was only 64 per cent. of the best. This offers strong evidence of the need for selection even in occupations requiring a low degree of skill. The present figures favour the 'sample' as against the 'analytic procedure' for selecting operatives for such occupations.

Danish Plaice Investigations in the Baltic Sea.[1]

FOR many years the problem of how the stock of plaice in the Baltic Sea is recruited has occupied biologists of that region. Peterson's view, expressed in 1894 (*Report Danish Biol. Stat.*, **4**, p. 13) and again in 1906 (*Cons. Internat. Rap. et Proc. Verb.*, **5**), was that the numbers were renewed by immigration from the German coasts around Kiel Bay. A. C. Johansen came to the conclusion that the deep water of the Baltic itself was the real home of the O-group in the eastern Baltic, whilst Reibisch concluded that this was not sufficient to account for the renewal of the whole stock, and that an immigration of *adult* plaice took place from the Kattegat and the western Baltic.

As the result of a systematic investigation carried out in 1925, H. Blegvad, however, holds the view that the renewal of the stock of plaice is brought about by the appearance of *young stages* on the shores of the Baltic proper. The supply from this source is erratic. He shows that the temperature and salinity of the bottom water during the early months of the year exhibit a distinct correlation with the numbers of the fry which are able to become established. When the temperature and salinity were relatively high during this period, a favourable fry year resulted, as, for example, in 1923 and 1925, whereas 1922 and 1924 (with the reverse conditions) were bad years.

A. C. Johansen goes into this matter more thoroughly, but deals with the adjacent waters of the southern Cattegat and the Belt Sea. A similar correlation is observable here also. The question then arises, Is this influence direct or indirect? Johansen is inclined to believe that it is mainly indirect, and that the paucity of young plaice in certain years is due to the presence of comparatively fresh water, deficient in plankton, which flows out from the Baltic during the winter months. If this hypothesis should be further confirmed, he suggests that a forecast of the yield in any particular year will be obtained most cheaply and easily by estimating the plankton in those waters and not by fishing for the young. The need for a solution of this problem is becoming more and more urgent on account of the very large increase in the intensity of fishing in the Baltic which has come about in recent years. Thus, although the Danish catch in 1917 was only 31,485 kgm., in 1924 it reached 2,909,011 kgm.

Blegvad; Studies on the Biology of the Oyster (*Ostrea edulis*), II-IV, by R. Spärck. Edited by Dr. A. C. Johansen. Pp. 65. (Copenhagen: G. E. C. Gad, 1927.)

University and Educational Intelligence.

CAMBRIDGE.—Mr. F. E. Baxandall and Mr. C. P. Butler have been reappointed as senior observers, and Mr. W. Moss as junior observer, at the Solar Physics Observatory, and Mr. H. E. Green has been reappointed as assistant observer at the Observatory.

LONDON.—A public lecture will be delivered at the East London College, Mile End Road, E.1, at 5 o'clock on Wednesday, May 16, by Dr. W. A. Goddyn, of the Rijks Herbarium, Leyden, on "Lotsy's Hybridisation Theory, demonstrated on South African Material."

Prof. Ross G. Harrison, of Yale University, will deliver a lecture on Monday, May 21, at 5.30 P.M., at University College. The subject of the lecture will be "Modern Trends in the Study of Animal Development."

ST. ANDREWS.—An additional lectureship in philosophy has been instituted, and the University Court has resolved to appoint to this lectureship Mr. A. R. Knight, of the Institute of Industrial Psychology, London. The work of the new lecturer will be principally in the Department of Psychology and Experimental Psychology. The Court has appointed Dr. F. Bath, formerly of King's College, London, as lecturer in mathematics in the University and assistant to the professor of mathematics in University College, Dundee.

VACATION courses for teachers and students in England and Wales, arranged for the year 1928, differ but slightly from those of last year. The list issued by the Board of Education (H.M. Stationery Office, pp. 23, price 6*d.*) shows among those arranged by the Board several courses for teachers of science: in rural science, botany, and biology (but not, this year, in laboratory arts) at Cambridge, in physical chemistry and engineering at Oxford, and in physics at Harrow. Courses for foreigners have been organised by the University of London, by University College, London, by the University of Oxford, and by University College, Exeter. Among the subjects of the twelve courses arranged by university bodies in connexion with the work of the Workers' Educational Association, economics, literature, history, and psychology figure in all or almost all cases: natural science, generally biology, in five. In the list of courses organised by associations, the Association for the Provision of Science and Specialist Teaching finds no place this year: nor does the Dalton Association.

ADULT education in America is developing rapidly. Some account of its recent growth is given in *Bulletins 18* and *21* of 1927 of the United States Bureau of Education, entitled "Public Education of Adults in the years 1924–1926" and "Public Evening Schools for Adults." Some of the activities described are concerned with attempts to promote by means of what used to be called 'Americanisation classes' the elementary education of illiterates. In such classes, organised by State departments of education, 315,000 students were enrolled in 1925–26. In public evening schools in cities of 10,000 or more inhabitants the enrolment was, in 1924, nearly a million. The most remarkable achievement in popularising such education is that of Gary, Indiana, where more than 12,000 men and women—one-sixth of the adult population—attend courses provided in the public schools. The total budget for evening schools, as reported by 412 towns, exceeded five million dollars, being at the rate of 15 dollars per student. Extension courses offered by colleges and universities are very various and are constantly assuming new forms. 'Radio talks' are increasingly used, and more and more institutions are installing, or procuring the use of, broadcasting plants and employing them in connexion with correspondence courses. So striking are the signs of growth of the adult education movement that the Bureau of Education's specialist in this subject anticipates developments during the second quarter of the century that will match the marvellous growth in the field of secondary education in the first quarter. A similar belief in a coming great revival in Great Britain was expressed by Prof. Robert Peers, of University College, Nottingham, in a public lecture on adult education delivered by him at King's College, London, some time ago.

Calendar of Customs and Festivals.

May 14.

St. Machudda or St. Cartagh (A.D. 637), one of the most noted of Irish saints, of whom many legendary stories are told. A celestial fire descended on his mother before his birth. As happened with many Irish saints, there was a lack of water at his baptism; but a spring burst from the ground for the office and flows to this day. Many miraculous acts are attributed to him, such as turning water into milk, and causing an apple tree to spring from the ground and bear fruit forthwith in a trial of strength with a pagan, Magus.

May 15.

St. Dymphna.—Seventh century. One of the most famous of medical saints, invoked in cases of possession, epilepsy, and lunacy, at Gheal, N. Brabant. She was the daughter of an Irish king who, inconsolable at the death of his wife, sought his daughter in marriage, and when she escaped to Gheal, followed and killed her. On May 15 her relics are carried in procession, followed by all the inhabitants and the lunatics, and on each day of the octave the lunatics, and those who seek the intercession of the saint for their friends and relatives, crawl around her shrine on all fours.

St. Caesarea.—Date uncertain. An Italian saint from the neighbourhood of Otranto who, when persecuted by her father in the same manner as St. Dymphna, took refuge in a cave which opened in the cliff and closed again behind her. On Ascension Day and through the octave the cave opens and the saint is seen seated, while rays of light shoot forth from the cave. During the same period the people of the neighbourhood fetch water from a medicinal spring in a cave of St. Caesarea near by.

May 16.

St. Carantog.—Sixth century. Son of a Prince of Cardigan. When the saint was conveying across the Severn a magnificent altar of stone sent by Christ from Heaven for a chapel which he had founded under the guidance of a dove, it was lost overboard. Confident that God would cast it up on the shore, he appealed to King Arthur for it to be restored to him. Arthur had intended to convert the altar into a table for himself and his knights, but returned it to the saint on his fulfilling the condition that he should capture a serpent which was devastating the Carr, a marshland district in Wales.

May 14-16. Rogation Days.

May 17. Ascension Day.

By the first Council of Orleans in the sixth century, it was enjoined upon the whole Church that the Rogation Days, previously only a preparation for Ascension Day, should have joined to them supplication for a blessing on the fruits of the earth. Rogation Week was also known popularly by the names of Cross Week, from the bearing of the Cross in procession, Grass Week, from the abstinences observed, such as salads, etc., being substituted for flesh, and Gang or Procession Week, from the perambulations for the purpose of blessing the fields. With this is associated the practice of making the circuit of the parish, otherwise "Beating the Bounds," and a curse on whomsoever moved a boundary was part of the Rogation Service.

As a popular custom, the civil purpose of fixing the bounds has overshadowed the religious side of the observance. In London the closing of the gates of the Temple to general traffic on Ascension Day is an affirmation of the boundaries which is more conspicuously observed in the formal procession of dignitaries to beat the bounds of the adjacent parish of St. Clement Danes. It is usual for the processions to be accompanied by boys carrying willow wands or staves. At Lichfield they bore green boughs, while at Wolverhampton children bore long poles decked with flowers. On Ascension Day at Nantwich, a hymn blessing the Brine was sung. An ancient pit called the Old Brine was decked annually with garlands. In Derbyshire, at Terrington, Ascension Day was observed as a holiday, and the five wells were elaborately dressed with flowers and overhung with boughs: the wells were visited in procession after services in church, and a hymn or psalm sung at each.

In many localities cakes and ale were provided for those taking part in the procession, while various devices were followed to impress the boundaries on the people, especially the boys. Sometimes a boy's head was bumped on a boundary stone; in Dorset someone was ducked in a brook, while at Exeter boys dammed streams in the streets and splashed passers-by with the water. At Wolverhampton 'gospel trees' marked the boundaries, and at Stanlake the gospel was read on a barrel-head in a cellar in the Chequer Inn, reported once to have been a hermitage or the site of a cross. About Keston and Wickham, in Kent, a number of young men used to assemble together and, making a hideous noise, run into the orchards, circling each tree and reciting a verse calling on God to send "Every twig, apple big, every bough apples now." For this "Youling" they expected a gratuity of money or drink.

The circling movement is important in many, especially of the more primitive, boundary observances. In the elevation of the Ceri at Gubbio each Cero circles three times before the specially favoured houses it visits, and in some of the observances of southern India the priest or officiant circles three times around the boundary stone. Apart from the act of circumambulation, the striking features of the custom in England, which connect it with primitive observance, are its essentially religious character, the meal of which the members partake, the carrying of an emblem of vegetation, and the marking of the boundary by some process painful to the individual, undoubtedly a remembrance of human sacrifice.

A suggested origin in the *Terminalia* or the *Arvalia* of ancient Rome must be referred to still earlier practice—the casting out of evil and the renewal of the benign magical influence of the deity. Hence at the festival of the goddess Mariamma in South India, the entrails of a sacrificed sheep are hung around the neck of a naked man of the scavenger class, who perambulates the boundaries, clearly representing both god and victim. The Tamils offer blood and rice on the boundary stones to renew the divine influence. Hence also the elaborate processions of the temple cars on special occasions. With these last must be compared the processions of the *alberi* and the *carrocci*, the poles and cars, which take place in a number of the Italian towns; and the elevation of S. Ubaldo, S. Antonio, and S. Georgio on the Ceri at Gubbio on May 15, the vigil of the first named, of which the elaborate ceremonial may possibly go back to the ritual prescribed in the Eugubine Tablets of Roman times, still preserved in the town. The similar processions of giants such as those at Lille, Bruges, and elsewhere, and recorded as having taken place in England until modern times, it has been suggested by Sir James Frazer, are to be derived from a practice such as the Druidical sacrifice of human beings in a wicker framework.

Societies and Academies.

LONDON.

Geological Society, April 18.—**G. H. Mitchell**: The succession and structure of the Borrowdale Volcanic Series in Troutbeck, Kentmere, and the Western Part of Long Sleddale (Westmorland). The area lies in the eastern part of the Lake District south of the High Street range. It is drained by the Rivers Sprint, Kent, and Trout Beck, all of which flow in a southward direction. Nine subdivisions are recognised in the rocks described. They have been subjected to severe earth movements. Two systems of folding are recognised, an earlier one of pre-Bala age and a later one of Devonian age. The former system, of simple character, shows axes trending in a north-north-easterly and south-south-westerly direction. In the latter the folding was intense, with an east-north-easterly and west-south-westerly strike, while the pitch of the folds was determined by the folds of pre-Bala date. The rocks are steeply folded in the south-east of the area, and the folds are even overturned to the north. Northwards the folding is less severe, and is marked by the presence of a broad anticlinal fold. No faulting of earlier date has been recognised. The rocks are strongly cleaved, the strike of the cleavage coinciding with that of the Devonian folding.—**L. J. Chubb**: The geology of the Marquesas Islands (Central Pacific). The Marquesas Islands, with one doubtful exception, are of volcanic origin. The southernmost, Fatu Hiva, consists of a caldera composed chiefly of lava-flows, within which an ash-cone has been built up. The western half of the whole structure has disappeared, apparently owing to submergence by faulting. Motáne is a small ash island. Tahuata is larger, and it also is composed chiefly of ashes in its northern part; its south-eastern side has been faulted down. In Hiva Oa there are three great craters in the western part, some of the coasts are faulted, and there is an elevated plateau at a height of 1300 to 1500 feet above sea-level. Nuka Hiva has a structure similar to that of Fatu Hiva, and it bears a plateau at an elevation of 2600 feet. It is considered that the group is situated, not on a crustal fold, but on a system of intersecting fissures. Elevation has occurred followed by subsidence. All the islands are surrounded by a shore-shelf, now standing, owing to a recent fall in sea-level, 3 or 4 feet above high-water mark. The poor development of coral-reefs in the group is due chiefly to periodic chilling of the water by extensions of the cold Peruvian Current, connected with cyclic climatic changes.

Linnean Society, April 19.—**R. D'O. Good**: The geography of the Sino-Himalayan genus *Cremanthodium* (Compositæ). The range of *Cremanthodium* is roughly within the triangle made by joining the Indus valley where it enters the N.W. Frontier Province, Lake Koko Nor in Kansu, and Lake Tali-fu in Yunnan. This total area is divisible into three main topographic regions—the western or Himalayan mountains, the eastern or western Chinese mountains, and the plateaux of Tibet. A statistical study of the distribution of the species shows that: (1) 14 species are found in both western and eastern mountains. (2) 4 species are found only in the Himalayan mountains (all in the eastern half of the range). (3) 30 species are found only in the Chinese mountains (almost all in the southern half). (4) The greatest concentration of species is in Yunnan. (5) Only two or three species extend on to the Tibetan plateaux. The present areas of greatest species population in the genus are within the zone of very high monsoon precipitation, but this distribution results largely from the configuration of the mountains, and the elevation of the Himalayas has probably caused the progressive desiccation of the northern mountains of western China.—**F. O. Bower**: The size-factor in plant morphology, with special reference to the stele. Physiological interchange is conducted through limiting surfaces, external or internal, and it may be assumed that, provided the surface be unbroken, such interchange will be proportional to the area of the surface involved. Accordingly, in an enlarging body, if the original form be retained, a practicable size-limit will ultimately be reached. In the ordinary vascular plant there are three important limiting tissue-surfaces: (i.) the outer contour; (ii.) the endodermal sheath, which delimits the primary conducting tracts from the enveloping tissues; (iii.) the collective surface by which the dead tracheal system faces upon the living tissues that embed it. The present discussion deals only with (ii.) and (iii.), and all secondary or cambial developments are left out of consideration. The common form of axis in primitive plants is conical, enlarging upwards; and the conducting system enlarges with the axis. Thus it will constantly be called upon to meet a diminishing proportion of surface to bulk. This is carried out chiefly by: (*a*) penetration of the primitively solid tracheidal tract by living cells, or replacement of those that are central by parenchyma; (*b*) its enlargement of surface by fluting, or segregation into parts; (*c*) involution of the endodermis, which is apt to follow the changes in the tracheidal tract, but does not always do so. Comparison of various plants shows that the stele may react to the size-factor independently of the insertion of appendages. This is seen in marked degree in roots; it is also evident in aphyllous and microphyllous forms, but where the appendages are large these exercise a correspondingly great influence upon the stelar development.

DUBLIN.

Royal Irish Academy, April 23.—**Thomas J. Nolan** and **Michael T. Casey**: The nature of the pigment of the elder berry (Part 1). The anthocyan pigment of the elder berry has been isolated as the chloride in the form of a powder with strong bronze reflex showing a pattern between crossed Nicols. The picrate is a brick-red product crystallising in flat prisms. The anthocyan chloride is readily soluble in water and in hydrochloric acid of various strengths. From the chloride, by hydrolysis with strong hydrochloric acid, the colour base chloride has been obtained in the form of prisms with rounded ends. The product contains no methoxyl groups and resembles delphinidin closely in its colour reactions with alkalis and with ferric chloride, its ease of isomerisation, its power to reduce Fehling's solution, and its difficultly soluble picrate. Direct comparison with a sample of delphinidin chloride, however, shows that it differs markedly from the latter in its reactions towards water and 10 per cent. hydrochloric acid, the elder berry anthocyanidin chloride being practically insoluble in water.

PARIS.

Academy of Sciences, April 2.—**Gabriel Bertrand** and **Georges Nitzberg**: The preparation, by the sorbose bacterium, of a new reducing sugar containing seven atoms of carbon. α-glucoheptite can be oxidised under the influence of the sorbose bacterium into a new reducing sugar with the formula $C_7H_{14}O_7$, α-glucoheptulose. It is probably ketonic, and further experiments regarding its constitution are in progress.—**Constant Lurquin**: The statistical analysis of successive differences of deviations.—**Georges Calugaréano**: Polygene functions of a complex variable.—**Henri Milloux**: Some properties of the roots of meromorph functions.—**Georges Valiron**: Some properties of meromorph functions.—**S. Mandelbrojt**: A fundamental point in the theory of the series of Dirichlet.—**Portevin**: The determination of the internal strains in circular metallic cylinders.—**Pierre Salet**: The errors due to the personal equation in observations of the angular position of double stars. Reply to a criticism of the prism method by de Glasenapp.—**Albert Nodon**: Relation between the regular oscillations of terrestrial electric and magnetic fields and the diametral solar foci.—**E. Kogbetliantz**: The velocity of propagation of attraction. A laboratory experiment is suggested which would be capable of measuring the velocity of propagation of the Newtonian attraction, if it is comparable with the velocity of light.—**Conti, de la Ville le Roulx, and Coret**: The selection of communications of departure and arrival in telephonic networks with a central battery.—**Pierre Jolibois, Henri Lefebvre, and Pierre Montagne**: The reversibility of a reaction produced by a spark or by the electric current. Starting either with carbon dioxide or a mixture of carbon monoxide and oxygen under suitable pressures, after sparking for some time the same equilibrium was reached, about 74 per cent. of the mixture remaining uncombined.—**P. Laffitte**: The influence of the temperature on the formation of the explosive wave. A description of experiments carried out with mixtures of hydrogen and oxygen and of methane and oxygen, the temperature of explosion varying from 15° C. to 350° C. The results clearly prove that the elevation of the initial temperature of a gaseous combustible mixture retards the formation of the explosive wave.—**A. Seyewetz and D. Mounier**: The action of light on diazo-compounds. The amount of nitrogen gas evolved was taken as measuring the effect of exposure to ultra-violet light. With diazo-sulphonilic acid, the gas evolved was proportional to the time of exposure. In acid solutions (*p*H less than 7), the diazo compounds examined were very sensitive to light; in alkaline solution (*p*H above 7), the light effect was much reduced. With rise of temperature, the sensibility is greatest in alkaline solution and reduced in acid solution.—**Marcel Godchot and Mlle. G. Cauquil**: Molecular transposition in the cycloheptane series. Phenyl-magnesium bromide reacts with *a*-chlorocycloheptanol giving phenyl-cyclohexyl carbinol, $C_6H_{11}\cdot CH(OH)\cdot C_6H_5$. The probable mechanism of the change from a seven-carbon ring to a six-carbon ring is discussed.—**J. Bougault and J. Leboucq**: The 1 and 2 substituted semicarbazides. 1-Benzylsemicarbazide and 2-benzylsemicarbazide.—**P. Teilhard de Chardin**: The nature and the succession of the post-palæozoic eruptions in northern China.—**M. Baudouin and Morel**: A unique case of palæopathology. An arrow-point in a human dorsal vertebra. In a cave at Sainte-Énimie (Lozère), amongst bones of the neolithic period, two were of special interest. One shows clear indications of chronic osteo-arthritis, the other an entire vertebra in which a flint arrow-head is firmly imbedded.—**Const. A. Kténas and P. Kokkoros**: The phases of the parasitic eruption of Fouqué-Haméri (Santorin) in 1928.—**P. L. Mercanton**: Nocturnal radiation at Lausanne.—**H. Chermezon**: The ensiform leaves of some Cyperaceæ.—**Paul Chabanaud**: The urohyal of some fishes of the Solea family.—**Raymond-Hamet**: The pseudo-non-excitability of the cardiac pneumogastric produced by uzarine and by extract of uzara.—**Léon Binet and René Fabre**: Variations of the amount of uric acid in the blood according to the state of the respiratory function: hyperuricæmia due to asphyxia. Mechanical asphyxia in the dog determines a marked increase in the proportion of uric acid present in the blood. The effect is temporary, and the uric acid assumes its original figure fifteen minutes after restoring normal respiration. The removal of the spleen does not affect the phenomenon.—**Mme. M. Phisalix and F. Pasteur**: Ultra-violet rays destroy the rabicidal power of the venom of *Vipera aspis*.—**R. Douris and J. Beck**: The action of mineral colloids on normal and syphilitic blood sera. In place of the unstable colloidal reagents employed in the serum diagnosis of syphilis by precipitation, the use is suggested of colloids of constant chemical composition and possessing the same physical state. The colloid reagent (sulphur, sulphides, etc.) are produced in the liquid under examination by a chemical reaction. Silicic acid has given the best results.—**Fauré-Fremiet and Mlle. Choucroun**: The measurement of the thickness of thin protoplasmic plates.

Brussels.

Royal Academy of Belgium, Jan. 7.—**A. de Hemptinne**: Hydrogen activated by the electric discharge. Under certain conditions the chemical activity of non-ionised activated hydrogen can be demonstrated. The effects produced depend partly on the state of the body on which it is acting.—**J. Verhaeghe**: The arc spectrum of uraninite from Kasolo (Belgian Congo). An attempt was made to strike an arc between electrodes of the mineral instead of the usual carbon electrodes, but a background of continuous spectrum rendered exact measurement of the lines impossible. The secondary minerals were freely soluble in hydrochloric acid, and the chlorides thus obtained were introduced into the arc. A tabular statement of the lines measured is given. Elements not previously shown by chemical analysis include titanium, iridium, vanadium, thorium, and tungsten.—**L. Godeaux**: The asymptotic lines of a surface and ruled space.—**Constant Lurquin**: The methods of calculation of the mean deviations of probability.—**P. Swings**: Some formal analogies between certain orbits.

Rome.

Royal National Academy of the Lincei, Feb. 5.—**F. Severi**: Simple and double algebraic integrals (4).—**U. Cisotti**: The rotor of tensors.—**G. Scorza**: Major determination of the intercedent relation between the row and the type of a group.—**G. Giorgi**: The functions of matrices.—**C. Somigliana**: The definition of normal gravity.—**N. Parravano and G. Malquori**: Equilibrium of the reduction of tungsten disulphide by means of hydrogen. The equilibrium expressed by the equation, $WS_2 + 2H_2 \rightleftarrows W + 2H_2S$, is reached more rapidly when the reaction proceeds from left to right. The mean value of *Q*, calculated by means of Nernst's approximate equation from the dissociation pressures of tungsten disulphide, is 73,400 cal.—**S. Franchi**: An exceptional vein of augitic porphyrite in the triassic dolomites of the upper valley of the Neva (Ligurian Alps).—**P. Nalli**: Geodetic co-ordinates.—**S. Cherubino**: The characteristic matrices of the symmetrics on real Abelian varieties.—**Ernesta Porcu-Tortrini**: Calculation of any functions of matrices of the second order.—**A. J. McConnell**: Parallel transport of a vector along a finite circuit. Discussion of the variation of a vector subjected, as suggested by Levi-Civita, to parallel transport along a closed circuit in a space of *N* dimensions, gives a double integral as the expression for this variation.—L. Fantappiè: The linear functionals of the functions of two complex variables (1).—G. Krall: Upper limits of dynamic cement.—P. Straneo: Kutta and Joukowski's theorem, Cisotti's supposed exception to this theorem is the result solely of the mode of interpreting the hydrodynamic phenomenon in the region of the irregularity, that is, at the edges of the lamina, where the velocity becomes infinite. The formal ambiguities leading to such interpretation may be eliminated by suitable consideration of the question *ab initio*.—E. Persico: Molecular velocities, conditions of excitation, and probability of transition in a degenerating gas (2). The formula previously deduced for expressing the distribution of kinetic energy among the molecules of a degenerating gas and the distribution of the molecules in the various quantic states, is applied to the two cases of slight and complete deterioration. It is found (1) that the number of molecules with kinetic energy exceeding 1·04 kT is greater, and the number of molecules with lower kinetic energy less, than required by Maxwell and Boltzmann's theory, and (2) that the molecules are divided among the different states of excitation solely on the basis of their volume and independently of the energy of the separate states. The same formula serves also to determine how Einstein's law is modified by the probability of transition from one quantum state to the other.—R. Brunetti: Polychroism and orientation of the ions in crystals of rare earths. The results of investigations on the absorption spectra of pentahydrated praseodymium sulphate at the ordinary temperature and at the temperature of liquid air, and of neodymium bromate at the ordinary temperature, lead to the conclusion that the spectra of the trivalent ions of the rare earth metals forming part of a symmetrical crystal contain (1) frequencies corresponding with linear vibrations in a direction close to that of the principal axis of the crystal, and (2) frequencies, in general distinct from the preceding, corresponding with vibrations occurring in the plane approximately orthogonal to the principal axis and decomposable into two vibrations equal in intensity and normal to one another in this plane.—R. Bilancini: The anemological regime of the Gulf of Spezia. The results obtained during the four years 1914–17, from ascents to heights of 3600 metres of about one thousand pilot balloons liberated at the aerological station in Varignano, on the Gulf of Spezia, show that, in general, the wind velocity increases with the height, the extent of the increase being greatest in summer and least in autumn and winter. The mean velocity is greatest in winter and least in summer, the value in the spring being approximately equal to that in the autumn at low altitudes but increasingly greater at higher altitudes.—G. Malquori: Thermal dissociation of cadmium nitrate. Anhydrous cadmium nitrate undergoes reversible decomposition at 325° C. in accordance with the equation,

$$2Cd(NO_3)_2 \rightleftarrows 2CdO + 4NO_2 + O_2,$$

the only two solid phases observed being the nitrate and the oxide. Nernst's equation gives the value 55,881 cal. for the heat of decomposition of the salt. —A. Galamini: The physiological action of alcohol. Further observations on rats fed with an insufficient aprotein, acarbohydrate, hyperlipinic diet.—M. Tirelli: Modifications of the chondroma and lacunoma in the intestinal cells of *Gambusia holbrooki* during the various phases of functional activity and during fasting.—M. Benazzi: The existence of particular interstitial cells in the connective tissue of the uterus of the rat.

Royal Society of Tropical Medicine and Hygiene (at 11 Chandos Street, W.1), at 8.15.—Dr. G. W. Bray: Vitamin B Deficiency in Infants—its Possibility, Prevalence, and Prophylaxis.

FRIDAY, May 18.

Royal Society of Medicine (Disease in Children Section), at 5.—Annual General Meeting.

National Institute of Industrial Psychology (at Royal Society of Arts), at 5.30.—F. M. Earle and A. Macrae: Choosing a Career.

Royal Photographic Society of Great Britain (Informal Meeting of Pictorial Group), at 7.—A. C. Banfield: Demonstration of Retouching.

Geologists' Association (at University College), at 7.30.—A. J. Bull and L. G. Jardine: A Section in Drift North of Upminster, Essex.—Miss B. R. Saner: On Some Features of the Taplow Terrace between Charing Cross and the Valley of the Fleet.—H. E. S. Brown: On an Unusual 'Pipe' in the Blackheath Beds at Bromley Hill.—Dr. S. W. Wooldridge: An Unmapped Outlier of the Boyn Hill Terrace at Herne Hill.—F. Gosling: A New Section in the Blackheath Beds of the Addington Hills.

Royal Society of Medicine (Obstetrics and Gynæcology Section), at 8.—Annual General Meeting.

Royal Institution of Great Britain, at 9.—Morley Roberts: The Sea in Fiction.

PUBLIC LECTURES.

MONDAY, May 14.

Gresham College, at 6.—W. H. Wagstaff: Geometry. (Succeeding Lectures on May 15, 16, and 18.)

TUESDAY, May 15.

Guy's Hospital Medical School, at 5.—Prof. J. B. Leathes: The Human Kidney and the Physiological Study of Human Urine. (Succeeding Lectures on May 16, 22, and 23.)

London School of Economics, at 5.—Prof. S. D. Wicksell: Some Aspects of Population Problems. (Succeeding Lectures on May 16 and 18.)

University College, at 5.—Prof. L. J. Henderson: Blood: a Study in General Physiology. (Succeeding Lectures on May 17, 18, 22, 24, and 25.)

British Medical Association (Tavistock Square, W.C.1), at 8.15.—Major W. Elliot: Sunlight—Natural and Manufactured, and its Use in Modern Medicine (Chadwick Lecture).

WEDNESDAY, May 16.

Royal Society of Medicine, at 4.30.—Prof. K. F. Wenckebach: The Heart and Circulation in a Tropical Avitaminosis (Beri-beri) (St. Cyres Lecture).

East London College, at 5.—Dr. W. A. Goddyn: Lotsy's Hybridisation Theory, demonstrated on South African Material.

THURSDAY, May 17.

Institute of Pathology and Research, St. Mary's Hospital, at 5.—Prof. H. Hartridge: Poisoning by Coal Gas and Products of Combustion.

FRIDAY, May 18.

Imperial College of Science and Technology, at 5.30.—Sir William J. Pope: Recent Progress in Stereochemistry. (Succeeding Lecture on May 25.)

King's College, at 5.30.—R. G. Collingwood: Roman Britain and Recent Excavations. (Succeeding Lectures on May 25 and June 1.)

Oxford University, at 5.30.—Prof. A. M. Carr-Saunders: Professions: their Organisation and Place in Society (Herbert Spencer Lecture).

SATURDAY, May 19.

Physiological Society (at Cambridge).

CONGRESSES.

May 11 to 15.

Chemical Industry Conference (organised by Society of Chemical Industry in connexion with its London Section, Chemical Engineering Group, and Institution of Chemical Engineers).

Friday, May 11 (at Les Gobelins Restaurant, 1 Heddon Street, W.1), at 8.30.—F. H. Carr: Some Chemical Engineering Aspects of the Fine Chemical Industry.

Saturday, May 12.—Visit to Rothamsted Agricultural Experiment Station.

Monday, May 14 (at Institution of Civil Engineers), at 10.30 A.M.—Sir Arthur Duckham: The Fuel Industries and the Work of the Chemical Engineer.—Prof. G. T. Morgan: The Chemical Study of Low Temperature Tar.

At 2.30.—Sir Alexander Houston: Water Purification.—J. H. Coste: The Pollution of Tidal and Non-Tidal Streams.

May 15 (at Institution of Civil Engineers), at 10.30 A.M.—Sir Alfred Mond, Bt.: Scientific Research as applied to Industry.—Sir John Russell: The Part played by British Workers in the Application of Fixed Nitrogen to the Soil.

At 2.30.—Lt.-Col. G. P. Pollitt: Developments in the Heavy Chemical Industry.

May 12.

Annual Conference of the Universities of Great Britain and Ireland (at the University, Liverpool), at 10 A.M.—The Contribution of the Universities to the Preparation of Teachers for their Vocation:—(a) Sir Charles G. Robertson, Prof. J. Strong, and others: Discussion on What is the Essential Service which a University can render to the Education of the Intending Teacher? (b) Mrs. E. D. Simon, Prof. T. P. Nunn, C. F. Mott, and others: Discussion on What should be the Relation of Universities to the Specialised Professional Training of Teachers?

May 14 to 16.

Italian Society of Medical Radiology (at Florence).

May 19 to 23.

Congress of Radiology of the Union of S.S.R. (at Kiev).—Subjects of Discussion:—The Consequences of the Changes of Elements of Cells under the Influence of Radiation. Classification and Radiodiagnosis of Diseases of Joints. Functional and Anatomical Changes of the Gastro-intestinal Canal after Operative Intervention. X-ray-therapy of Diseases of the Circulatory System. Temporary Sterilisation with X-rays. Radiodiagnosis of Intestinal Diseases.

May 25 to 27.

French Societies of Oto-neuro-ophthalmology (at Marseilles).

SATURDAY, MAY 19, 1928.

Imperial Agricultural Research.

THE augmentation of the scientific research services of the British Empire is such an immediate necessity that at the conclusion of the preliminary plenary sessions of the Imperial Agricultural Research Conference, held last October, the view was expressed in these columns that the representatives of the home government should have been in a position to state "what further financial provision the government is prepared to make, and what financial support has been promised or is expected from the dominions and non-self-governing dependencies, for the effective carrying out of the schemes submitted to the delegates for their consideration." The hope was also expressed that some definite statement of this character would be made before the break-up of the conference.

It is very unfortunate that no such endorsed statement appears in the recent Report and Summary of Proceedings of the Conference (London: H.M.S.O. 1*s.* net). The Administrative Commission which considered the proposed chain of research stations, bureaux for the interchange of information, and the recruitment, training, and interchange of workers, contented itself with making a number of recommendations regarding the machinery which should be put into operation to effect the objects in view, and with very vague and non-committal suggestions as to the methods by which funds might be raised. Some of the various sub-committees dealing with specialist subjects, for example, veterinary science, animal nutrition, animal genetics, soils and fertilisers, plant breeding, backed their proposals for the encouragement of research with estimates of their cost, but while the conference agreed with their proposed schemes of work, it was not in a position to recommend the allocation of funds for putting them into effect.

Lord Bledisloe, who occupied the chair throughout the proceedings, rightly said that the conference was noteworthy for its comprehensively representative character—albeit more reality would have been lent to it if the proportion of overseas research workers to administrative agricultural officers had been larger—that it served the useful purpose of bringing together a large number of persons for the interchange of views on the impact of scientific research upon Empire development, that it was able to reach a considerable measure of agreement upon the nature, the place, and the character of the machinery necessary for the development of the research services, and that it afforded research workers the opportunity of seeing something of the research workers and stations in Great Britain and Northern Ireland, which in itself is a useful precursor to a fuller measure of co-operation. Nevertheless, it is permissible to ask why, apart from the actual fact of its meeting, the direct and tangible results of the conference should have been left in the air until such time as further reference could be made to the home and the overseas governments. There is surely something radically wrong with the machinery for imperial co-operation if the accredited representatives of the constituent parts of the Empire, the local governments of which have been notified of the object of a conference at least twelve months in advance, can be empowered to agree upon policy but cannot be given the necessary authority to commit their governments to any expenditure for carrying a policy into effect.

Admittedly, on the basis of the various recommendations passed by the delegates to the Agricultural Research Conference, the home government could, out of the funds at the disposal of the Empire Marketing Board, establish a chain of research stations, create bureaux for the interchange of information regarding soil science, animal nutrition, animal pathology, animal and plant genetics, and so on, and launch an energetic campaign for the training and recruitment of agricultural research workers. Doubtless it would need additional funds for these purposes, but they should be forthcoming, for the home authorities are quite aware of the value of scientific research applied to agriculture, whether in Great Britain or overseas. As Sir Daniel Hall pertinently remarked in the closing session of the conference, if the ultimate goal is to make the British Empire self-supporting in the fundamental and all-important matter of food, we must effect an extension of the area under crops and cattle by means of research. The results already achieved in this direction by means of research in Canada, the Punjab, South Africa, and the tropical colonies, amply justify an ambitious programme of research.

The ideal before the conference was, however, the organisation of co-operative research throughout the British Empire in which each constituent part of the Empire shall play its part, and unless each of the overseas governments makes a contribution to a common fund for the furtherance of this object, there is a very real danger that the delegates to the next conference, which is to be held in Australia in 1932, will find that they are as far removed from its attainment as they were in the autumn of 1927. If governments share financial responsibility for any undertaking, they will keep a critical eye on the activities of the departments or persons on whose behalf expenditure has been incurred. If the whole responsibility is borne by the home government, it will be difficult to arouse and impossible to maintain any interest of the overseas governments in the schemes recommended by their respective delegates.

Were the promotion of agricultural research a contentious issue like fiscal policy, the reluctance of governments to delegate authority to their representatives to commit them to a limited expenditure could be understood. If the scientific workers of Great Britain had no contributions to make to the progress of science as applied to agriculture in the dominions and colonies, if our agricultural research and teaching institutions were lacking vitality, or compared unfavourably with those in other parts of the Empire, there might be justification for the extreme caution displayed. Furthermore, if the overseas governments were still unconvinced that they are losing a large percentage of their agricultural produce yearly through plant and animal diseases, and are not realising to fullest extent the known potentialities of the soil, largely due to the inadequacy of their research services, their attitude could be understood. Judging, however, from the utterances of the statesmen of the dominions and India at the Imperial Conference in 1926, and those of the representatives of the non-self-governing dependencies at the Colonial Office Conference in May 1927, the Empire as a whole is completely convinced of the need for more and still more scientific investigation of the problems facing it, most of which are related to the foremost industry of the Empire, agriculture. Apparently they are also convinced of the need for co-operation in research as in other matters affecting the welfare of the peoples whom they represent. They are represented, directly or indirectly, on the Empire Marketing Board. It can only be suggested to them, that as unanimous agreement has been reached on detailed schemes for co-operation, they will use every endeavour to place the necessary funds at the disposal of their representatives on that Board without further delay.

Since the appearance of the Report and Summary of Proceedings, a memorandum has been issued by the secretariat of the conference outlining the action which has been taken on the recommendations made; nothing in it leads us to modify the views expressed above. Regarding the chain of research stations, the memorandum states that the North Queensland Station "is at the moment the subject of correspondence between the Commonwealth Council for Scientific and

Industrial Research and the Empire Marketing Board"; the Empire Marketing Board "are consulting the Government of the Union of South Africa on the proposals that the facilities of the Onderstepoort Station should be increased to enable it to undertake the functions of a central research station in animal diseases"; the recommendation that an irrigation research station should be set up "has been forwarded to the Committee of Civil Research. That committee has formed a Sub-Committee to deal with the recommendation." The question of research stations in the Colonial Empire has been considered by a Colonial Office committee under Lord Lovat's chairmanship, and this committee recommends that until the Amani Research Institute in East Africa is thoroughly re-established no other links be forged in the chain. The recommendations relating to the creation of more central research bureaux and clearing-houses of information for the Empire have been accepted by the governing bodies of the institutions to which it is recommended they should be attached, but the British Treasury has only just "been approached in regard to the acceptance of the principle of a United Kingdom contribution towards the cost. When the question of the home contribution is determined the countries of the Empire will be asked, as a first step, to nominate representatives on the financial supervisory body."

The same note runs all through this last memorandum. Everything is to wait until the home departments or committees concerned have reconsidered the recommendations with which they are concerned, after which presumably they will have to be referred to the corresponding authorities overseas and to the British Treasury. The delay involved in this procedure is illustrated by the time taken—three years—before the recommendation of the East Africa Parliamentary Commission regarding the resuscitation of the Amani Institute was put into effect, and in the meantime the Institute was falling further into desuetude. We can only express the hope that more energetic steps will be taken to achieve some positive results before the next meeting of the conference in Australia. At the same time, we should like to suggest that the best means for ensuring that no time will be lost between passing schemes for co-operative research and putting them into effect would be to create immediately a central fund, based upon contributions of each constituent part of the Empire, and large enough to permit of immediate action being taken by an Empire Research Council upon which the Dominions, India, and the Colonies are properly represented.

The Languages of India.

Linguistic Survey of India. By Sir George Abraham Grierson. Vol. 1, Part 1: Introductory. Pp. xviii + 517. (Calcutta: Government of India Central Publication Branch; London: High Commissioner for India, 1927.) 11.12 rupees; 19*s*.

THIS year there have been completed two very notable works in the field of linguistic science: one is the "New English Dictionary," finished after seventy years of labour; the other is the great "Linguistic Survey of India," of which the last volume to be published is now before us. No scholar can work at any problem connected with the history of English without constant appeal to the Dictionary, and no scholar can work at any problem connected with the languages of India without constant appeal to the Survey. Indeed, we can scarcely recall during the last fifteen years an article or book on the history of any of these languages (and shortly it will be seen how numerous and diverse they are) in which reference has not been made to the facts set forth in the Survey, often for the first time.

The only linguistic work which can be compared with the Survey is the "Atlas linguistique de France." But the intention, the scope, and therefore the method of the Atlas are different: in it a certain number of isolated linguistic phenomena (particular words, grammatical forms, and the like) were studied in as many of the local patois of France as possible: it does not pretend in any way to provide a description of any given dialect or even of its most salient features. The author of the Survey, on the other hand, set himself the task of describing, as fully as materials or space allowed, every language and every dialect spoken over vast areas of the Indian Empire by some 300 million people.

The New English Dictionary provides us with an unrivalled history of one language; the "Atlas linguistique" supplies invaluable information concerning the distribution of linguistic phenomena over a whole dialect-area. But the Survey has given us descriptions, not of one language only, not even of the different dialects of one language, nor even of a group of connected languages (as, for example, the Romance in Meyer-Lübke's "Romanisches etymologisches Wörterbuch"), but of four separate and distinct families of languages—the Austro-Asiatic, the Sino-Tibetan, the Dravidian, and the Aryan—excluding two languages as yet unclassified; and these families are represented in India alone (or rather in that part of India with which the Survey deals) by 179 separate languages (of which the test is mutual unintelligibility) and 544 dialects.

It may at first seem strange that so many different languages should be spoken in a country which geography and politics incline us to look upon as one. Briefly, the linguistic history of India has been this. In the prehistoric period there were spoken over northern India, probably from the mouths of the Ganges to what is now the North-West Frontier Province, languages belonging to the Austro-Asiatic family: to this belong also languages still spoken in parts of Burma and the Malay Peninsula, and by considerable populations in Indo-China. Pater W. Schmidt makes the Austro-Asiatic a part of a wider whole, the Austric, which includes Indonesian, Melanesian, and Polynesian, spoken from Madagascar in the west to Easter Island in the east, and from Hawaii in the north to New Zealand in the south. However that may be, the Austro-Asiatic branch was at one time strongly represented in India, for even to-day in widely separated districts the descendants of these languages still survive—in the Khassi and Jaintia Hills of Assam (Khāsī); in the jungle country of the Central Provinces south of the Narbada; in scattered islets along the southern face of the Himalaya as far north as the Simla Hill States (Kanāwarī). But their greatest mass is in Orissa, where the best known of the many dialects are Santālī and Muṇḍārī. This opens the way to an interesting speculation. The name for an aboriginal inhabitant of Orissa is *ōṛa*, which derives regularly from *ōḍra-*, itself recorded early in the history of India as the name of an outcaste tribe. The same word survives in many other modern languages as the designation of a caste or occupation: in Gujarat *ōḍ* is the name of a caste that dig and carry earth and build mud-houses; in the Panjab the *ōḍ* are a tribe that clear out watercourses and build houses; in Sindh *ōḍru* is a caste that build mud-walls, in Nepal, where stone has largely taken the place of mud for building, *ōṛ* has become a stonemason.

Attention has recently been directed to the discovery of the cities of the past in the valley of the Indus, the ruins of Mohenjo-daro and Harappa with their great brick buildings. Who the builders were, we do not know; nor have we as yet any clue as to their language. But that it was Austro-Asiatic is possible, or even probable. Were they the *ōḍras*, makers of mud-bricks, whose name eventually passed into the languages of the Aryan conquerors as that of a caste of mud-workers, who dug out irrigation channels and built mud-houses? It is, at least, not impossible. For J. Przyluski has recently shown that several culture words of ancient and modern India—such as those designating cloth, cotton, the bow for carding cotton or for shooting with, the plough, the peacock, the elephant, and so on—are of Austro-Asiatic origin, borrowed from the aborigines by subsequent invaders. But whatever their extent and importance in India in the prehistoric period, Austro-Asiatic languages are to-day spoken by only a few jungle tribes, small in numbers (the census of 1921 counts them as 4½ millions only) and doomed to disappear eventually before more dominant languages.

Also in prehistoric times there was in India another family of languages, the Dravidian. Whether these preceded the Austro-Asiatic or themselves entered from the north-west and pushed back the Austro-Asiatic, we cannot say. At the present day their chief mass is found in the south of the peninsula, but at one time they certainly stretched farther north. As in the case of the Austro-Asiatic languages, isolated dialects are found in the jungle country of the Central Provinces and of Bihar and Orissa, where the most northerly (Malto) actually reaches the Ganges. Most interestingly situated of all is Brāhūī, a Dravidian language spoken in Baluchistan and separated by nearly a thousand miles, and all the deserts of Sindh and Rajputana, from its nearest relative, Gōndī on the Narbada. Unfortunately, however, its position can be interpreted in two ways, for, as Sir George Grierson points out, Brāhūī may be either the rear-guard of a Dravidian invasion from the north-west or the vanguard of a movement from the south. These isolated Dravidian dialects, again like the Austro-Asiatic, are giving way before the languages of subsequent invaders; but in the south their compact mass and, in particular, their use for literature and administration have enabled them to resist the attack of their northern neighbours. Telugu, Tamil, Kanarese, and Malayalam all have literatures of considerable antiquity. For all Dravidian speakers the census of 1921 gives the number of some 64 millions.

North and east of India lies the huge mass of the Sino-Tibetan family of languages. These are divided into two sub-families, the Siamese-Chinese and the Tibeto-Burman. Of these the former have penetrated Siam, driving before them the Austro-Asiatic languages: but, except for two small dialects, Khāmtī and one of Shān, they have not come within the area of the Survey. But the other sub-family, the Tibeto-Burman, has many representatives within India proper. Throughout almost the whole of the historical period they have been spilling over the barrier of the Himalaya or round its ends. In the east they have occupied almost the whole of Burma, and have formed or left many colonies in the valley of the Brahmaputra; while along the whole southern face of the Himalaya are spoken Tibeto-Burman dialects, extending to the extreme north-west beyond Ladakh. But they are without literature, and they do not serve as languages of administration. They are yielding, therefore, to the languages south of them, which serve both purposes—to Kashmiri, Panjabi, Hindustani, Nepali, Bengali.

Here first we meet the names of some of the Aryan languages, which are spoken by more than 230 millions in India itself. At some time during the second millennium B.C. there appeared on the north-west frontiers of India tribes who spoke a language akin to our own, and to Latin and Greek and Keltic and Slavonic, that is to say, one of the so-called Indo-European languages. Behind them were the Iranians, speaking closely related dialects. Indeed, they must at a recent period have formed a single linguistic community. This is termed Aryan or Indo-Iranian. Those that pushed on into India are called Indo-Aryan. The earliest documents that we have of their language are the hymns of the Rigveda, some of which were composed about the time of their entry into India, some perhaps earlier, some later. These, though mainly religious and sacrificial in substance, give hints of the fights that took place between the invaders and the aborigines and between different Aryan tribes. The conquest, however, proceeded steadily, and the ever-increasing extension of Aryan power was followed by an extension of Aryan speech, as it was learnt by the conquered aborigines. The language of the Vedic hymns, becoming the language of religion and of a priesthood—the Brahmans—ever increasing in authority, and with various modifications affecting its vocabulary and grammar rather than its sounds, was stereotyped eventually as the chief language of literature, named Sanskrit, 'the perfected.' But the spoken language did not, of course, stand still in this way: it changed continually from generation to generation in sounds, in grammar, in vocabulary; and, with the widening of the area over which it was spoken and the diversity of the aborigines who learnt it, greater and greater differences began to appear in the way it developed in various parts of the Indo-Aryan domain. Hence arose those forms of speech which are classified in the Survey as 38 separate languages with 402 dialects.

Lastly, on the north-west the Iranian languages have somewhat advanced their boundaries, and some, such as Pashtu and Baluchi, are spoken actually within the borders of British India.

It is, then, this huge mass of differing languages and innumerable dialects which the 18 volumes of the Survey have analysed, classified, described. The task would seem to be beyond the power of one man. Yet in Sir George Grierson was found one equal to it. The reader, lost in astonishment at this achievement, does not know which to admire the most, the depth and breadth of the author's scholarship and his vast stores of knowledge, the acuteness of his analytical power, or the application and force of will which have carried this colossal undertaking to so complete and so brilliant a conclusion. For some years Sir George Grierson had the help of another distinguished Indianist, Prof. Sten Konow, now of Oslo, from whose pen come some five or six of the volumes. But the plan and the direction and some twelve complete volumes, including this the Introduction, are Sir George's. It is an achievement without parallel in the annals of philology.

R. L. Turner.

Scientific Fact and Fancy.

Possible Worlds, and other Essays. By J. B. S. Haldane. Pp. viii + 312. (London: Chatto and Windus, 1927.) 7*s.* 6*d.* net.

These essays, covering a wide range of subjects—including, for example, "The Last Judgment," "Vitamins," "Cancer Research," "What Use is Astronomy"—have mostly been published before, some in popular scientific journals, others in the daily and weekly press. Those dealing with physiology, where Mr. Haldane is on his own ground, well bear re-publication, but it seems unfortunate that some articles of merely ephemeral value should have been included. At any rate, a clue to the original date of appearance would have been helpful as a reminder of the events which originally inspired them. On the other hand, some of the articles, particularly those on research, could have been enlarged with advantage.

The last ten years have seen a great increase in public interest in questions immediately affecting the welfare of children and the improvement of health in nations weakened by four years of war conditions. Among educated persons, even the least serious discuss vitamins, cures for tuberculosis and cancer, food-bacteria, and so on; and authoritative articles on such subjects published in the daily press, and reaching all classes of people, can be of great use. But the time has come when the non-expert, more interested and better educated in science than his and her predecessor of twenty-five years ago, would like to hear more, and would be capable of understanding and profiting by more than can be covered in two or three octavo pages. This applies particularly to "Immunity," "Cancer Research," "The Fight with Tuberculosis," and "Vitamins," which could all with advantage have been enlarged from their original form and contained more detail.

The best part of the book is that devoted to various aspects of research: "Scientific Research for Amateurs," "The Future of Biology," "On Being One's own Rabbit." In the last paper the author describes how he and a colleague, in desiring to discover "what happens to a man when we make him more or less alkaline," attempted to get further than the merely preliminary work which can be done on animals. "It is difficult to be sure how a rabbit feels at any time, and indeed, many rabbits refuse to collaborate with one," so they began experiments on one another; the author in this essay traces the varying methods by which acidity and alkalinity were arrived at and the resulting symptoms. It is interesting to note that many of the latter were the symptoms of well-known diseases, and he goes on to suggest that it would be well for patients to have some understanding of their own symptoms when relating them to a medical man, and to realise, for example, that a pain near the heart is more often indigestion than heart disease. "Finally," he concludes, "since the public has begun to pay for medical research, it has a perfect right to know how its money is spent. During the last year, about one part in four million of the national revenue was employed during some weeks in keeping me awake during attacks of tetany, and in analysing blood samples drawn from me in the course of them. It has been the object of this article to suggest that one four millionth of the nation's money was well spent" (p. 119).

On the question of research for amateurs, Mr. Haldane writes:

"Until the last century, scientific research was almost entirely the work of men who earned their living by some other method or possessed private means. Until fifty years ago there was no such thing as training for research, and every researcher began his work as an amateur" (p. 162). Natural history, fallen into disrepute towards the end of last century, is coming into its own again. But while the field is narrowed, and there is less to be discovered in a broad sense, there is now even greater scope for detailed accurate observation; though research in chemistry, physics, human anatomy and so on is impossible to any but trained scientific workers, there remains an infinity of unexplored ground along the lines of animal and plant inheritance, habitat and distribution, and in meteorological and astronomical investigations, which will repay study by the amateur. All this can be done without special training and without expensive apparatus. Much valuable suggestion is given for carrying out such work.

The essays on speculative matters, particularly those dealing with religion, are probably of more interest to Mr. Haldane as a setting in order of his own thoughts on these subjects than they can be to other people. Of these, "Possible Worlds" is the most suggestive, dealing as it does with the possibility of regarding the world other than from the present human point of view, of imagining, for example, a 'dog' or 'smell' world, or a world in which our perceptions and senses are enhanced and increased.

"Meroz," a tract against the clergy in relation to the War, seems scarcely in good taste in 1928. The book as a whole, will, however, be of great value in spreading an interest in, and appreciation of, scientific research and the scientific point of view.

Leonhard Euler.

Léonard Euler et ses amis. Par Prof. L.-Gustave Du Pasquier. Pp. ix + 125. (Paris: J. Hermann, 1927.) 22 francs.

THIS is a short sketch of the life and work of Euler. In little more than 100 pages it gives us an interesting account of his early life, his first sojourn at St. Petersburg (1727–1741), his call to Berlin by Frederick the Great, when, soon after his accession, that monarch planned the formation of a new Prussian Academy and was collecting about him the men who were to set it going, among them Wolff, Maupertuis, Algarotti and Euler ("le grand algébriste," as Frederick called him in his letter to Suhm of June 14, 1740); his part in the formation and working of the Nouvelle Société Littéraire, afterwards combined with the Société des Sciences founded by Leibniz into L'Académie Royale des Sciences et Belles-Lettres de Prusse; the years of his co-operation, as director of the mathematical class, member of the directorate, and member of the literary committee, with Maupertuis the director of the Academy, and of his sole direction of the Academy while Maupertuis was in France recruiting his health; his relations with Frederick, and the circumstances in which, after the accession of Catherine the Great to the throne of Russia, he overcame the resistance of Frederick and returned (in May 1766) to the directorship of the Académie des Sciences de St-Pétersbourg, with which he had all along maintained his connexion; and lastly, his second stay at St. Petersburg, including the period of his total blindness from 1772 until he died of apoplexy on Sept. 7, 1783, while still in full possession of his intellectual powers and in the midst of labours never interrupted (he is said, between 1773 and 1782, to have written no fewer than 355 memoirs).

Applying the new methods due to Newton and Leibniz, Euler indelibly impressed his personality on the whole of mathematics; he left no branch untouched, and "he touched nothing that he did not adorn." He made great advances not only in algebra, geometry, analysis, theory of numbers and pure mathematics in general, but also in acoustics, optics, mechanics, hydrodynamics, engineering science from the theory of turbines to gunnery and the science of navigation, astronomy, the theory of the planets and comets, lunar theory, to say nothing of the calculus of probabilities and its applications to life insurance, statistics and games of chance, mathematical recreations, magic squares, etc.

Euler won the prize offered by the Académie des Sciences de Paris no fewer than fourteen times (the first time at the age of twenty). The mere bulk of his writings must, we suppose, be unapproached by any other scientific writer. Diogenes Laertius says that the output of the philosopher Epicurus was unprecedented, running to about 300 "rolls." What would he have said of Euler's, which in the collected edition (of which 23 volumes have appeared) will fill 69 volumes with about 600 large quarto pages in each?

Euler's powers of work were extraordinary, and he had the advantage of a prodigious memory. He could recite by heart the whole of the Æneid from one end to the other; and at the age of seventy he could still remember what particular lines began and ended each page of the edition from which he learnt it in his youth. Suffering from insomnia, he calculated in his head one night the first six powers of all the integral numbers up to 100; he remembered the numerical table so obtained and reeled it off several days afterwards to the great surprise of his entourage.

In Chapter iii. ("Léonard Euler à Berlin") we may read again the story of Frederick the Great's attitude towards Euler. Frederick admired him but had no sympathy for his subject. So we find Frederick writing to Voltaire about "un gros cyclope de géomètre," and, at the end, congratulating himself on "having exchanged a one-eyed geometer for one with two eyes" (Lagrange). Again we find Frederick writing: "Quoique je n'aye pas appris à calculer des courbes, je sais pourtant, mon cher Euler, que 16,000 réisdallers sont plus que 13,000," and (in letters to D'Alembert): "Un certain géomètre qui a perdu un œil en calculant, s'avisa de composer un menuet par *a* plus *b*," and "M. Euler, qui aime à la folie la Grande et la Petite Ourse, s'est approché du nord pour les observations plus à son aise. Un vaisseau qui portait ses *xx* et son *kk* a fait naufrage; tout a été perdu, et c'est dommage, parce qu'il y aurait eu de quoi remplir six volumes in folio de mémoires chiffrés d'un bout à l'autre; et l'Europe sera vraisemblement privée de l'agréable amusement que cette lecture lui aurait donné." T. L. H.

Our Bookshelf.

The Yearbook of the Universities of the Empire, 1928. Published for the Universities Bureau of the British Empire. Pp. xiii + 866. (London: G. Bell and Sons, Ltd., 1928.) 7*s.* 6*d.* net.

We live in a busy age, and a perception and appreciation of the necessity for economy of time has, whether we like it or not, penetrated even the serenity of the academic world. Each university publishes its own calendar, and sets out, either briefly or at length, particulars concerning its personnel, organisation, regulations, and activities. But all those separate calendars form a library of some 50,000 pages; and, as the universities come more and more to interest and influence a wider circle than their own professors and students, the "Yearbook," with its admirable condensation and presentation of essential information, satisfies more and more a very real need.

It would, however, be a mistake to imagine that the book succeeds merely in condensing and presenting uninteresting (if necessary) regulations, and tiresome strings of names and qualifications. Indeed it goes far to show how fascinating a 'yearbook' can be made. There are, for example, a few pages summarising the history of the universities which, read in conjunction with the appendices dealing with professions and careers for which university studies are a fitting preparation, form a study in evolution not to be missed by anyone who desires evidence of how university life adapts itself slowly but surely to the changing needs of civilisation.

Since each university undertakes some form of specialised work in addition to the courses common to all, the section on professional schools, specialist studies, and post-graduation courses, has an outstanding value. There is also a list of centres of research outside the university institutions; and, in both these connexions, there is information concerning inter-university scholarships, grants for research, etc.

The 1928 edition of the "Yearbook" maintains the high standard of its predecessor (which we noticed in these columns a year ago): it would not be easy to pay it a higher compliment

Plants of the Past: a Popular Account of Fossil Plants. By Dr. Frank Hall Knowlton. Pp. xix + 275. (Princeton: Princeton University Press; London: Oxford University Press, 1927.) 16*s*. net.

This book is written for readers with no special knowledge of either botany or geology, but is intended to arouse interest as well as to impart a fair amount of information. It should be successful, for it has many good points, and in any case it covers a field which no other book attempts to cover

The first chapters are introductory, most of the remainder of the book describes the floras of the different formations from the Cambro-Silurian to the Pleistocene, one chapter being devoted to each formation. The result is that while the treatment is proportionate from a geological point of view, chapters which lack important material are loaded with detail The British reader will find the chapters on the Tertiary especially troublesome, because they are full of the names of many unfamiliar American plants. The book ends with chapters on evolution, on the influence of man on plants, and on the formation of coal.

The author deals with a wide subject proportionately, accepts his data cautiously, and writes clearly. The general reader will find the book easy to follow, though sometimes dull. Students, on the other hand, are likely to be somewhat disappointed, because the author, in endeavouring to be simple, misses much of the interesting speculation on the evolution of plant structure, and on the changes of past climates, their place being taken by straightforward description.

The Collection and Preparation of Herbarium and Timber Specimens By J. Burtt Davy and L Chalk. Pp. 28. (Oxford: The Imperial Forestry Institute, 1927.)

This handbook is intended primarily for the use of forest officers, and should prove of value to those district forest officers and their subordinates who can give the time, amidst their multifarious duties, to the collection of specimens for local forest herbaria.

Some forest officers, as the past has shown, have neither the gift nor the temperament of the collector, but for those possessing these attributes, the preparation of this handbook should prove of great service. Not only are the lines upon which the collection of individual specimens clearly laid down, but also the inadequate resources which face the forest officer whilst on tour in the forests are borne in mind. For example, under "Drying the Specimens," after detailing the methods of placing the material in the press, the practical suggestion is made: "In very humid localities or during rainy weather, the press may be suspended endwise over a small camp fire or a portable paraffin stove, surrounded by an improvised tent of branches, grass, etc, with a hole at the top. The hot air penetrates the bundle by way of the corrugated cardboard."

The handbook may be recommended to all those who wish to collect botanical specimens which shall be serviceable for the herbarium, whilst at the same time ensuring that the results of the arduous work often entailed shall not be lost owing to subsequent bad packing and consequent irremediable damage during transit.

The Locomotive-God. By W. E Leonard Pp. v + 434. (London: Chapman and Hall, Ltd., 1928) 18*s*. net.

This is not a cheerful book, but it will be read with zest by psychologists. The author, a man of literary and academic distinction in America, in early middle life became the victim of distressing and disabling, yet quite groundless, terrors He could not walk more than a few hundred paces from home without panic, and he suffered besides from attacks of acute melancholia. Believing that the causes must somehow be infantile, he resolved to reach them. "I knew indeed there was something *down below.* What was it? I estimate by careful computation that my efforts to answer this question have been, up to date, equivalent to four semesters of laboratory research"

University colleagues assisted Mr. Leonard, and in the end it appeared that the first trauma had been caused by a shock received at the age of two years and four months when, straying near the metals, he had nearly been caught by a locomotive (hence the title of the book). Other distressing experiences, one in particular at the age of ten, were also unearthed, and the whole record takes the form of an autobiography, the details of which had in some cases long passed out of conscious memory. The book is far more personal than the mere medical record of a distressing case of distance-phobia, and is therefore more widely interesting. It is pervaded by a spirit of indomitable stoicism, for the suffering endured has been incredible On this account, if for no other, the book makes invigorating reading J. C. H.

Elektrostatische Versuche mit Anwendung des Universalelektroskops. Von Theodor Wolff. Pp. viii + 85. (Berlin und Bonn: Ferd Dümmlers Verlag, 1928.) 2 85 gold marks.

In this volume the author describes his universal electroscope, and gives descriptions of numerous experiments, ranging from elementary experiments in electrostatics to measurements of ionisation currents of various types, and of atmospheric potentials. The experiments described are ingenious and well thought out, and teachers wishing to arrange a course of practical instruction in electrostatics will find some useful hints.

Light-Year *versus* Parsec.

THERE comes a time in every science when merit is acquired by the introduction of a new unit of measurement, and all will admit the occasional necessity of such in a world of expanding physical sciences. Does astronomical science need another unit of stellar distance?

It would seem that, in general, any new unit should satisfy some or all of the following conditions:

(1) It should be urgently needed, to express a magnitude of an order not adequately represented in the existing system of units.

(2) It should be a logical unit, in that it follows customary formation for units of its type; it should depend directly upon other units or dimensions of fundamental nature.

(3) So far as possible, it should be easy of comprehension by men of science who are not specialists in its particular province.

(4) Where it is suggested as a replacement for a unit sanctioned by long usage, it must be in every way a better and more convenient unit. Age does not imply sanctity; it does, however, demand an improvement.

Does the word 'parsec' meet the requirements outlined above? From the viewpoint of the purist, nothing could well be worse than this hybrid, but the nomenclature of science includes a few other verbal monstrosities, and this, in itself, is no argument against the term.

(1) The 'parsec' is equal to 3·26 times the customary unit known as the light-year; it does not indicate a magnitude of an order different from the older unit.

(2) The light-year is a highly logical unit. In mechanics, our best definition of a length is still given by $s = vt$; that is, a length equals a certain velocity multiplied by the time. This is precisely the construction of the unit known as the light-year, and it rests upon two other units, the velocity of light, and the length of the year, which are regarded as highly fundamental.

(3) The light-year is a unit the significance of which is instantly grasped by the layman, or by the man of science in unallied fields. Which is the easier (and the more logical)? Is it the concept of a star at such a distance that light needs 159 years to make the journey therefrom, or the concept of a star at such a distance that, as seen from the star, the semi-major axis of the earth's orbit subtends the 48·7th part of the 1,296,000th of a circumference?

(4) While long usage does not necessarily give authority, the fact that the concept of visualising stellar distances by the time of light travel goes back at least to the year 1740, deserves thoughtful consideration. The actual term, light-year, is not nearly so old.

Aside from its ease of comprehension and its logical structure, we lose historical 'side-lights' of great interest and value by abandoning the light-year. The fact that a distant Milky Way, apparently a replica of our own stars in its integrated light, is to us as it actually was three million years ago, adds a genetic datum which is utterly lost in the distance of one million 'parsecs.'

But the term 'parsec' was introduced to make computations easier. The skilled computer will smile at this; he cares little whether he has to take a reciprocal, or to add in any one constant log. as against any other. In fairly representative computations involving parallax and distant spiral nebulæ data, I have never yet had to use the 'parsec' unit.

The trigonometric method of determining star distances has given undue prominence to the angle subtended by the semi-major axis of the earth's orbit, an importance which will inevitably be greatly diminished by the further application of the methods of spectroscopic and dynamical parallax determination. Such probable progress will further diminish the excuse for a unit like the 'parsec.' Why use it at all? HEBER D. CURTIS.

Base Exchange and the Formation of Coal.

IN an article entitled "Base Exchange and the Formation of Coal" (NATURE, Sept. 24, 1927) I discussed the probable influence of base exchange between the roofs of coal seams and sodium chloride solutions on the formation of bituminous coal. I suggested that base exchange might form the connecting link between the coal seams of various geological formations. Since writing the article, I have had an opportunity of examining the roofs of bituminous coal seams of Jurassic, Cretaceous, and Tertiary ages, and they agree with those of the Carboniferous age in showing evidence of base exchange and hydrolysis. It appears, therefore, that bituminous coal always occurs under a roof which has undergone base exchange and which contains sodium as the main replaceable base. The final stage in coal formation appears to have been the bacterial decomposition of the accumulated plant material under alkaline anaerobic conditions.

The base exchange theory of coal formation affords a method by which the 'drift' and 'in situ' theories may be reconciled. If drifted material accumulated in the sea, the characteristic roof constituent would be sodium-clay. If the material accumulated by drift in fresh water and the roof were deposited in fresh water, base exchange could take place by submergence in the sea. If the material accumulated 'in situ' on land or in fresh water, a slight alteration in land level, such as geologists maintain occurred at intervals during the coal-forming periods, could result in base exchange taking place with capillary solutions of sodium chloride raised from subsoil water containing this salt. It follows, therefore, that whether the material accumulated by 'drift' or 'in situ,' the same final roof conditions have been present.

Base exchange appears also to have a bearing on the formation of petroleum. Petroleum-bearing strata are usually overlaid by shales. The fossil evidence indicates that the material from which the shales have been formed was deposited in salt water. Base exchange between the material covering the petroleum-bearing strata and solutions of sodium chloride must therefore have taken place. The subsequent hydrolysis of the sodium-clay would provide alkaline anaerobic conditions for the bacterial decomposition of organic matter.

An investigation of the bacterial decomposition of fats under a roof which has undergone base exchange and hydrolysis is now in progress. The result of such a decomposition is shown in Fig. 1.

The fat was distributed through a sand layer at the bottom of a beaker and the sand layer moistened and inoculated with a soil suspension. A roof containing hydrolysing sodium-clay was deposited on the sand and a layer of water maintained on top of the roof. The beaker was then incubated at 30° C. The development and accumulation of gas under pressure is shown. The decomposition of triacetin results in the formation of methane alone. The decomposition of tributyrin results in the formation of a mixture of gaseous paraffins. Decompositions of other pure fats and naturally occurring mixtures of fats are in progress. The appearance of these decompositions is similar to that in the figure Gycerol on decomposition under alkaline anaerobic conditions is converted into methane, the oxygen being probably eliminated as carbon dioxide and absorbed by the alkaline roof.

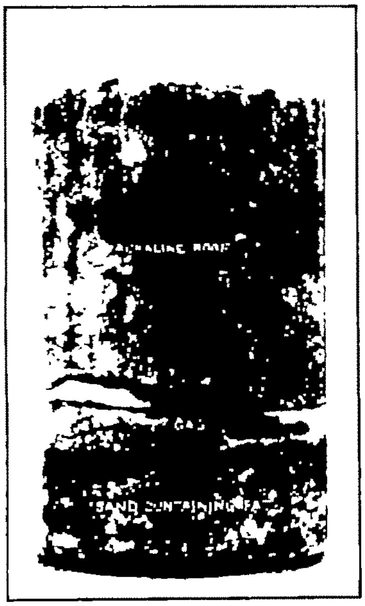

Fig 1.

From the results so far obtained, it appears that the fat is hydrolysed, the resulting glycerol being converted into methane, and the fatty acid being reduced to a corresponding paraffin As petroleum occurs under deposits which appear to have undergone base exchange, the investigation now being carried out suggests that it may have resulted from the bacterial decomposition of animal or vegetable fats under alkaline anaerobic conditions. The close relationship that is supposed to exist between the formation of coal and the formation of petroleum lends support to the suggestion, as under the conditions indicated both would be formed by similar types of bacterial action in similar circumstances.

Temperatures of Stars in Planetary Nebulæ.

During the past summer, when working at the Dominion Astrophysical Observatory in Victoria, I secured some quantitative data as regards the luminosity of planetary nebulæ. I did not have occasion to elaborate the material until this winter, which I spent in Pasadena, on my leave of absence from the University of Washington at Seattle.[1] The method consists of taking a slitless spectrogram of the nebula with its central star, and impressing on the same film on which this spectrum is taken a series of comparison spectra of varying intensities and of the same time of exposure as the nebula. The comparison spectra are obtained from a sensitometer having the daylight sky as a source, a real image of the sensitometer patches being formed at the slit of the spectrograph. The photographs yield the total intensity of each monochromatic picture of the nebular envelope in terms of the intensity per frequency unit of the adjoining star spectrum of approximately the same wave-length.

In working out our data we have taken a somewhat idealised view which leads to different independent determinations of the temperature of the central star, assumed to be a black body.

1. *Mechanism of ionisation and recombination.*—For a certain type of atom or ion, it is assumed that all the ultra-violet star light beyond the head of the series is completely absorbed, causing ionisation of the atoms or ions in the nebula. From the intensity data of the spectrum, which is assumed to be produced by the subsequent recombination, the approximate temperature of the star is derived. This method may be applied to the data for H, He, and He^+, giving independent determinations for each type. This mechanism was first applied by me to hydrogen in diffuse nebulæ (*Astrophys Jour.*, 65, 50 ; 1927).

2. *Bowen's secondary mechanism of electron excitation.*—It is assumed that the so-called nebulium lines are excited by the photo-electrons freed according to the first mechanism, and that the excess of energy absorbed by an atom or ion above its ionisation energy is completely given out as energy in the observed resonance nebulium lines; in other words, that a photo-electron freed from any atom or ion is only recaptured after its energy as a free electron has been completely exhausted in producing the nebulium lines. Hence the data on the nebulium lines provide another independent temperature determination which, of course, may give somewhat low values. This mechanism was put forward by Bowen (*Astrophys. Jour.*, 67, 1 ; 1928) in order to account for the abnormal intensity of those lines which, according to his well-known identification, originate in many cases from metastable states of known ions. The images of the hydrogen lines and of the green nebulium lines are nearly coincident, apart from the somewhat larger size of the latter and, for the lower temperature nebulæ at any rate, it is likely that the photo-electrons originating from the hydrogen atoms are the main agents in exciting the nebulium lines. In the present temperature determinations the approximation has therefore been introduced that the hydrogen absorbs all the ultra-violet energy of the star beyond the head of the Lyman series, and that the electrons thus freed lose their energy completely in exciting the nebulium lines. For the lower temperatures this approximation is justified, but the higher temperatures derived from nebulium may thus come out somewhat low, so that, for example, a temperature of 70,000° derived from nebulium might be 20,000° or 30,000° low, and that from about 100,000° on, the figures obtained have only significance as lower limits.

For the three nebulæ investigated provisional results have been obtained which are as follows :—

Method	N G C 6543	N G C 6572	N G C 7009
H	38,000°	39,000°	
He		34,000° to 41,000°	
He^+			70,000°
Nebulium	36,000°	37,000°	

In the first two nebulæ the results of different methods are in very good agreement. Of the third nebula, N.G.C. 7009, the pictures are hard to measure on account of the small intensity of the star and the fact that there is a strong moonlight background which has to be corrected for. The given value of 70,000° from He^+ is fairly trustworthy on account of the sensitivity of the method in this case. The hydrogen and nebulium give values which are decidedly lower, less by roughly 20,000°, but the determinations are not accurate. This means that the He^+ is abnormally strong, as compared with nebulium and hydrogen, which, as Mr. Bowen pointed out to me, is also borne out in the abnormal place this nebula occupies in the sequence of his Table II. However, as they stand, the data show already that the assumption that the star is a black body and the luminosity caused by known physical mechanisms appears to be a fair interpretation of the facts.

---

[1] A complete account of the work will appear in the *Publications of the Dominion Astrophysical Observatory*

The temperature determination based on the strength of the nebulium lines by Bowen's secondary mechanism may be extended so as to include a great number of cases for which data are already available. Taking into account that the photographic brightness of the central star may be assumed to vary approximately as the intensity of the wave-length 4250 A. (Brill), and that the visual brightness of the nebula is mainly due to the green nebulium lines, a table can be made relating the difference d between those quantities expressed in magnitudes with the temperature T expressed in thousands of degrees. The result is

T	35	40	50	60	80	100	150	200
d	2·4	3·3	4·4	5·3	6·6	7·5	9·0	10·1

The scale has been fixed using the results for the temperature determination due to nebulium for N.G.C. 6543 and 6572. Photographic magnitudes of the star have been determined by Curtis and total visual magnitudes of the nebula by Holetschek; these are subject to corrections according to Hubble or Hopmann, and the error in d may probably go so high as one magnitude. Values of the stellar temperature for eighteen nebulæ, including the three original, have thus been obtained. Examples are: N.G.C. 7009, 51,000°; N.G.C. 6720, 68,000°; N.G.C. 6826, 35,000°; N.G.C. 6210, 40,000°; N.G.C. 7662, 48,000°; N.G.C. 6818, 72,000°.

The first nebula is that already discussed. The second is the ring nebula in Lyra; and the others, besides the three original ones, are those common to Bowen's and the present investigation. Among the eighteen nebulæ treated there are only two that yield a temperature so high as 100,000° by this method. They are N.G.C. 6445, 134,000°, and N.G.C. 1952, 100,000°.

In the case of N.G.C. 6445, there is much obscuring matter in neighbouring regions, as Dr. Hubble informed me. The high difference in magnitude may therefore be due to partial obscuration of the star, and the high temperature should be regarded with suspicion, if not entirely discarded. Dr. Hubble informed me also that there is strong evidence that the second case, N.G.C. 1952, the Crab nebula, is an old nova, and hence that there is good reason to expect an abnormally high temperature. An error of one magnitude might make the stellar temperature for this nebula about 20,000° lower, but on the other hand, the underlying assumptions in the present work are such as to make the higher temperatures come out rather low, so that for N.G.C. 1952 it is very likely that a temperature of 100,000° is reached.

Though in planetary nebulæ such high temperatures occur, as has also been stated by Bowen, it must be remarked that the lower temperatures are of the same order as those known for ordinary O stars, and that the present treatment appears to give the much desired continuity of the temperature scale.

The Blubber of Whales.

THE blubber of whales does not appear to have received the attention it deserves; some writers pass it over in silence, others regard it as the mere counterpart of hair and assign to it only a non-conducting function.

Unlike the blubber of seals, which is thick at one season and thin at another, that of whales undergoes no changes in thickness except those which are incidental to age and growth. A tissue so constantly present, and subject to so little change, must be an essential one and must fulfil a very important purpose.

That the blubber has other functions besides a non-conducting one is shown by the fact that its thickness in different species is not related to the temperature of the water inhabited; for example, in the Greenland whale it is many times thicker than in the Narwhale, although both inhabit the same seas, and in the same whale it may be many times thicker than in the Saddle-back and Bladder-nose seals which also inhabit the Greenland Sea, and which, moreover, are obliged at times to go on the ice and expose themselves to a temperature below freezing point and sometimes to one below zero.

The blubber is merely the skin modified to enable its possessor to lead an aquatic life. As Bennet, the author of a whaling voyage round the globe in 1833–36, says, its most important function is doubtless a hydrostatic one; its lightness doubtless diminishing the whale's specific gravity and helping it to float, and its elasticity perhaps helping it to withstand the pressure of the water at great depths.

Whales—at any rate some of them—can rest at the surface without effort, with a small part of their bodies above water, and when extended in this manner, as Scoresby states, can sink downwards in a few seconds beyond the reach of their human enemies. These feats the whale doubtless performs with the aid of its lungs; when resting at the surface it keeps them distended, when it wants to 'settle' or sink it either expels air from them or compresses them by muscular effort, as Delage suggests. The blubber is, therefore, thick enough to buoy up the whale's body with, but not without, the aid of the lungs.

With the exception of the lungs, when in a distended condition the blubber is the only tissue of the whale that is lighter than water, and the only one that can be used at all times to diminish the specific gravity of the body. Whales probably differ but slightly from one another as regards the relative weight of their internal parts, but obviously do so as regards their external ones—their 'whale-bone,' their fins, and the outer layers of their skin. Consequently, the blubber is thickest in species in which these parts are large and heavy, and the reverse in whales in which the opposite obtains.

In the Greenland whale the parts to be buoyed up appear to reach a maximum size and weight, and the blubber which has to sustain them a maximum thickness.

In a large Greenland whale killed in the Greenland Sea in 1887, the marketable whale-bone cleaned and dried alone weighed 25 cwt., a single plate (the longest one) weighing 9 lb. 5 oz. How much the other parts weighed is uncertain, but the following are their dimensions; namely, pectoral fin, length externally, 8 feet 2 inches; breadth, 5 feet 1 inch; caudal or tail fin, breadth from tip to tip about 24 feet; epidermis, thickness, ¾ of an inch; while the thickness of the blubber that buoyed up these parts and made it possible for the lungs to bring the body into equilibrium with the water displaced, was 15-18 inches (on the body or over the muscular parts) and yielded 25 *tons* of oil.

In the young Greenland whale the epidermis is even thicker than in the adult, and the blubber relatively thicker as well. In a calf examined by Scoresby the epidermis was 1¾ inches thick: "It was so extremely fat," says this trustworthy witness, "that we obtained a quantity of blubber from it calculated to yield six *tuns* of oil, a produce equal to that of a 'size fish' of six or seven feet bone . . . and the body when stripped of the fat, that is, the blubber, was so small as to be quite within the power of our tackles (to heave up). In another 'sucker' or 'calf,' 19 feet in length, the blubber on an average was 5 inches in thickness, the largest of the whale-bone measured only 12 inches, of which about one-half was imbedded in the gum."

During adolescence, and until the adult stage is reached, the epidermis and blubber (and consequently the yield of oil) both diminish in thickness; the first absolutely, the second only relatively.

Seven young animals captured in the Greenland Sea in 1886, with the 'sample' or longest plate of whale-bone averaging 6 feet in length, yielded only 36 tons, or on an average about the same as Scoresby's calf; and in another killed in 1888—42 feet in length, with the longest plate of whale-bone 7 feet 6 inches in length—the thickness of the epidermis was less than an inch, that of the blubber being 8 inches.

Except in early life, the weight of oil yielded by the blubber is definitely related to the length of the longest or sample plate of whale-bone and to the total weight of the marketable whale-bone—in other words, the thickness of the blubber is in proportion to the size of the animal.

Photochemical Clustering.

In a paper describing experiments on the photochemical decomposition of nitrous oxide (*J. Chem. Soc.*, 1; 1928) Dr. James Younger Macdonald finds among other things that four molecules of N_2O decompose for each quantum of energy absorbed. The striking agreement between this value of $M/h\nu$ and the value obtained for M/N in the α-ray reaction suggests, according to Lind (*J. Phys. Chem.*, **32**, 575; 1928), a similarity in the mechanism of decomposition, namely, *clustering* about an excited N_2O molecule on one hand and about an ionised one on the other. This suggestion deserves consideration, especially in view of the failure of mechanism proposed by Macdonald, namely,

$$\begin{aligned}&(1)\ N_2O + h\nu = N_2O'\\&(2)\ N_2O' + N_2O = O_2 + N_2 + 2N\\&(3)\ 2(N + N_2O = NO + N_2).\end{aligned}$$

The second step, according to the best data, requires at least 80,000 calories more energy than is available. In view of this, Dr. Macdonald, who originally used a minimum value for the energy of dissociation of nitrogen, has now abandoned the special mechanism which he put forward (private communication). The clustering, however, of three molecules about an active one leading to decomposition as

$$4N_2O = 3N_2 + O_2 + 2NO$$

is very possible thermodynamically.

With Dr. Macdonald's permission to publish the contents of his letter, it may be said that other mechanisms proposed therein are pure speculations, as he himself realises. The best of them admits of differences between oxygen atoms in their effects on N_2O. Furthermore, he proposes to add H_2 to the decomposing N_2O. In the event that O atoms are formed he expects water would result from

$$H_2 + O = H_2O.$$

It is doubtful whether this reaction would go in spite of its exothermic nature to the extent of about 140,000 calories, since H_2 can be considered a pseudo-atom with a helium-like structure. Furthermore, unless radiation is emitted and the water molecule occupies a definite quantised state, the principle of conservation of energy and momentum is violated, except in the almost zero probability case, in which the relative kinetic energy of the colliding systems plus the energy of combination corresponds exactly to a quantised state of the water molecule. Therefore a third body would have to intervene in order to remove the energy. Such triple collisions would be rare in view of the atomic pressure. If the life period of the activated N_2O is of the same order of magnitude as that of other systems involving roughly similar electron jumps, then it is possible to distinguish between the *clustering* theory and Macdonald's idea of a binary collision as the first step, by working at low pressures, using a method employed by the writer in his work on hydrogen iodide (*Proc. Nat. Acad. Sci.*, **13**, 720; 1927; *J. Phys. Chem.*, **32**, 270; 1928).

One hesitates to put forward any definite and general theory regarding clustering in photochemical reactions. The examples in which agreement is found between the photochemical and α-ray yields are exceedingly few (see Lind, "Chemical Effects of Alpha Particles," second edition, p. 144, 1928). In one of these at least (photochemical decomposition of hydrogen iodide or bromide), the experimental work of the writer (*loc. cit.*) indicates that clustering is out of the question. The others involve either reaction between two different systems or else yields of less than unity. Even in the decomposition of N_2O, it is difficult to understand the survival of two impacting molecules having more than sufficient energy to decompose, since it has been shown that two N_2O molecules undergo thermal decomposition when the energy increment is only 58,000 calories (Hinshelwood. "Kinetics of Chemical Change in Gaseous Systems"). Such survival would imply electronic stability of the excited molecule until sufficient 'clustering' impacts had been undergone.

Still, cases involving survival of an excited molecule after collision are not lacking. On the other hand, much can be said for the idea of photochemical clustering in reactions involving association or polymerisation. It is important that examples of association be found for comparing the photochemical and α-ray yields; Lind ("Chemical Effects of Alpha Particles," p. 145) has studied the ionic clustering of certain unsaturated hydrocarbons. For acetylene he finds a value for $M/N = 20$. Interest is therefore attached to the yield in the photochemical polymerisation which is reported to take place (Berthelot and Gaudechon, *Compt. rend.*, **150**, 1169; 1910; Bates and Taylor, *J. Am. Chem. Soc.*, **49**, 2444; 1927).

Negrito Racial Strain in India.

The presence of a negrito strain in the aboriginal population of India has been suspected for a long time, but any definite evidence as to its existence has been lacking so far. Thus in the opinion of the Sarasin Brothers "no one has yet succeeded in finding pure woolly hair in India" (*Ergebnisse naturwissenschaftlichen Forschungen auf Ceylon*, 3, 355; 1893), a view which has also received the support of Turner (*Transactions of the Royal Society of Edinburgh*, 40, 114; 1905), Lapicque (*Revue Scientifique*, 6, July 1906), Thurston ("Tribes and Castes of Southern India," vol. 1, Introduction, 1909), and Risley ("The Peoples of India," p. 15, 1915).

During a recent visit to the Kerala country I measured a large number (seventy) of Kadars living in the Cochin Hills (Fig. 1). The majority of this people are not unlike the other jungle tribes of southern India, having a head of hair varying from wavy to curly, but in the extreme interior of the hills I was fortunate enough to find five men and one woman with undoubtedly spirally curved hair, one of whom was pure woolly with short spirals, and the rest were of the frizzy type, similar to that seen among the Melanesians. Besides their spirally curved hair, the Kadars are short (average stature, 1516 mm.), of very dark complexion (the skin colour varying from 29 to 33 in von Luschan's scale), prognathic, and have not infrequently receding foreheads. I was informed by Mr. K. Govinda Menon, Conservator of Forests of the Cochin State, and one who has known the Kadars very intimately for the last quarter of a century, that in the early years of his service he noticed at least a dozen men and women with woolly and frizzy hair, but who must have died out since.

Fig. 1.—Two Kadar men from the Cochin Hills.

The head measurements of the Kadars do not show them to be brachycephalic, the average cephalic index of the five men (with spirally curved hair) measured by me being only 75·06. Of these five men, however, two are mesocephalic, with 79·29 and 77·34 as their respective cephalic indexes, while the rest are in the lower grades of dolichocephaly. It is not improbable that the negrito element among the Kadars was originally brachy-, or at least mesocephalic, but in its admixture with the long-headed Vedda-like race, which forms the dominant element among the Kadars to-day, the head has become considerably elongated.

It would not be safe to assume anything more until further investigations take place, but it is just possible that the detailed analysis of the measurements to be published later may throw some light on the question. In this connexion it is interesting to note that the designs on the bamboo combs worn by Kadar women ("Die Zauberbilder Schriften der Negrito in Malakka," by K. T. Preuss, *Globus*, 1899) are strikingly similar to those of the Semangs—a negrito tribe of the Malay Peninsula with short stature, dark complexion, and medium head (Av. C.I. 79), who are not unlike the Kadars in general appearance.

New Regularities in the Band Spectrum of Helium.

By the work of Curtis and Fowler, the structure of the band spectrum of helium has become well known. More recently, Weizel and Füchtbauer (*Zeit. f. Phys.*, 44, 431; 1927) added considerably to our knowledge of the spectrum by detecting a number of new bands which they could ascribe to transitions between terms with the oscillational quantum number one. Nevertheless, there appear to be in the spectrum still many lines which have not yet been arranged into bands. As the helium band spectrum is of considerable theoretical interest, we have analysed those parts not yet studied by previous investigators.

As these parts are very rich in lines, it was necessary to use high dispersion. With a suitably constructed powerful discharge tube it was possible to photograph the spectrum with sufficient intensity in the first, second, and third orders of a 15 ft. concave grating. We were able to find more than twenty new bands, and a number of parts of other bands which we hope to be able to complete in the near future. Most of the new bands have the $2p$ state as final state. The initial states have, however, a structure different from that of the terms discovered by Curtis as they cannot be represented in first approximation by a quadratic formula. This and the fact that they combine in a different way with the $2p$ terms causes the appearance of the new bands to be much different from that of the other helium bands, and bands of a similar structure do not seem to have been found either in other band spectra.

The band $2p - 3z$, for example (we designate provisionally the new terms by the last letters of the alphabet), has only a P- and a Q-branch, the R-branch being absent. The band $2p - 3x$ has a strong P- and R-branch; the Q-branch is absent or very weak. The band $2p - 3y$ has three branches which have the appearance of a Q-branch, a P-branch and a branch in which the *effective* rotational quantum number decreases by two units. Whereas many bands overlap in the more refrangible side of the spectrum and make its structure there extremely complicated, the arrangement of bands is quite open in the region between 5700 A. and 6700 A. There we have, except the bands $2p - 3d$ and $2p - 3s$ discovered by Curtis, the bands $2p - 3x$, $2p - 3y$, $2p - 3z$, and the *five* analogous bands for par-helium, which have exactly the same structure but are much fainter than the ortho-bands. The absolute values of the $3x$, $3y$, and $3z$ terms lie between those of the $3s$ and $3d$ terms. We have not yet succeeded in unravelling the structure of par-helium $2P - 3D$, but only locate its position.

Besides bands in which terms of a new type are involved, we found new bands originating from the combination of Curtis's terms with the vibrational quantum number one and two, and could thus extend the results of Weizel and Füchtbauer. For the transition $2s - 3p$, *e.g.*, the following bands are now known $0 \rightarrow 0$ (λ465 mμ); $0 \rightarrow 1$ (505); $1 \rightarrow 1$ (467); $1 \rightarrow 0$ (432); $1 \rightarrow 2$ (505); $2 \rightarrow 2$ (468). Of these, 465 is the main band analysed by Curtis, 505 and half of 467 were found by Weizel and Füchtbauer. Evidence was found that the discrepancy between the zero lines of the $p - R$ and the Q-branches found by Curtis is due to the slightly different vibrational frequencies of the p_a and p_b terms (especially well marked in the $2p - 3d$, $1 \rightarrow 1$ band for the $3d_a$ and $3d_b$ terms). If it can be postulated—as theoretical considerations and the results obtained from other band spectra make probable—that the *a*- and *b*-states are exactly coincident for the vibration- and rotationless molecule, this discrepancy can be regarded as another experimental proof for the half-integer values of the vibrational quantum number.

In another note we hope to discuss the theoretical significance of the new levels. Details about the work can be found in a series of forthcoming articles in the *Zeit. f. Physik* and the Scientific Papers of the Institute of Physical and Chemical Research, Tokyo.

New Type of Discharge in Neon Tubes.

It was found some years ago by one of us (J. W. R.) that if a condenser of the order of a microfarad capacity was discharged through a tube containing neon at a pressure of about 10 mm. with an adjustable resistance in series, then when the resistance was reduced below a certain value there was a marked change in the character of the discharge, distinguishing clearly the new type of discharge from others obtainable in such tubes.

Further study now makes possible a brief statement of the general properties of discharges of this type.

The appearance of the tube during the passage of the heavy current discharge is quite different from that for the normal neon glow discharge, which in the tubes used amounted to a few milliamperes only. The heavy current was marked by a small bright spot or scintillation of bluish light at a single point on the surface of the cathode. In this neighbourhood the nickel spectrum could be seen. The spot was almost always either on the weld between the cathode disc and its supporting wire or on the square-cut edge of the disc. When the discharge passed a sharp click could usually be heard. Occasionally, instead of the bright spot, there was a violet flash between the electrodes, and the current recorded was about one-half the expected value. Conspicuous fluorescence of the glass usually occurred.

That some special conditions at the electrodes are necessary is shown by the fact that in some tubes when one of the two apparently similar electrodes is made cathode heavy currents are obtained, whereas with the other as cathode they are not.

It was found that the value of the current depends chiefly on the circuit conditions external to the tube, particularly the resistance and the condenser voltage. Currents of various magnitudes between 100 amp. and 1·6 amp. were measured and were found to repeat fairly well for successive discharges under any given set of conditions.

A point of clear distinction between this and the glow discharge is that a change in the area of the electrodes (over a range of at least 10 to 1) did not affect the value of the current.

The voltage across the tube at the moment of maximum current falls to a low value, about 20 volts for the smallest currents, rising to a constant value of 60 volts for all currents above 20 amperes.

After the discharge is over, the condenser is usually found to have some charge still remaining, the voltages varying from zero up to about 90 v.; with a normal neon glow discharge this voltage would be about 130 v. Where there is no resistance in circuit the final voltage is sometimes of the opposite sign to that of the original charging, indicating that the discharge was oscillatory. For this to occur in the circuit used, the effective resistance of the discharge could not have exceeded one or two ohms.

A further characteristic property of the discharge should be mentioned. If the capacity of the condenser or alternatively the charging voltage is sufficiently low, a heavy current is not obtained every time the condenser is discharged; indeed, there is a regular relation between the value of the capacity and the probability of a heavy current discharge.

Disappearance and Reversal of the Kerr Effect.

A beautiful confirmation of recent theories of the electric birefringence in liquids (C. V. Raman and K. S. Krishnan, *Phil. Mag.*, April 1927) is furnished by observations of the phenomenon in electric fields oscillating with radio-frequency such as may readily be obtained with thermionic valves. The Kerr effect arises from the orienting action of the field on the molecules, and the time taken by the latter to adjust themselves to a state of statistical equilibrium has naturally to be taken into account. It may be pointed out here that the orienting couple acting on the *permanent* electric moment of the molecule (assumed to be chemically polar) stands on a different footing from the couple acting on the oscillating *induced* moment in it. The couple acting on the permanent moment is purely periodic, and its effect must tend to disappear at sufficiently high frequencies. The couple on the induced moment, on the other hand, has a quasi-static part and tends to persist even at optical frequencies.

The Kerr effect expressly due to the polarity of the molecule must thus disappear at high frequencies, while the non-polar part will continue. In certain polar liquids, for example, chloroform or the higher alcohols, the Kerr effect is negative and may be considered as the resultant of a *negative polar*, and a *positive non-polar* Kerr effect. In all such cases we should expect the Kerr effect to *diminish and vanish as the frequency is increased*, and then to *reappear* at still higher frequencies.

Observations with octyl alcohol made by us confirm this remarkable prediction, the Kerr effect disappearing at 32 metres frequency and reappearing at still shorter wave-lengths. Cooling the liquid with a freezing mixture shifts the frequency of disappearance and reversal to longer wave-lengths, as might be expected.

The *Discovery* Expedition.

By Dr. STANLEY KEMP.

IN a previous issue of NATURE (Oct. 30, 1926, p. 628) an account was given of the work of the *Discovery* Expedition up to the end of June 1926: the investigations since that date, to the conclusion of the commission on Sept. 29, 1927, form the subject of the present article.

The work at whaling stations during this period has been continued mainly under the direction of Mr. N. A. Mackintosh, and a note by him on this side of the investigations is given below. This shore work has now been in progress for two and a half seasons at South Georgia and for one season in South Africa, and the whales examined, nearly all Blue and Fin, have reached a total of 1685: never before has so large a number been the subject of scientific investigation. The task of working up the data has only just begun, but already there are indications that results of great economic importance will be gained.

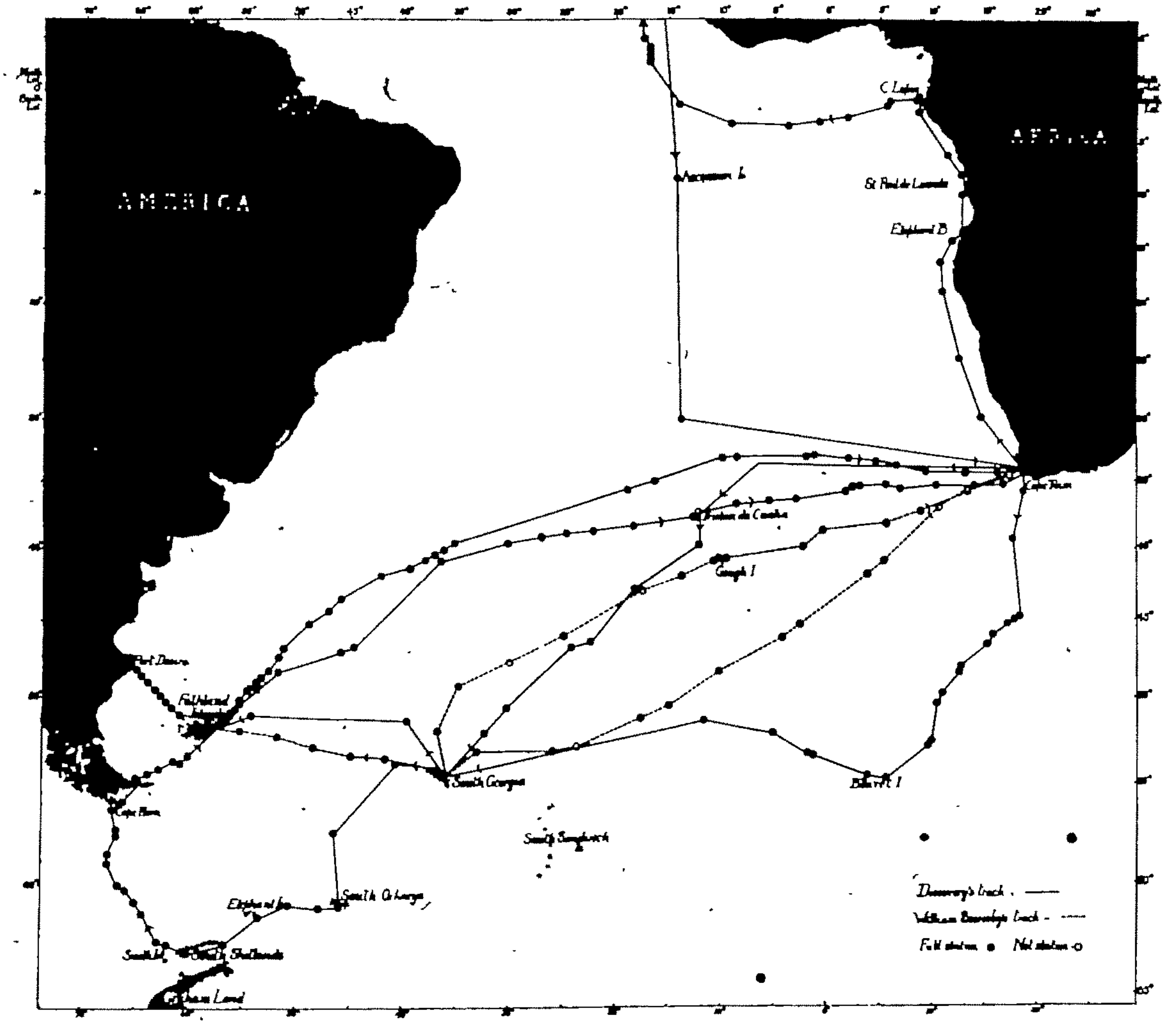

FIG. 1.—Chart of the South Atlantic, showing the tracks of the *Discovery* and *William Scoresby*.

Among other work at the South Georgia station reference may be made to investigations on the elephant seal and on birds by Mr. L. H. Matthews: it is hoped that papers embodying his results will be published at an early date.

As noted previously, the *Discovery* reached Cape Town after her first season's work on June 29, 1926, and she proceeded almost immediately to the Admiralty Dockyard at Simonstown for refit. Hitherto the excessive rolling of the ship had been a serious hindrance to the work, and to minimise this defect sister-keels were fitted. The keels proved very effective in reducing the extent of the roll, but they unfortunately interfered with reception from the echo-sounding apparatus, and in consequence the deep water gear could not be used. On completion of the refit, the *Discovery* left for a short cruise on the south-west coast of Africa before returning to South Georgia for the next season's work. Off Saldanha Bay, where two whaling stations are located, a line of planktonic and hydrographic stations was taken and a series of hauls with large closing nets was made in deep water. In order if possible to obtain some knowledge of the diurnal movements of the plankton on the whaling grounds, hauls with closing nets, towed horizontally, were made every four hours during a 24-hour period.

In the meantime the second vessel of the expedition, the *William Scoresby*, had arrived from England, and in October both ships left for South Georgia. The tracks of the two ships are shown in Fig. 1. The *William Scoresby*, with Mr. J. E. Hamilton in charge of the scientific work and Capt. G. M. Mercer in command of the ship, took a direct course, making a series of observations on the plankton during the passage. The *Discovery* attempted a more southerly route with the object of testing the theory that the entire fringe of the Antarctic continent is potential feeding ground for whales. It was our aim to proceed due south past Bouvet Island and to work to the west in high latitudes where easterly winds might be expected to prevail; but abnormal ice conditions frustrated this hope. Near Bouvet Island, which we approached within a short distance, dense pack-ice was encountered, through which it was impossible to make headway, and we were obliged to turn west while still in the track of the westerly winds. With shortage of coal the passage proved one of exceptional difficulty, and we counted ourselves fortunate when we reached Cumberland Bay on Dec. 5.

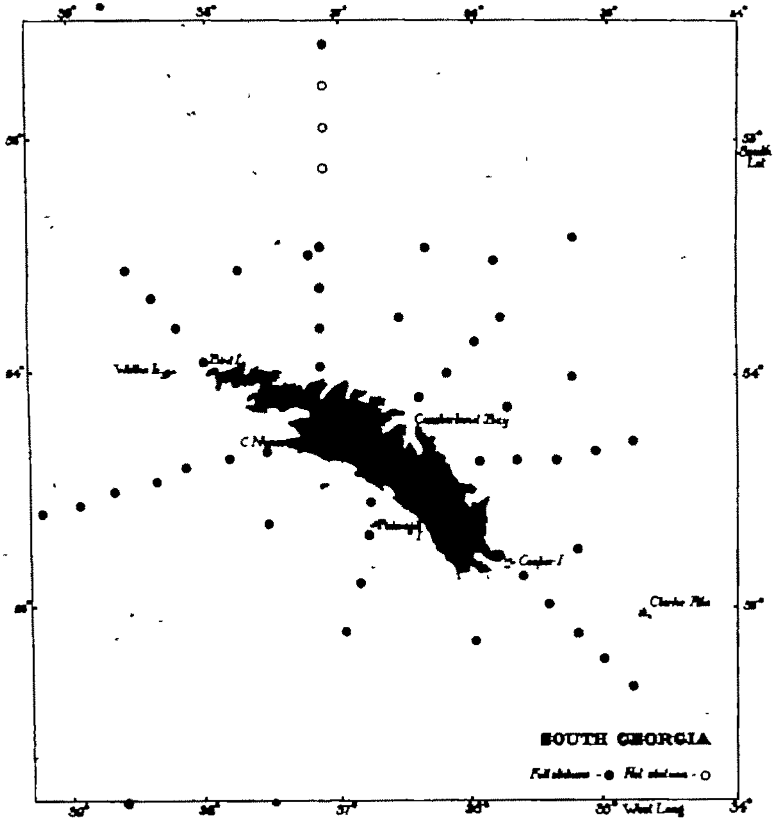

Fig. 2.—Chart illustrating work carried out off South Georgia during December 1926 and January 1927.

The *William Scoresby* had arrived earlier, and before long the two ships set about an intensive study of the conditions on the South Georgian whaling grounds. Mr. A. C. Hardy, in charge of the work on the *William Scoresby*, was in wireless touch with me throughout, and, thanks largely to the great enthusiasm of everyone concerned, the full programme, as illustrated in Fig. 2, was completed. At each of the stations a series of vertical hauls was made with closing plankton nets, covering in standardised sections a column of water from bottom to surface, and two flights of nets towed horizontally, one of coarser and one of finer mesh, were taken in the upper layers between the surface and a depth of about 150 m. The hydrographic observations include full serial readings of temperature, salinity, and phosphate at each of the stations, oxygen determinations at every alternate station, and hydrogen ion concentration values over a considerable area on the north-east side of the island. As a result of this work, we possess material and data from which a precise picture can be drawn of the organic and physical conditions on the whaling grounds at this period. Much can be learnt from a study of these data, and if the observations can be repeated in subsequent years the conditions in different seasons can be compared.

At the conclusion of this survey the *William Scoresby*, with Mr. N. A. Mackintosh in charge, left for Port Stanley, taking a line of hydrographic and plankton stations on the passage, and then began a trawling survey of the continental shelf between the Falkland Islands and South America. The trawl was used at thirty separate positions, and a line of hydrographic stations taken between West Falkland Island and Port Desire in Patagonia. The trawling survey is being continued during the present season, and an account of the results obtained cannot usefully be given until it is completed.

The *Discovery*, after dredging and trawling for a short time on the South Georgian coast, left for the South Orkneys, arriving after a slow and very rough passage, during which only two stations could be taken. At the South Orkneys great numbers of icebergs were encountered, and on the further passage to the South Shetlands one was found which was 35 miles long; another, reported by the whaling community, was said to have exceeded 100 miles in length. All these bergs appear to have come from the Weddell Sea.

We reached Deception Island, the centre of the South Shetland whaling industry, on Feb. 26, and after a few days steamed south to Melchior Harbour in Schollært Channel and to Port Lockroy in Wiencke Island—both in the Palmer Archipelago. We passed through Bismarck Strait and made plankton observations at a station situated in latitude 64° 58′ S., but were unable owing to bad weather to undertake any hydrographic work. Some trawling and dredging was done in the sheltered channels among the islands, where the fauna was found to be one of very great richness. A large species of *Umbellula* was abundant, together with another remarkable alcyonarian probably belonging to the family Xeniidæ. Elasipod and other peculiar holothurians were plentiful, and, among cephalopods, a very large purple *Cirroteuthis* was taken: amphipods and pycnogons occurred in great quantity. Several species of *Cephalodiscus* were found, and with them what appear to be some early developmental stages. On the return passage to Deception Island a line of stations was taken in Gerlache Strait. Work in this area ended with two lines of full plankton and hydrographic stations across Bransfield Strait (not shown in Fig. 1), in the course of which we took immense numbers of larvæ of *Euphausia superba*, the euphausian which in these waters and on the evidence obtained constitutes the sole food of Blue and Fin whales.

The return passage to the Falkland Islands was taken by way of Cape Horn, and owing in no small degree to a spell of particularly favourable weather, good series of observations were made across Drake Strait. Results of considerable interest were obtained in both plankton and hydrography, the most significant feature being the presence of a warm mid-water layer of water on the southern side of the Strait. After a few days at St. Martin's Cove in Hermite Island, close to Cape Horn, the passage to the Falklands was continued, a series of further observations being made on the way. We arrived at Port Stanley on May 6 and found the *William Scoresby* awaiting us after completion of her trawling programme.

Shortly afterwards both vessels left for Cape Town. The *William Scoresby*, with Mr. A. C. Hardy in scientific command, first went to South Georgia, where, with the view of ascertaining the conditions at the close of the whaling season, she repeated a line of stations on the north-east side of the island. Her subsequent course to Cape Town was made via Gough Island, where a party landed, and throughout the passage systematic observations were made on the plankton. The *Discovery* took a direct course via Tristan da Cunha —a second visit to the islanders proving impossible by reason of weather conditions—and made a similar series of plankton investigations on the way.

Soon after her arrival in Cape Town, the *William Scoresby* sailed for England, while the *Discovery*, after a brief period in dock, cruised up the west coast of Africa. The line of stations off Saldanha Bay was repeated, and throughout the passage until arrival at St. Vincent plankton observations were continued. The plankton throughout this passage was of very considerable interest. Among cœlenterates, siphonophores of great beauty were taken, some belonging to the genus *Crystallodes*, and a mysterious form, which defied the zoological knowledge on board but has since been identified as 'Semper's larva.' At some positions cymbuliid pteropods were found in astonishing numbers, and a small fresh-water prawn (*Atya*) was caught in the open sea many miles off the mouth of the Congo river. Fish and crustaceans, often provided with great numbers of luminous organs, were abundant. One night a remarkable luminescent effect was observed, due to a ctenophore of the genus *Deiopea*. Most surface forms which are capable of producing light luminesce only when some mechanical stimulus is provided, such as contact with the ship, the movement of the propeller, or a rough sea. The *Deiopea*, however, on a perfectly calm night, and over an area which extended as far as could be seen in every direction, were emitting momentary but most vivid flashes. Owing to the numbers present in the water, the effect produced was one of the most remarkable seen during the voyage.

We touched at Elephant Bay and St. Paul de Loanda in Angola, and at Port Gentil in French Congo, with the object of visiting whaling stations, and also landed on Annobon Island in Spanish Guinea. Whaling has unfortunately proved unprofitable on this part of the coast, and the stations visited were found to have ceased operations. The *William Scoresby* reached England on Aug. 14 and the *Discovery* on Sept. 29.

One or two points remain to be noticed. It may be remembered that when the *William Scoresby* was commissioned, it was hoped that she would be able to undertake the marking of whales with the view of tracing their migrations. In this work we have so far had little success, for it was found in practice that owing to certain structural defects in the vessel, the operation of marking was unexpectedly difficult. The necessary alterations were made, however, while the ship was in England, and we hope for better results in the future. The experience we have had indicates that the marking of whales is a practicable method of research.

In the brief outline of the work of the two ships it will be noticed that plankton observations have been made at a great number of points covering a very considerable part of the South Atlantic. This work has been done to a carefully standardised programme and in working up results the hauls may be regarded as strictly comparable if the assumption is made that the plankton is uniform over comparatively large areas. To ascertain the truth of this theory was one of the objects for which the 'continuous plankton recorder' was invented by Mr. Hardy (see NATURE, Oct. 30, 1926), and with this instrument records of plankton extending over nearly 2400 miles of our course have been taken. We have also on several occasions made continuous hauls over long distances with surface nets. Both methods show an almost startling lack of uniformity in the plankton, and teach us that it is only by working on broad lines that results of real value can be obtained.

Opportunities for survey work were limited, but Lieut.-Commdr. J. M. Chaplin made the utmost use of all that came his way. Harbours in South Georgia and the South Shetlands were surveyed, and numerous corrections made in our charts of these little-known regions.

It will be seen that in the second season's work we have been more successful than in the first—a result due in no small measure to the efficient help given by the *William Scoresby*. We have made a detailed survey of the conditions on the whaling grounds of South Georgia, with some work on the same lines in Bransfield Strait and off Saldanha Bay in South Africa. We also have a considerable number of observations on plankton and hydrography in the region bounded by Cape Horn, the Falkland Islands, South Georgia, and the South Shetlands, and plankton material obtained on a system of comparable hauls over a much more extensive area.

My thanks are due to Commdr. J. R. Stenhouse, Capt. Mercer, and to all officers and men for their continuous efforts to carry on the work, often in the face of very considerable difficulty, and to the scientific staff, both on the ships and at the shore station, for their enthusiastic support in every programme that was attempted.

In the course of the work a great number of hydrographic observations have been made, and very large zoological collections obtained, and this material is being studied, with particular reference to its economic value, by those of the scientific staff who are now in England. The systematic treatment of some of the zoological collections is being undertaken by specialists, and the publication of results will shortly begin.

The *William Scoresby*, with Mr. D. D. John and Capt. H. de G. Lamotte respectively in scientific and executive command, is again at work in South Georgia, and the shore station, with Mr. F. C. Fraser in charge, has been reopened. It is expected that most of the scientific staff at present in England will leave for further work in the south towards the end of this year.

WORK AT THE WHALING STATIONS.

By N. A. MACKINTOSH.

The previous description of the work of the marine station at Grytviken (included in the article in NATURE, Oct. 30, 1926) dealt mainly with the observations made there at the whaling station from February 1925 until March 1926. Since that period a further 455 whales were examined at Saldanha Bay, Cape Colony, from June to October 1926, after which work was resumed at South Georgia, where 490 whales were examined between November 1926 and April 1927. The material and data obtained are now being studied in England.

As was previously explained, it was desirable that work should be continued in South Africa during the southern winter in order that observations should extend over the whole year. Records of the lengths of fœtuses obtained at South Georgia clearly indicate that both pairing and parturition take place for the most part during the southern winter, and it was therefore hoped that the work at Saldanha Bay would lead to a more accurate knowledge of the breeding of whales. Observations on the adult females taken there were very instructive, but it was not possible to examine nearly as many as was desirable, since the vast majority of whales taken in this locality are immature. Evidence of œstrus taking place at this time of year was, however, found, and several very small fœtuses were collected. Three of these measured 20 mm. to 30 mm., and one, a Sei whale embryo, measured 2 mm. to 3 mm.

As at South Georgia, the catches at Saldanha Bay consisted almost entirely of Blue and Fin whales, other species being practically negligible. Between 80 and 90 per cent of the Blue and Fin whales we examined were, however, immature, and both the abundance of whales and the proportion of adults remained roughly constant during the period we were there. During the final season's work at South Georgia, whales were caught throughout in large numbers, Blue whales being specially abundant.

An interesting comparison can now be made between the whale 'populations' of South Georgia and the south-west African coast. At the latter locality we have two classes of whales—the small immature whales which are abundant, and the large and fully mature whales which are comparatively scarce. The number of intermediate sized whales is very small. At South Georgia the whale community is quite different and much more complex. The population is more representative, but undergoes important changes during the season through the arrival and departure of different 'sets' or herds of whales which may differ in respect of sex, age, condition, etc. The constitution of the whale community may also differ from season to season. In view of these fluctuations, it is necessary to exercise caution in drawing conclusions from such estimations as the percentage of immature whales caught, the ratios of pregnant and lactating females, etc., as one cannot assume that the catches are representative samples of the whole stock.

A further study of the lengths of fœtuses which have been examined indicates that the period of gestation is about 10 months. The uncertainty regarding the rate of growth in the earliest stages of gestation, however, is the principal difficulty in making a precise estimation of the length of this period.

It appears that birth mostly takes place early in the southern winter, and a study of the lengths of young calves occurring in different months suggests that the nursing period lasts for five or six months, mostly in the winter. The young Blue whale appears to be weaned at a length of about 15 or 16 metres, and the young Fin whale at a somewhat shorter length. Growth is thus very rapid during the nursing period, but there are indica tions that it slows down very considerably after weaning.

It may be mentioned that external parasites which are rare on Blue and Fin whales at South Georgia, are abundant on those taken at the Cape, *Pennella* being particularly plentiful. Many of the whales examined at Saldanha Bay were also notable for the numerous and peculiar scars which are found on the body, mostly towards the tail. These are in the form of clean, cup-shaped holes in the blubber, and in the majority of whales they are found in all stages of healing. Old scars are quite common in this position on whales at South Georgia, but the unhealed pits are very rare.

The Problem of Artificial Production of Diamonds.

THE relations between the allotropic forms of carbon constitute one of the most baffling problems in chemistry. The hardness and incompressibility of the diamond point to its structure as being an exceedingly stable one, and the examination by X-rays proves it to have the tetrahedral lattice which accords with the known chemical properties of the carbon atom. On the other hand, graphite has its atoms arranged in sheets made up of hexagons, the carbon atoms in that plane being actually closer than in the diamond (1·42 instead of 1·53 Angstrom units), but the sheets are widely separated, their distance being 3·41 A., so that the structure is a loose one, corresponding with the easy cleavage. Graphite is readily produced from diamond at high temperatures, but the converse change has presented the greatest difficulties, graphite having shown itself under all conditions to be the more stable modification. It has been supposed that the atoms of carbon in the two substances differ in their electronic structure, the atom in diamond having four 2_1 orbits, and that in graphite only three 2_1 orbits and one of the 2_2 form, an arrangement which is consistent with the two space lattices and also with the great difference in electrical conductivity between the two modifications. It is doubtful whether specimens of graphite have ever been obtained quite free from other elements, and Prof. H. E. Armstrong has maintained that it always contains hydrogen, which is the cause of its open structure.

The diamond is found in Nature under conditions which afford little clue as to its genesis, but as it is converted into graphite by heat in the laboratory, it has seemed probable that it has been formed under a high pressure, and most attempts at its artificial production have started from this assumption. Of these, the most famous were those of Prof. Henri Moissan. Moissan's most successful experiments were made by melting pure iron with sugar charcoal in an arc furnace, and plunging the crucible containing the molten mass into cold water. The pressure produced by the rapid chilling of the outer crust was relied on to bring about the conversion of the carbon, so that it would crystallise from its solution in iron as diamond, and not, as usual, as graphite. The iron was successively treated with nitric and hydrochloric acids, with oxidising mixtures, and with fused potassium hydrogen fluoride to remove all minerals except diamond, and after the operation minute crystals were found, some of which had the optical properties of diamond and yielded carbon dioxide on combustion. Molten silver was also used as a solvent, with similar results. Sir William Crookes, working with the residues found in a bomb in which cordite had been exploded, the pressure being calculated to reach 8000 atmospheres, obtained similar crystals after the same chemical treatment. Crookes arrived at the conclusion that carbon, if sufficiently heated under a pressure of 2350 atmospheres, would be liquefied, behaving in this respect like arsenic, and should then crystallise on cooling.

Sir Charles Parsons carried out extensive experiments on this subject, the results of which were communicated in his Bakerian Lecture of the Royal Society for 1918. The main conclusions were:

1. That carbon, if melted or vapourised under a pressure of 15,000 atmospheres does not crystallise, as predicted by Moissan and Crookes.
2. That Moissan's supposition that great pressure was produced by quenching molten cast iron is erroneous.
3. That if the crucible, instead of being quenched, were subjected to a pressure of 100 tons per in.^{2} in a steel die under a press, less crystal residue was obtained.
4. That impurities in the iron, such as silicon, aluminium, magnesium, and chromium, greatly increase the amount of crystalline residue, whilst commercially pure iron melted and carburised with graphite yielded practically no residue.

All attempts to produce diamond by the rapid compression and adiabatic heating of acetylene and other substances (as by firing rifle bullets into cavities which they fitted closely), without the use of iron as a solvent, failed to give a crystalline residue.

The method of analysis adopted was that used by Prof. Moissan. Great uncertainties are involved, as there are no chemical reagents which can be relied on to dissolve every crystalline substance formed at such high temperatures other than diamond. Some of the minerals are extremely resistant to acids, even after prolonged boiling, whilst fusion with alkalies cannot be used, as it destroys diamond. The only certain test is that of combustion, microscopical examination being uncertain in view of the hardness and transparency of some of the spinels and carbides. When the crystals are very minute, all that can be done is to place them in a silica boat and heat in a current of oxygen, watching for a luminous flash when combustion occurs.

According to Prof. Le Chatelier, Moissan's supposed discovery has not been generally accepted in France, but at the time of the Bakerian Lecture his authority was such that Sir Charles Parsons accepted the statement that diamonds had been obtained, although he found it necessary to correct a number of details in the original account. Crookes also, speaking with high authority, confirmed the statements of Moissan, and described crystals which he regarded as being undoubtedly diamonds. He found one crystal, in particular, to show octahedral planes with dark boundaries due to a high index of refraction. He was able to distinguish such crystals with ease from those of carborundum, which are doubly refracting, but optical appearance alone would not serve to distinguish them from minerals of the spinel group. Unfortunately, although Moissan states in his book on the electric furnace that he prepared many artificial diamonds, no microscopical slides containing them are known to exist. The sketches reproduced by Crookes in his little book on diamonds only indicate that the crystals are of octahedral form and of high refractive index.

In view of the doubts which have been expressed as to Moissan's results, Mr. H. M. Duncan, who was associated with Sir Charles Parsons in his experiments, has repeated very carefully the various analytical processes, and his observations have been placed at our disposal by Sir Charles Parsons. It is found that spinels formed at a high temperature from magnesia and alumina, for example, are exceedingly resistant to repeated treatment with concentrated hydrofluoric and boiling sulphuric acids, and being colourless and crystallising in the regular system, they may readily be mistaken for diamonds. When a residue containing crystals of this kind is placed in a platinum boat and heated in a stream of oxygen in a tube of transparent silica, flashes are often observed, but the crystals of spinel are found to be unchanged. The flashes are to be attributed to carbon dust, which is often present in the air to such an extent that when an apparently clean boat is placed in the tube, many flashes are still seen.

Whenever Moissan's experiments with cast iron have been repeated, although many particles resembling diamond in appearance have been obtained, they have never withstood the combustion test. In order to prove that the methods adopted for removing foreign substances are not too severe, five very small fragments of boart have been placed in a platinum dish, and their size and appearance under the microscope noted, after which they were mixed with 15 gm. of iron filings and about a gram of graphite. The mixture was then subjected to chemical treatment until the whole of the iron and graphite had been removed. Microscopical examination showed that the particles of boart had not been destroyed, so that had similar particles been present in any of the residues from cast iron fusions they would not have been lost.

When repeating the experiments, the most characteristic residues were selected for combustion, and a blue pencil used to mark the position of each small crystal in the silica boat under the microscope, before placing it in the combustion tube. After heating at 900° in oxygen, which had been previously filtered through cotton wool, the boat could be again placed under the microscope. In one of these tests, five very characteristic crystals, photographs of which had been exhibited by Sir Charles Parsons at the Royal Society soirée in 1918, were tested in this way, and were found to be unburnt.

It is possible that Moissan's residues had become contaminated during the long period of their preparation. It is stated that in order to obtain sufficient material for a quantitative combustion test, no less than 80 ingots were made and dissolved. As the extraction with successive reagents is a most tedious process, there was ample opportunity for accidental contamination with carbon in the course of the operations.

Sir Charles Parsons and Mr. Duncan have also repeated the experiments of other workers who have claimed to have produced diamonds by artificial processes, but in every case the results have been negative. The conclusion seems inevitable that diamonds have not yet been produced in the laboratory, and that investigators have been misled into regarding as diamonds various transparent, singly-refracting minerals which happen to be very resistant to chemical reagents.

When graphite is heated to very high temperatures under pressures as great as 15,000 atmospheres, it remains perfectly soft, and there is no indication of the production of a new phase. This was confirmed by the experiments of Sir Richard Threlfall, published in 1908. The pressure produced in quenching molten cast iron in water or lead is not remarkably high, being limited by the yielding of the iron shell under stress, and the supporters of Moissan's views have therefore supposed that the action was not one of pressure, but of crystallisation from a solvent, which might be expected to give the less stable phase, whilst prolonged heating would convert it into the more stable graphite. Success had been claimed by Friedlander for experiments in which fused olivine was used as the solvent, but a repetition of the fusions, described in the Bakerian Lecture, gave negative results, and with such a solvent the chance of producing crystals which might be mistaken for diamond on a casual inspection is evidently great. Inconclusive experiments were made by O. Ruff in 1917, which showed that minute diamonds introduced into heated hydrocarbons under high pressure did not increase in size, but minute crystals which might have been diamonds were obtained from carbon in metallic solvents. The sources of error in all such observations having been detected, it must be admitted that the origin of the diamond in Nature remains an unsolved problem.

C. H. D.

Obituary.

DR. W. B. BLAIKIE.

WALTER BIGGAR BLAIKIE, LL.D., who died on May 3, was an extremely well-known figure in Edinburgh circles. Born in 1847, the son of a remarkable mother, his death severs a link with a past period. Educated at Edinburgh Academy, and the Universities of Edinburgh and Brussels, he began life as a railway engineer in the Public Works Department in India. He returned to Edinburgh after his marriage and joined the firm of T. and A. Constable, printers, with whom he remained associated until his retirement a few years ago.

In each of these very different professional tasks Blaikie showed the same remarkable vitality and intellectual energy. In particular he raised the productions of Constable's to a very high stage of artistic excellence. He was also warmly interested in the infirmary and other good works in Edinburgh. But besides, his activity overflowed into two channels in special, Scottish history and astronomy. In matters of history he was a recognised authority on special points and local history; in particular his "Itinerary of Prince Charles Edward" shows infinite pains in verifying details. In astronomy his interest was direct and original, especially in what he could himself create, preferably with his own hands. He devised numerous ingenious methods of prosecuting 'astronomy without a telescope.' He used to draw, print, and issue annually to his friends a book of monthly star maps, showing the position of the moon and planets, with tabular particulars. These issues were supplemented in different years by appendices on such subjects as the names of the stars, the fables of the constellations, etc., the product of a considerable amount of accurate, original work.

Perhaps the best of all Blaikie's devices was a graphical method of solving many common cases of spherical triangles, by means of two circular discs, engraved on celluloid, with two nests of coaxial circles, and rotatable about a common centre. By means of this, for example, the hour angle of a known star can be read at once from the usual observed data of a theodolite without engaging in any calculations. Blaikie preserved all his life a singularly boyish activity, so that, though actually he died at an advanced age, he never seemed to his many friends an old man. R. A. S.

PROF. WILHELM VON BRANCA.

THE eminent geologist and palæontologist, Prof. Wilhelm von Branca, died in Munich on Mar. 12, aged eighty-three years. Descended from an old Lombardy family, he was born in Potsdam on Sept. 9, 1844, and graduated as Ph.D. at Heidelberg in 1876. He began his academic career as *docent* in the University of Berlin in 1881, and his first professorship of geology and palæontology was in Königsberg in 1887. He succeeded Quenstedt in Tübingen in 1890, and was next for a short time at the Agricultural High School at Hohenheim. Finally, he succeeded Dames in Berlin in 1899, and remained there until his retirement in 1917.

Branca's earliest researches were in vulcanology, and he continued to be actively interested in the study of extinct volcanoes until 1894, when he published his well-known account of 125 'volcano-embryos' in Würtemberg. In stratigraphical geology, he added much to our knowledge of the Jurassic formations. In palæontology, he will be remembered for his researches on the initial chamber and the development of the suture lines in cephalopod shells, and for his memoirs on the ganoid fish Lepidotus and various other extinct vertebrates. As director of the geological-palæontological institute in the University of Berlin, he encouraged the systematic collection of fossils, and he was largely responsible for organising the expedition to German East Africa (now Tanganyika Territory) which made so many important discoveries of Dinosauria.

Branca was also an inspiring teacher, beloved by his numerous pupils, and throughout his career he exerted an important influence on the promotion of geological science in Germany.

WE regret to announce the following deaths:

Henri Bosmans, of the Jesuit College of Saint-Michel, at Brussels, author of many papers relating mainly to fifteenth, sixteenth, and seventeenth century mathematicians, whose works are not generally accessible, on Feb. 3, aged seventy-six years.

Dr. C. G. Cumston, president in 1925 of the International Congress of the History of Medicine and author of "An Introduction to the History of Medicine," on April 14, aged fifty-nine years.

Prof. Julius Hirschwald, who occupied the chair of mineralogy at the Technische Hochschule in Berlin from 1877 until 1921, aged eighty-three years.

Dr. John P. Munson, head of the department of biology at the Washington State Teachers' College, distinguished for his work in comparative cytology, on Feb. 27, aged sixty-eight years.

Mrs. Flora Wambaugh Patterson, formerly mycologist in charge of the pathological collections, U.S. Bureau of Plant Industry, on Feb. 5, aged eighty years.

Prof. W. W. Payne, of the observatory of the National Watch Company, Elgin, Ill., and founder of *Popular Astronomy*, on Jan. 29, aged ninety years.

Dr. E. C. Schroeder, superintendent of the Experiment Station of the Bureau of Animal Industry, United States Department of Agriculture, who had made important contributions to our knowledge of animal diseases, on Jan. 24, aged sixty-two years.

Mr. W. C. Tait, of Oporto, Portugal, author of "The Birds of Portugal" and a pioneer in the introduction of the eucalyptus tree in Portugal, aged eighty-three years.

Dr. Willard P. Ward, of Savannah, Georgia, known for his work on the metallurgy of manganese, on Jan. 17, aged eighty-two years.

Dr. Theodor Zincke, professor of chemistry in the University of Marburg from 1875 until 1913, author of a large number of publications, particularly in the field of aromatic chemistry, on Mar. 17, aged eighty-four years.

News and Views.

THE British Association has issued the preliminary programme of its meeting to be held in Glasgow on Sept. 5-12, under the presidency of Sir William Bragg, who in his address will deal with modern developments of the physical sciences and their relation to national problems. The subjects of the presidential addresses and discussions in the various sections include the reflection of electrons by matter, the photography and measurement of radiation, ancient geography in modern education (by Prof. J. L. Myres), the nature of skill (by Prof. T. H. Pear), the influence of engineering on civilisation (by Sir William Ellis), the archæology of Scotland (by Sir George Macdonald), and increasing returns and economic progress (by Prof. Allyn Young). Dr. Cyril Norwood will give the presidential address in the education section, which also will hold a discussion on broadcasting in the service of education, opened by Sir John Reith. One of the customary evening discourses will be given by Prof. E. A. Westermarck, on the study of popular sayings; this will be the Frazer Lecture in social anthropology, which is due for delivery in Glasgow, and to which members of the Association will, by the courtesy of the University authorities, be admitted. The other evening discourse will be given by Prof. F. G. Donnan under the title of "The Mystery of Life," the subject being considered from the viewpoint of physical chemistry. The delegates of corresponding societies, under the presidency of Dr. Vaughan Cornish, will discuss the preservation of scenic beauty in town and country. All the meetings, except those in the evening, will be held in the University, an unusually convenient arrangement. The Lord Provost and Corporation of Glasgow will give a reception and dance in the City Chambers, and the local committee a reception in Kelvingrove Art Galleries. Ample opportunity will be provided for visits to places of scientific interest in the country around Glasgow, and for studying the manifold economic interests of the city and the Clyde area, with their many outstanding examples of the value of applied science in industry and social conditions.

THE Royal College of Physicians has been celebrating this week the tercentenary of the publication of William Harvey's "De Motu Cordis," which was referred to in these columns on Mar. 31 (p. 507). In his Lumleian lectures before the Royal College of Physicians delivered in the spring of 1616, Harvey had explained his discovery of the circulation of the blood, but his views met with so much criticism that he was deterred from publishing an account of his work until 1628, when his little book, in Latin, was published from the press of William Fitzer, of Frankfort. This event marked the veritable birthday of modern physiology and scientific medicine. In honour of Harvey's memory, delegates from all parts of the world have gathered in London. H.M. the King received the company on Monday morning, May 14, and, in reply to the address by Sir John Rose Bradford, president of the Royal College of Physicians, remarked that we honour Harvey not as the author of a fundamental discovery alone, but as one who "discerned and taught that the true method of scientific progress is by observation and experiment." On Monday afternoon the delegates were formally welcomed at the Royal College of Physicians, addresses were presented on behalf of universities and scientific bodies, and the president conferred honorary fellowships of the College on Lord Balfour, Sir Ernest Rutherford, Prof. I. P. Pavlov (of Leningrad), and Prof. K. F. Wenckebach (of Vienna). This distinction has only been conferred in the past by the College very occasionally. After this ceremony, addresses on Harvey and his work were delivered by Sir Charles Sherrington, Prof. A. Chauffard (of Paris), and Prof. F. Keibel (of Berlin). The celebrations during the week included visits to University College, London, where demonstrations of Harvey's work were arranged. We hope to give a fuller account of the proceedings in a later issue.

THE recent celebrations commemorating the two-hundredth anniversary of the birth of John Hunter recall that his brother, Dr. William Hunter, F.R.S., was born on May 23, 1718, having thus a seniority of ten years. William was born at Long Calderwood, Lanarkshire, and after studying at Glasgow and Edinburgh he entered at St. George's Hospital, London. Thereafter his career was one of distinction and authority, though marked by conflict with his distinguished younger brother, with whom at one time he was a co-lecturer on anatomy at the Great Windmill Street School. In 1747, William had become a member of the Corporation of Surgeons, but, applying in 1756 to the Court of Assistants to be disfranchised, his request was granted, subject to the payment of forty guineas. He did not pay the fee, and shortly afterwards, when admitted a licentiate of the College of Physicians, he was ordered by the Court to pay a fine of twenty guineas for joining the College of Physicians without the consent of the Court. Hunter became physician extraordinary to Queen Charlotte in 1764, and, in 1768, first professor of anatomy to the Royal Academy. He was elected a fellow of the Royal Society in 1767 (also the year of his brother's election), and he contributed papers to that body. There is a three-quarter length portrait of Hunter, by Zoffani, in the apartments of the Royal College of Surgeons, but none in the National Portrait Gallery.

IN the early part of 1780, William Hunter, in a communication to the Royal Society, claimed the credit for an anatomical discovery made by his brother John twenty-five years previously. The latter dealt with the assertion in a caustic manner, avowing that his silence might be misinterpreted into an acknowledgment that he had intentionally claimed what was not his due. "I am as tenacious as he is of anatomical discovery," he wrote to Sir Joseph Banks, "and I flatter myself as tenacious also of truth." He then recounts the mode and incidents of the discovery, recording that "Dr. Mackenzie had injected the subject, and being unable as I conceived to explain an Appearance which he had found in dissecting it, sent for me. I came to him and having examined it further, explained the appearance in question then for the first time to my own satisfaction and that of Dr. Mackenzie; on the evening of the same day, full of my discovery, I came to Dr. [William] Hunter, and brought him with me to Dr. Mackenzie's to see and judge of the Explanation which I had given, and Dr. Mackenzie agreed to. This is my state of the fact upon which I grounded my belief of myself being the author of this anatomical discovery." William Hunter died on Mar. 30, 1783.

SIR JAMES WALKER, who delivered the Arrhenius memorial lecture before the Chemical Society on May 10, instead of speaking with the historian's detachment of one who, although so human and genial a personality, was an outstanding figure in contemporary science, chose to present a delightfully intimate sketch of the life and work of a close friend and one-time fellow student. Arrhenius was of course a pioneer of modern physical and biological chemistry. In selecting the conducting power of solutions for early investigation, he was doubtless influenced by the contemporary researches of Van 't Hoff, Raoult, Kohlrausch, and Ostwald, and by the theories of Grotthus, Clausius, Hittorf, and Helmholtz, but his choice was primarily due to a recognition of the potential value of a method for determining the molecular weight of substances which are not volatile without decomposition. His first measurements of electrolytic conductivity were directed to this end, but he soon recognised that the state of the conducting salt is a matter of primary importance. In his memoir, the record of experimental results was followed by an exposition of the germ of the later theory of electrolytic dissociation, although a precise account of the nature of the active (electrolytic) and inactive (non-electrolytic) portions was not then given. The important statement was made, however, that the active portion increases with dilution. In correlating theoretical considerations with experimental data, Arrhenius's next step was to show that "the molecular conductivity of the active part of an acid (in dilute solution) is constant and independent of the nature of the acid," and hence "the better the solution conducts electricity, the greater is its active part." Final formulation of the theory of electrolytic dissociation followed during the period 1886–1890, while Arrhenius was working with Ostwald in Riga or Leipzig, with Kohlrausch in Würzburg, with Boltzmann in Graz, or with Van 't Hoff in Amsterdam.

ARRHENIUS was indebted to Van 't Hoff for the nucleus which determined the crystallisation of his theory, for the application of the equation $PV = iRT$ to dissolved substances led to experimental values of i which for aqueous salt solutions were greater than unity. Arrhenius immediately realised that the value of i reflected the number of ions produced by the salts, and in a letter to Van 't Hoff in March 1887 he was able to state positively that the 'active molecules' are the dissociated molecules, and that (in opposition to Clausius's view) at extreme dilutions all salt molecules are completely dissociated. Arrhenius's work on other physico-chemical subjects, however, also merits recognition. He investigated, for example, the viscosity of pure liquids and solutions, the phenomena of conduction in hot gases and flames and of diffusion in aqueous solution, and studied also the velocity of hydrolysis of esters and the inversion of sugars. Although offered the chair of chemistry at Giessen in 1891, Arrhenius preferred to remain in his native country, and was appointed chief of the laboratory of physics at the Högskola at Stockholm, being designated professor in 1895; again refusing a foreign post, he became, in 1905, the director of the new Nobel Institute for Physical Chemistry. The stormy period of his career was now over, and until his death on Oct. 2, 1927, he was in Sweden a scientific oracle. His interest extended even to cosmic and meteorological problems, and in the beginning of the present century he directed his attention to serum therapy, contributing to the foundations of the new study of immunochemistry. Sir James Walker remarked that the character of much of Arrhenius's work is explained by his union of an aptitude for scientific speculation with an extraordinary facility for dealing with figures. Sweden can, he said, boast of many eminent names in science, of which two—Linnæus and Berzelius—are of the first magnitude; since the death of Berzelius she has had none to rank with these save that of Arrhenius.

THE subject of the discourse by Prof. Doris MacKinnon, delivered at the Royal Institution on Friday, May 11, was the intimate association of living organisms of different kinds for mutual benefit, especially those associations in which at least one of the partners is an animal. The phenomenon of luminescence in certain marine animals has recently been discovered to depend on the presence within the animal's body of captive bacteria having the power to emit light. In the colonial ascidian, *Pyrosoma*, these bacteria are intra-cellular, whereas in the cuttle-fishes they live in the cavity of the so-called accessory nidamental glands. In both these animals there are elaborate devices for ensuring that the developing young receive their bacterial supply from the parent. The majority of the other known associations have probably to do with food capture and with its digestion: and the very different methods in which green plants, fungi, bacteria, and animals feed, have to be borne carefully in mind. The green marine worm *Convoluta* is a good example of the more intimate sort of symbiosis associated with nutrition. Here the obligate partner is a minute green plant living in the worm's tissues and supplying it throughout most of its life with carbohydrates and fat in return for shelter and carbon dioxide. Many insects living on plant-juices or on blood are provided with pockets in the gut which contain yeasts or bacteria. Since here again precautions are taken to insure the infection of the next generation, it seems possible that these micro-organisms are not 'parasites,' but helpful symbiotes that somehow assist in the preparation of food for digestion. In one case, the wood-eating termites, that constantly harbour enormous numbers of tricho-nymphid flagellates in their guts, it has been shown experimentally that the host cannot get on without its guests.

IN an address on currency and credit delivered at the Royal Institution of Great Britain on May 4, the Right Hon. Reginald McKenna, chairman of the Midland Bank, referred to controversies relating to the proper constitution and functions of a central bank. He showed that the quantity of money in circulation varies with gold movements into and out of the country. The effect of these movements, however, can be counteracted or intensified by the buying or selling of securities on the part of the Bank of England, and indeed the Bank may go further and increase or diminish the amount of money on its own initiative. To give the Bank greater freedom in the exercise of these powers, proposals have been made to modify its constitution. This is a debatable question, as on one hand the Bank has behind it since 1844 a fine record of disinterested and public-spirited work, but on the other hand, with the present constitution of the Bank, important movements in gold supplies, wholly unconnected with monetary conditions in Great Britain, may react on trade and employment through their effects on currency and the price level. It might be argued that trade considerations should be taken into account in determining Bank policy, though Mr. McKenna admitted that a policy of leaving well alone has a great deal to recommend it, in view of the esteem in which the Bank is justly held. These questions, he pointed out, have a direct bearing on national prosperity, and are more worth public inquiry than some of the subjects which at one time or another have engaged the attention of Royal Commissions.

FURTHER particulars of the arrangements which have been made by the Society of Chemical Industry, in association with the Institution of Chemical Engineers, for the visit to Canada and the United States of America, and for the annual general meeting of the Society to be held in New York, are now available. Sailing from London on Aug. 10 in the s.s. *Megantic*, the visitors will reach Quebec nine days later, and full use will be made of facilities for night travelling to visit and inspect some of the most important and interesting cities and industrial plants. Thus, Aug. 20 will be spent at Shawinigan Falls; on the following day, a glimpse of Montreal and Ottawa will be afforded, and Aug. 22 will be devoted to the gold mines at Kirkland Lake. On Aug. 23 the International Nickel Company's refineries at Port Colborne will be visited, followed by a three days' stay at Niagara Falls, an important electro-chemical and electrometallurgical centre. Monday, Aug. 27, is reserved for a visit to Akron, Ohio, a great rubber manufacturing centre, and the next day for an inspection of a modern glass factory, the U.S. Bureau of Mines laboratories, and the Mellon Institute of Industrial Research at Pittsburgh. Thereafter follow visits to the E. I. du Pont de Nemours Company's dye works at Wilmington, Del., and to the famous Edgewood arsenal. During a three days' stay at Washington, D.C., visits will be paid to various U.S. Government scientific departments and laboratories, New York being reached in the evening of Sunday, Sept. 2.

THE annual meeting of the Society of Chemical Industry begins on the following day, Sept. 3, with informal and social meetings, and continues in business and technical session—with due provision for pleasurable social intercourse—on Sept. 4 and 6; Sept. 5 is entirely devoted to an industrial trip by boat, and to the Messel Medal award and address by Dr. R. A. Millikan, whilst on Sept. 7 there will be an excursion up the Hudson River, details of which are not yet available. By leaving New York on Sept. 8 by the s.s. *Celtic*, England is reached on Sept. 16. The total cost of the trip, excluding expenses incidental to the stay in New York, but covering tourist class steamship accommodation in both directions, single berths on trains, all meals and hotel accommodation up to arrival in New York, is £77, 2*s.*, with corresponding additions should superior arrangements be desired. Some members may prefer to visit only New York for the meetings; the cost of travel (tourist cabin) with hotel and other expenses for Sept. 2-8 will be about £60 in that case.

IN a recent speech at Birmingham, Sir Samuel Hoare dealt with air tragedies, and in particular with those that have arisen from high-speed and trans-Atlantic flights. After directing attention to the tremendous progress that has been achieved in aviation since an independent Air Force was created ten years ago, he stressed the cost that must be paid in human life for these advances and dealt with the question whether it is worth while. "Does the pursuit of speed," he asked in reference to Lieut. Kinkead's death, "justify the sacrifice ?" If it were only the pursuit of speed, no world's record would be worth it, he said, but just as many of the improvements in the motor-car are directly attributable to motor racing, so a definite advance in aeroplane design and in engine improvement results from high-speed flying. While paying tribute to the daring spirits that undertake trans-Atlantic flights, however, he denied that the effort is a wise one or that it serves a sufficiently useful purpose. On grounds of practicability, he does not consider it desirable to attempt either to prohibit these flights directly, or on grounds of expediency to impose such restrictions as will make them possible.

NINE new members were elected to the National Academy of Sciences of the United States at the meeting held on April 25, and Science Service of Washington, D.C., has issued some particulars of them: Dr. John August Anderson, astronomer at the Mt. Wilson Observatory in California, is known specially for his invention of a new type of earthquake recorder, in collaboration with his colleague, Dr. Harry O. Wood. Prof. William Mansfield Clark, of the Johns Hopkins University Medical School, has been largely responsible for the development of hydrogen ion concentration determination in the United States; he worked on the chemistry of cheese while in the bureau of dairy chemistry of the U.S. Department of Agriculture and later he was with the U.S. Hygienic Laboratory. Mr. Arthur Keith, of the U.S. Geological Survey, is an authority on the geology of the Appalachian Mountains. Mr. Charles Franklin Kettering, a vice-president and director of the General Motors Corporation, and head of the General Motors research laboratory, perfected and put on the market the 'Delco' lighting system; he developed the tetra ethyl anti-knock fuel for motor-cars and also perfected the 'Delco' ignition system. Dr. Alfred L. Kroeber, professor of anthropology at the University of California, is one of the leading authorities on the languages of the American Indian. Dr. Rudolph Ruedemann, State palæontologist for New York, is distinguished for his work on the fossils and geology of the Ordovician and Silurian of New York, and on pre-Cambrian continents. Prof. Philip A. Shaffer, professor of biochemistry at the Washington University Medical School, St. Louis, has carried out important investigations on human metabolism. Dr. George Malcolm Stratton, professor of psychology in the University of California at Berkeley, has investigated the psychology of vision and related subjects. Dr. Lewis Madison Terman, professor of psychology at Stanford University, California, is the author of the Stanford Revision of the Binet-Simon tests, and has done important work on intelligence measurement in children and others. Dr. Joseph S. Ames, provost of the Johns Hopkins University, was elected treasurer of the Academy, while Dr. W. B. Cannon, of the Harvard University Medical School, and Mr. Gano Dunn, a distinguished engineer of New York, were elected members of council. Dr. George K. Burgess, director of the U.S. Bureau of Standards, was elected chairman of the National Research Council, succeeding Mr. Gano Dunn.

MR. WILLIAM H. WRIGHT, astronomer of the Lick Observatory, Mount Hamilton, California, has been awarded the Henry Draper medal of the National Academy of Sciences. It will be remembered that Mr. Wright is to give the George Darwin Lecture of the Royal Astronomical Society on June 8 on the photography of planets.

RECENT appointments to scientific and technical departments made by the Secretary of State for the Colonies include two agricultural chemists, Mr. D. Manlove and Mr. W. A. Watson. Both are appointed to the Agricultural Department, Nigeria, chiefly for work on the products of the oil palm. The expansion of the inspection staff of the Nigerian Agricultural Department is continued, and six new produce inspectors are appointed: Messrs. J. R. Brown, D. W. P. Irons, L. J. Jackson, J. K. Peile, F. S. Philip, and N. W. Hardwick.

THE following have been elected foreign members of the Linnean Society of London: Thore Gustafsson Halle, chief of the Palæobotanical Department, Naturhistorika Riksmuseum, Stockholm; Robert Almer Harper, professor of botany, Columbia University, New York; Axel Johan Einar Lönnberg, Chief of the Vertebrate Department, Naturhistoriska Riksmuseum, Stockholm; Thomas Wayland Vaughan, director of the Scripps Institution of Oceanography, La Jolla, California; and Friedrich Zschokke, professor of zoology, University of Basle.

THE Council of the Royal Geographical Society has received a radio message from Captain Wilkins at Green Harbour, Spitsbergen, thanking the Society for the award of the Patron's Medal, and offering for the Museum of the Society the small British flag which he has carried through more than 15,000 miles of Arctic flying. The Council has gratefully accepted this gift, which will be placed beside the Union Jack flown by Sir Edward Parry on his sledge journey to Lat. 82° 45′ North a century before. Captain Wilkins will receive his medal at the anniversary meeting to be held on June 18; it is expected that both he and Lieutenant Eielson will be guests of the Society at the anniversary dinner on the same evening.

THE Empire Cotton Growing Corporation, Millbank House, 2 Wood Street, Millbank, S.W.1, announces its intention to award in June next not more than twelve studentships as follow: (*a*) research studentships to enable graduates with a leaning towards research to receive training in research under leaders in their subject, and (*b*) advanced study studentships to enable those holding them to receive specialised instruction in equipment for agricultural posts in cotton-growing countries. Both classes of studentship are of two kinds, namely, senior and junior. Each studentship will be tenable for one year, and of the value of £250, plus a further sum for travelling and other expenses. Forms of application can be had upon application to the Secretary of the Corporation. The latest date for their return is June 5.

A PUBLICATION grant of £2500 is receivable by the Royal Society from H.M. Government during the current year. The grant is available for assisting the publications of other scientific societies, as well as for assisting the separate publication of books, memoirs, etc., of a scientific nature. Applications for grants will be adjudged by the Council of the Royal Society at its meeting early in July, but should be received before the council meeting of June 14. Applications from societies will be received by the secretaries of the Royal Society; those from individuals must be brought forward by members of Council.

THE British Empire Cancer Campaign announces that an International Conference on Cancer has been convened to be held on July 16-20 in London at the house of the Royal Society of Medicine. Doctors, surgeons, pathologists, and radiologists from all parts of the world whose work has been closely associated with inquiry into the causes and cure of cancer will attend, whilst the Royal Society and the principal universities, medical schools, and scientific bodies of Great Britain are sending delegates. Sir John Bland-Sutton, Bart., past president of the Royal College of Surgeons and a vice-chairman of the Grand Council of the British Empire Cancer Campaign, will preside, and Sir Richard Garton, chairman of the Finance Committee, has been elected honorary secretary of the International Conference. H.R.H. the Duke of York, president of the British Empire Cancer Campaign, and H.R.H. the Duchess of York will receive the delegates and their wives at a reception to be held at Lancaster House (London Museum), which has been lent by the trustees for this purpose, on July 18.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—An assistant lecturer in the Department of Navigation of the Cardiff Technical College—The Principal, Technical College, Cardiff (May 26). Two physicists with electrical engineering experience for research work under the Safety in Mines Research Board—The Under Secretary for Mines, Establishment Branch, Mines Department, Dean Stanley Street, S.W.1 (May 29). An assistant to the Leeds City Analyst—The Town Clerk, 26 Great George Street, Leeds (June 6). A lecturer in electrical engineering in the University of British Columbia—H. Vickers, 54 High Street, Connah's Quay, Chester (June 8). A head of the department of pure and applied physics, a lecturer in municipal and sanitary engineering, and an assistant lecturer in municipal and sanitary engineering, each at the Manchester Municipal College of Technology—The Registrar, College of Technology, Manchester (June 9). A lecturer in electrical engineering at Loughborough College—The Principal, Loughborough College, Leicestershire (June 18). A part-time professor of dietetics at St. Thomas's Hospital Medical School—The Academic Registrar, University of London, South Kensington, S.W.7 (June 22). An assistant lecturer in the zoological department, the University, Birmingham—The Secretary, University, Birmingham (June 30). An assistant lecturer in metallurgy in the University of Birmingham—The Secretary, University, Birmingham (June 30). The George Henry Lewes studentship of the University of Cambridge—Prof. Barcroft, Physiology School, Cambridge (July 10). A junior assistant under the directorate of metallurgical research, Research Department, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18. A chief lecturer in building at the Huddersfield Technical College—The Director of Education, Education Offices, Huddersfield. A geography master at St. Dunstan's College, S.E.6—The Headmaster, St. Dunstan's College, Catford, S.E.6. An assistant lecturer in education in the Department for the Training of Teachers, of the University of Reading—The Registrar, The University, Reading. A woman teacher of physiology at the Chelsea Polytechnic—The Secretary, Chelsea Polytechnic, Manresa Road, S.W.3. Civilian education officers in the R.A.F. Educational Service for teaching engineering subjects—The Secretary, Air Ministry, Gwydyr House, Whitehall, S.W.1.

Our Astronomical Column.

NOVA PICTORIS.—A photograph of this star, taken at Johannesburg, was shown at the meeting of the Royal Astronomical Society on May 11. Dr. Jackson noted that from examination of the plate, the Greenwich observers considered it probable that the rings round the star were not objective, but arose from the fact that the star, being probably red (as is the rule with novæ on their decline), did not give a sharp image on the plate, being somewhat out of focus. In fact, similar rings were seen round the images of red stars on the Franklin Adams plates. However, the Johannesburg observers stated that the rings were expanding at the rate of a second a day, which, if confirmed, would be evidence of their reality. Dr. Wood was evidently alive to the possibility of optical rings, since he stated that he examined other images on the plates of the Nova without finding similar rings.

RECENT SOLAR ACTIVITY.—Since the beginning of May the sun's disc has offered a number of spots for observation. Of these, the most interesting has been a very long stream of spots nearest the centre of the disc on May 8. The stream originated when on the invisible hemisphere, but its maximum development evidently occurred when turned earthwards. The longitudinal distance between the centres of the leading and following spots reached a maximum of 16°, or more than 100,000 miles. About this time the aggregate area of the stream exceeded 1500 millions of square miles. A single spot of this size would have been easily seen with the naked eye, but as the stream was drawn out into a number of component spots, it was a difficult object for naked-eye vision. This is the largest group of spots seen since February (NATURE, Mar. 3, p. 335).

In the interim, a few other fairly large spots have appeared, but were not of special interest. The largest of these were nearest the centre of the disc on Mar. 18 (lat. 14° N.), Mar. 19 (lat. 8° N.), and April 19 (lat. 16° S.) respectively. Particulars are appended of the recent large group.

No	Date on Disc.	Central Meridian Passage.	Latitude.	Maximum Area
2	May 2-14	May 8·4	14° S.	1/650 of hemisphere.

At the meeting of the Royal Astronomical Society on May 11, Mr. Evershed showed photographs illustrating the violent disruption of a large solar prominence of the type not usually subject to sudden changes. This prominence was photographed by Mr. Evershed at his observatory at Pitch Hill on May 8 and 9, the disruption and subsequent disappearance of the prominence taking place on the morning of May 9 at the sun's east limb.

COMETS.—Dr. Carrasco obtained a photograph of Giacobini's comet on Mar. 26 8472 U.T., from which he derived the position R.A. (1928·0) 6h 5m 2s, N. Decl. 14° 50′ 24″ (*I.A.U. Circ.*, No. 203). Dr. A. C. D. Crommelin has obtained the following parabolic elements from the observations of Mar. 17, 26, 28:

T 1928 Mar. 27·4335 U.T.
ω 345° 27 11′
Ω 106 20·45
i 2 49·71
log q 9·99769

Dr. Carrasco obtained similar elements, but the above give a better representation of the middle place.

Ephemeris for 0h:

	R.A.	S. Decl	log r.	log Δ.
May 20	16h 58m 6s	14°33′	0·1260	9·5316
28	16 53 32	14 53	0·1544	9·6219
June 5	16 49 40	15 15	0·1814	9·7047
13	16 47 0	15 40	0·2074	9·7812
21	16 45 50	16 6	0·2325	9·8530

The small inclination suggests possible periodicity. However, the observations are satisfied better by a parabola than by an ellipse.

Research Items.

NORTH AMERICAN INDIAN STATISTICS.—A study of the population of America north of Mexico, which was begun by the late Mr. James Mooney as a contribution to the "Handbook of American Indians," but grew beyond limits suitable for that publication, has been published as No. 7, vol. 80, of the *Smithsonian Miscellaneous Collections*. It was still incomplete at the time of the author's death in 1921, but was sufficiently advanced to warrant publication. The territory is divided into fourteen areas. The figures show the relative strength of the tribes and an approximate estimate of losses and gains, with notes on the causes, epidemics and other, responsible for the decline. In the North Atlantic States, including New York, New England, New Jersey, and Pennsylvania, as well as part of Quebec, at the time of first colonisation, about 1600, the Indians probably numbered about 55,000. They are now reduced to about 22,000, of which number about 18,000 are Iroquois. In the South Atlantic States—Delaware, Maryland, Virginia, and the Carolinas—leaving out the Cherokee territory, there are not to-day twenty full-bloods keeping their own language, though there are about 1000 mixed bloods. It is estimated that in the early seventeenth century they numbered 52,000. Decline was noted so early as 1607. In the Gulf States the numbers have fallen from 114,000 to 62,700, though this latter figure includes large numbers with white admixture. Of the remaining regions the largest decrease is shown in the southern plains, where the population has fallen from 41,000 to 2861, and in California from 260,000 in 1769 to 18,797 in 1907. The figures for the whole area, including Alaska and Greenland, are: early figure, 1,153,000; latest figures, 406,000. The early figure, it will be noted, includes the first estimate or calculation for each area, but is not composed of synchronous figures, some belonging to the seventeenth century, others to the eighteenth or even early nineteenth centuries.

ANTLERS CARRIED BY FEMALE DEER.—Except in the case of the reindeer, it is the exception for the female of any species of deer to carry antlers. Interest, therefore, attaches to three recent records, collected by Joseph Dixon, of such abnormality in the case of the Rocky Mountain mule deer (*Jour. Mammalogy*, vol. 8, 1927). Other accounts of horned does in this species have been given by woodsmen and hunters, but though heads were occasionally preserved, the authenticity of the statements could not be tested. The present records come from one general region. In each case the antlers were well developed, but although all the deer were shot about the same season of the year, two had clean, hard, regularly forked horns, while in the third the antlers were gnarled and malformed and remained in full velvet. The last was evidently an old individual, and in this case senile degeneration of the ovaries may account for the abnormality, but the others were young individuals, and "there was no evidence noted that would lead one to believe that their reproductive organs were aberrant." It is a pity that opportunity was not taken to settle the questions aroused by the abnormal antler development, by critical examination of the reproductive organs.

NORTH AMERICAN SHORE BIRDS.—The United States National Museum has issued at intervals a series of volumes describing with great thoroughness the life-histories of related groups of wild birds frequenting the sea or inland waters. The seventh and latest of the series, by A. C. Bent, describes the "Life-histories of North American Shore Birds" (*Smiths. Inst., U.S. Nat. Mus., Bull. 142*). Under the head of each species the author has collected all the essential information regarding its migrations, breeding range, courtship, nesting, behaviour, plumages, and so forth, so that to each of the forty-one species of waders described in this first instalment, goes the goodly allotment of an average of some 8½ pages of print. To the British reader the volume is of special interest, since many of the species are migrants familiar on our shores during the winter months, and others nest in Great Britain as well as in North America; moreover, the group dealt with includes some of the most remarkable of migrants, 'globe-spanners,' which range from the Arctic almost to the Antarctic circle.

FISH MORTALITY IN FRESH WATER.—Major R. B. Seymour Sewell, in his "Investigations regarding an Epidemic of Fish Mortality in the tank in the Indian Museum Compound" (*Jour. As. Soc. Bengal*, vol. 22, 1926, Art. 25), gives a general account of the mortality of animal life in the tank on Feb. 16 and 17, 1926. The mortality among the fish is for the most part confined to the members of the carp family, which respire through the gills only. Post-mortem examination of fishes indicated that death was primarily due to asphyxia, either from insufficient oxygen or from excess of carbon dioxide in the water of the tank. A gas analysis of the surface water, taken on the morning of Feb. 17, showed 8·3 c.c. of carbon dioxide, 3·2 c.c. of oxygen, and 13·8 c.c. of nitrogen at N.T.P. per litre. Thus the percentage of carbon dioxide in the deeper layers of the tank must have been very near the lethal concentration of 10 c.c. per litre, especially as there was no wind and an insufficient temperature gradient to create a circulation in the tank. Hence it would appear that the epidemic was due to a rise in the carbon dioxide content, assisted by a reduction in the amount of free oxygen, both changes being brought about by the meteorological conditions. It is suggested that either by periodic introduction of water weeds and green algæ, or by circulating the water by artificial means or by treating the water with lime, such occurrences of mortality in tanks may be prevented. Dr. B. Chopra (*ibid.*, Art. 26) records that the fishes in the Indaw River in Upper Burma die in large numbers three or four times a year. This is said always to follow a heavy fall of rain on the hills, the water of which is collected by the Namtig stream. During the rainy season the Namtig brings down an exceptionally large quantity of water, some of which forces its way up the Indaw. The deadlock caused by the upstream of Namtig water and the downstream from the lake, brings about the fish mortality. Death is probably due to the water being fouled, preventing respiration. In spite of the periodic mortality every year, the stock of fish living in the river does not appear to be affected.

VARIABILITY IN CYCLOPS.—Z. Koźmiński (*Bull. Internat. Acad. Polonaise Sc. et Lettres*, Classe des Sciences Math. et Nat. B, No. Suppl. I., 1927) records in 114 pages and 19 plates detailed observations on the variability of Cyclops of the *strenuus* group. 640 specimens from varied sources were examined, carefully measured, and compared. He concludes that within the group *strenuus-insignis* four species are distinguishable—*scutifer*, *vicinus*, *strenuus*, and *insignis*, for which and for their *formæ* he provides full diagnoses, and adds notes on their ecology, local and seasonal variations, and on their geographical distribution.

The Digestive Enzymes of a Holothurian.—E. Sawano has investigated the digestive enzymes of a holothurian *Caudina chilensis* (*Sci. Reports Tohoku Imp. Univ.*, Sendai, Japan, vol. 3, No. 2, January 1928), and finds evidence of the presence of lipase, butyrase, amylase, invertase, maltase, ereptase, tryptase, and rennet. Examination for cellulase, lactase, pepsinase, and tyrosinase yielded negative results.

Erythraea scilloides.—This small but beautiful plant is one of the species selected for descriptive treatment in *Curtis's Botanical Magazine*, vol. 152, Part 2. Its chief interest lies in the fact that it is one of the latest additions to the flora of Great Britain, having been noticed for the first time on the cliffs at New Port Bay, Pembrokeshire, South Wales, in 1918. The nearest other localities in which it is found are in the Cherbourg Peninsula, and in the Monts d'Arré in Brittany. The species, one of the Gentian family, is described very fully and critically, and illustrated by a hand-coloured and lithographed plate.

Mildew on Cotton Goods.—Various species of *Aspergillus* responsible for a large proportion of the cases of mildew on cotton goods have been worked out and identified by George Smith (*Jour. of Textile Institute*, vol. 19, No. 3). The forms have all been isolated in pure cultures in the laboratory, and the morphology and characteristics of each species are described. Species of *Aspergillus* described in this paper are divided into two conventional groups: first, those which have been identified as causal agents in actual cases of mildew damage of yarns and cloths; and secondly, forms which have been found to occur commonly as spore infections on commercial yarns, but have not so far been found growing on cotton goods. It is considered that the presence of living spores of such species on cotton constitutes a probable source of trouble. For each species or group, the variations in dimensions and colonial characteristics recorded are those noted in the actual strains isolated from cotton goods, and are not necessarily so wide as those cited in systematic works on the Aspergilli. In all, seventeen species are described, of which only one, *A. effusus*, has not been otherwise encountered on cotton goods.

The Focal Depth and Origin of Earthquakes.—As the late Prof. Omori showed, the distance of the origin of an earthquake from a neighbouring station is given by the duration of the preliminary tremor recorded there. If the distance of the epicentre is also known, it is a simple matter to calculate the depth of the focus. Mr. K. Suyehiro, of the Earthquake Research Institute, Tokyo, has recently determined the focal depths of 17 earthquakes, all of them with epicentres less than 100 km. from Tokyo (*Proc. Imp. Acad.*, Tokyo, vol. 4, pp. 41-44; 1928). He finds that the earthquakes fall into two classes, the focal depth ranging in one from 25 km. to about 50 km., and in the other from 55 km. to 95 km. These earthquakes were also recorded by a new form of seismographic analyser recently erected in the laboratory of the Institute. The instrument is strongly damped and its period is adjusted to agree with the usual period of vibration (0·3 sec.) of the ground below. As the instrument after disturbance rapidly comes to rest, it is easy to detect the number of separate shocks in an earthquake. In the first class, each earthquake shows several groups of waves, in one case as many as eleven, while those of deeper origin had only one or two groups. This seems to suggest that, in the upper and more brittle layer, the initial movements start in succession or in different places; while in the lower stratum, a single movement as a rule takes place throughout the focus.

Positive Ion Kinetics.—The curious fact that some positive ions suffer very few effective collisions in passing through a gas has been confirmed by G. P. Harnwell in an investigation described in the April number of the *Physical Review*. The experimental tubes used were very similar to cylindrical thermionic valves, but the ordinary filaments were replaced by small troughs containing material which emitted the ions of potassium or of cæsium when it was heated. For speeds corresponding to accelerating potentials of fifteen hundred volts or less, the singly charged atoms of these two elements produced no detectable ionisation of the five gases that were studied. The free paths for transfer of kinetic energy proved to be many times what would be expected from the kinetic theory of gases, when the impinging particles were treated as elastic spheres, and although a closer agreement between theory and experiment could be obtained by an appropriate assumption about the force of attraction between ions and molecules, the similarity of the phenomena to those found with protons of comparable velocities, where the fields are presumably less complex, seems to indicate that there is some fundamental explanation that is valid in both instances. The analogous Ramsauer effect for slow electrons has been already accounted for by the wave mechanics.

The Measurement of Capacitance.—Maxwell's method is the one that has been most commonly used for the absolute measurement of capacitance (capacity). It was first used by J. J. Thomson in 1883, who proved the accurate formula for computing the capacitance. In a valuable paper by H. L. Curtis and C. Moon, of the U.S. Bureau of Standards (No. 564), a very thorough investigation is made of the accuracy of the method, and an appreciative account is given of the work of preceding investigators. In order to determine experimentally the accuracy that can be obtained, two independent Maxwell bridges were set up and used to measure the same capacitance. The bridges were entirely distinct, using different resistances, galvanometers, and batteries. A rotating commutator was used on one bridge and a vibrating commutator on the other. With the former the balance was made by adjusting the speed and determining the frequency of the charge and discharge by means of a chronograph. With the latter the adjustment was made by a resistance and by determining the rate of vibration of the commutator by comparison with a pendulum. The experiments extended over several months, various anomalous results having to be investigated. The final value of the capacitance as found by the first bridge method was 0·249236, and by the second 0·249242. This shows a difference between the results of 2·5 parts in 100,000. The authors conclude that even with excellently designed and carefully adjusted apparatus, there may be an error of 3 parts in 100,000 when measuring a capacitance of 100,000 by Maxwell's method. They recall that Glazebrook showed in 1890 that the method was not suitable for measuring any condenser which had absorption, that Orlich was the first to point out the importance of earthing the bridge, and that Russell showed that ballistic galvanometers when used with a mutual inductance do not always integrate correctly.

The Volumetric Estimation of Sulphuric Acid.—In the *Chemiker-Zeitung* of April 21, Dr. O. Nydegger directs attention to the fact that the benzidine method of estimating sulphuric acid deserves far more attention than is usually paid to it; he claims that if properly carried out the errors due to the appreciable solubility of benzidine sulphate in water and to its tendency to adsorb benzidine hydrochloride, can be reduced to a maximum of 0·5 per cent Investigation has shown that the presence of small quantities of iron, nitric acid, and other substances in the solution have no effect upon the results, so that the method is particularly suitable for the rapid estimation of sulphur in iron pyrites.

THE BUDDE EFFECT WITH BROMINE VAPOUR AND AIR.—In 1871, Budde observed that chlorine expands on exposure to light, but later workers have claimed that this effect does not take place with dry chlorine. An investigation of the Budde effect with mixtures of pure bromine vapour and air is described by E. Brown and D. L. Chapman in the *Journal of the Chemical Society* for March. Their results indicate that mere removal of water from such mixtures has no detectable influence upon the increase of volume which occurs on exposure to light. This conclusion is not in agreement with recent work of Ludlam, and also Lewis and Rideal, who state that no Budde effect can be observed with bromine vapour which has been thoroughly dried.

SPECTRUM OF THE GLOW OF PHOSPHORUS.—The spectrum produced by passing a discharge through phosphorus pentoxide vapour was recently investigated by H. J. Emeléus and R. H. Purcell (*Jour. Chem. Soc.*, 788; 1927), who found that it partially corresponded with the ultra-violet band spectrum of the glow of phosphorus. R. C. Johnson has pointed out that these measurements also correspond below 3000 A. with the band spectrum of the singly ionised oxygen molecule, and it therefore appears possible that the ultra-violet emission from glowing phosphorus s due to oxygen. In view of the fact that ozone is produced at the same time, this suggestion is of considerable interest, and the available evidence is discussed by Emeléus and Purcell in the *Journal of the Chemical Society* for March. They conclude that, owing to lack of sufficient knowledge of the spectra concerned, the origin of the spectrum of glowing phosphorus must still be regarded as unsettled.

AN ATTEMPT TO PREPARE TRIATOMIC HYDROGEN.—According to a number of investigators, hydrogen can exist in an active form which is said to be capable of reducing certain elements, such as sulphur and nitrogen, to their hydrides, and, unlike monatomic hydrogen, is not completely destroyed by passage hrough glass wool. Wendt and Landauer claim that ts formation in a closed system is accompanied by a decrease in pressure, and this observation has led to the assumption that this active form is triatomic hydrogen. In the *Journal of the American Chemical Society* for March, H. M. Smallwood and H. C. Urey describe a series of experiments to produce this substance. The methods employed include the combustion of oxygen in hydrogen, the passage of hydrogen over heated metals, and the effect of corona and vacuum discharges on hydrogen. The latter method was investigated in great detail, but it was found to be impossible to obtain a product which would definitely reduce sulphur to an appreciable extent. The experiments all gave negative results, and it is suggested hat previous workers have failed to carry out adequate blank tests. Smallwood and Urey conclude that the existence of triatomic hydrogen has not yet been established, and that if it does exist its preparation is very difficult.

GASES IN BRASS INGOTS.—The work described in a paper, read at the spring meeting of the Institute of Metals by G. L. Bailey, on "The Influence of Gases on he Soundness of Brass Ingots," consisted in the production of ingots of brass and bronze which were treated, prior to pouring, with nitrogen, hydrogen, and sulphur dioxide and were then allowed to solidify over a fairly wide range of time. It was shown that a bronze containing 5 per cent of tin was very nearly sound after treatment with nitrogen, except in the case of the ingot poured in the warm, dry, sand mould. With more rapid chilling the rate of solidification played no very important part. Ingots of the bronze through which hydrogen had been bubbled were slightly less sound than those which were treated with the nitrogen, except in the case of the most slowly cooled ingot, which contained again about 10 per cent of cavities. Brass containing 30 per cent of zinc proved to be practically completely sound after both the nitrogen and hydrogen treatment, except, again, in the case of the slowest cooling in dry sand. Sulphur dioxide rendered the casts only very slightly more porous. It is concluded that whatever be the conditions of casting, 70:30 brass is not liable to unsoundness due to gases. The spherical cavities, of varying size and unequal distribution, frequently found in brass ingots, are attributed not to the evolution of dissolved gas, but to the mechanical entrapping of gases within the mould during pouring. This view is supported by the fact that the use of low casting temperatures is followed by an increase in the number of spherical cavities, and that with very low casting temperatures large cavities of entrapped air can be produced. The results suggest that molten brass has very little solubility for gases. Even, however, if such gases are occluded, it appears that they will remain in solution after solidification. Very slow rates of solidification, however, cause the casting to be unsound, but probably for other reasons connected with the dressing of the mould.

THE ACTION OF FUSES.—It is well known to electricians that if the current through a carbon arc is increased, the length of the arc being kept constant, then, at a certain value of the current, the arc suddenly begins to hiss and there is a sharp drop in the voltage and a sudden rise in the current. If a graph of the voltage and the current is drawn, there is a discontinuity in the curve. For values of the current between definite limits it is impossible to maintain an arc of a given length. In a paper by P. D. Morgan, read to the Institution of Electrical Engineers on Mar. 22, on the rating of fuses, a somewhat analogous phenomenon was described in connexion with the melting of fusible wires. For example, in one of the experiments tinned copper wires No. 19 S.W.G. of given length were fixed in succession between two terminals, and the times taken for them to melt with given currents were observed. It was noticed that when the current was greater than 70 amperes, the wire always melted in less than 30 seconds, but when the current was not greater than 69·3 amperes, the wire always took at least five minutes to 'blow.' For currents lying between these somewhat narrow values there appear to be two times of operation, the short time being less than 30 seconds and the long time never being less than four minutes. For smaller values of the current the curve connecting the 'blowing' current and the time of operation is a perfectly definite 'smooth' curve. Similar discontinuities were noticed over the whole range of wires tested. The phenomenon is due apparently to the oxidation of the wires. Above a certain temperature, oxides form quickly on the surface. These have a better emissivity than the bright wire, and the improvement is so appreciable that the temperature of the wire actually falls. This fall in temperature is accompanied by a change in brightness which is clearly visible to the eye. There is a decreased resistance, and since the current is maintained constant, a consequent fall of potential across the ends of the wire. Suggestions are made for improving the methods in use for rating fuses.

Problems in the Physiology of the Cerebral Hemispheres.[1]

THE function of the nervous system is to maintain dynamic equilibrium within the organism and between the organism and its environment. In the latter case the equilibrium is, in the higher animals, extremely complex and is achieved mainly by means of the hemispheres. These continuously analyse and synthesise events occurring in the environment, and in correspondence with its changes establish temporary connexions between events, whether simple or complex, and various activities of the organism, in particular those of the skeleto-muscular system, which is preponderantly concerned in reacting to environmental changes and is likewise itself highly differential and integrative in its response.

At present the physiology of the hemispheres exists only in outline—as a framework consisting of a limited number of known factors, such as excitation and inhibition, their two-directional movement in the form of irradiation and concentration, and their mutual induction. The working out of the innumerable details of their intimate mechanism is a colossal problem of the future. A few of the latest investigations carried out by the author and his co-workers (*i.e.* subsequent to the publication of the author's book, "Conditioned Reflexes") are here summarised.

(1) The development of new temporary connexions between external agencies and definite reactions of the organism (development of conditional reflexes) depends on the coincidence in time of the action of these agencies upon the receptor mechanisms of the organism, with the various activities of the organism evoked either by external stimuli effective since birth, or by external stimuli which have become established as such after birth, or finally by changes in the internal condition of the organism (automatic stimuli). The formation of the connexion is then a physiological law.

In order to become a firmly established, powerful, conditioned stimulus the external stimulus *must* begin to act slightly before the particular activity of the organism, and *may* even cease a few seconds before the beginning of the activity. If, on the other hand, the given activity constantly begins before the stimulus, either no connexion is established, or if any is established it is weak, and survives only for a short time, and the specialised excitatory effect of the stimulus is invariably replaced by general inhibition. The biological significance of this fact is not yet clear. Where the stimulus begins to act before the given activity of the organism and continues during that activity, the reflex tends to increase in strength and stability. The mechanism underlying these phenomena cannot yet be expressed in terms of the general properties of the cortical tissue.

(2) The analysing activity of the nervous system is founded in the first instance on the peripheral receptor organs, which constitute not only a receptive mechanism but also an analysing apparatus of the organism. To the peripheral points of the analyser separate points correspond in the cortex (the primary and simplest cortical mosaic). A good proof of this is that by applying definite external stimuli belonging to the same analyser, for example, different auditory stimuli, it is possible to produce various disturbances or fatigue at different strictly localised cortical points. In this manner a very delicate method is opened up for investigating the construction of the cortical parts of the analysers, and it is possible to distinguish special areas in the cortex corresponding to the different analysers (visual, auditory, etc.) from certain other cortical elements of those analysers, which are dispersed probably over the whole mass of the cortex of the hemispheres. Not only are these dispersed elements incapable of performing any higher synthesis and analysis, but they have a very low degree of vitality, as evidenced by the rapidity of their transition into an inhibitory state under the influence of external stimuli.

(3) The conditions determining the characteristics and the magnitude of the excitatory and the inhibitory effects of conditional stimuli are bewilderingly complex and are only gradually being classified.

It is obvious that the magnitude of the positive effect is directly related to the amount of energy applied to the receptor organ. The phenomenon of summation of weak stimuli comes out clearly. The limit of normal excitability and the optimum strength of stimulation are also definite. In the case of very strong stimuli and of the summation of medium stimuli, the excitatory process rapidly changes into an inhibitory one. Of course the strength of stimulus is a relative quantity, varying greatly with individua differences of nervous system.

Since most probably the points between which the new connexions are established are in the cortex, it follows that the variations in the effect of conditioned stimuli will be dependent on the mutual relation between the different cortical points corresponding to the different conditioned stimuli, and also between the different points of those areas of the hemispheres which are affected by the unconditioned stimulus. For example, the conditioned stimuli based on food and acid respectively, both become connected with the chemical analyser of the hemispheres, and therefore, if in the experiments both sets of conditioned stimuli are used, their effect will be determined not only by the interrelation of the points corresponding to the stimuli, but also by the relation existing between the alimentary and 'acid' points of the chemical analyser.

(4) The accumulation of observations upon the normal and pathological activities of the hemispheres gives grounds for distinguishing various types o nervous system. There is the excitable type, which always displays partial or complete failure when confronted by difficult relations between the excitatory and inhibitory processes, and if the experiments are continued, ends by developing an abnorma and extremely protracted weakening of the inhibitory activity, attended by an exaggerated general excitation. At the other extreme stands the inhibitable type, which very easily becomes subjected to inhibition by stimuli either unusual or slightly stronge than usual, and, when confronted by comparatively difficult relations between the excitatory and inhibitory processes, passes into a state of complet inhibition for prolonged periods of time.

In between can be placed the well-balanced typ which, successfully and without any signs of abnormality, establishes in all cases a balance between the opposed nervous processes. This type comprise two varieties of animal, differing greatly from on another in external appearance—the stolid anima always quiet, and the animal which is lively unde ordinary conditions, but becomes drowsy with surprising rapidity under monotonous conditions. Th latter variety has some difficulty in obtaining balance between the two processes. This groupin of the types of nervous system corresponds closely to the ancient classification of temperaments; th excitable type—choleric temperament; the inhibitable type—melancholic; the quiet, balanced typ —phlegmatic; the lively balanced type—sanguine.

---

[1] Abstract of the Croonian Lecture delivered before the Royal Society on May 10, by Prof. I. P. Pavlov, For. Mem. R.S.

The University of Liverpool.

THE University of Liverpool has just been celebrating its twenty-fifth anniversary, and in the city were gathered representatives from all branches of civic life and from many universities to take part in the rejoicings and to bring messages of goodwill and encouragement. A service of thanksgiving and of dedication was held in Liverpool Cathedral on the afternoon of Thursday, May 10, and was conducted by Dr. David, Bishop of Liverpool. In the evening the University Association entertained the delegates from the universities, the representatives of civic authorities, and those who on the following day were to receive honorary degrees. In a publication issued for the occasion, a brief record was given of the work and progress of the University of Liverpool from its foundation in 1907.

On the afternoon of May 11, Lord Derby, Chancellor of the University, presided over a large gathering in St. George's Hall, and conferred honorary degrees on twelve people of eminence in academic and civic life. Representatives of every department of the university and civic life of Lancashire and Cheshire attended, accompanied by delegates from the American University Union, the University Colleges of Exeter, Southampton, and Nottingham, King's College, London, and the Universities of Reading, Bristol, Queen's University, Belfast, Leeds, Birmingham, Wales, Manchester, London, Durham, Trinity College, Dublin, Edinburgh, Aberdeen, Glasgow, St. Andrews, Cambridge, and Oxford. Having welcomed the visiting representatives, Lord Derby paid high tributes to the late Sir Alfred Dale and Dr. Adami, former vice-chancellors of the University, and to the many benefactors whose munificence has made the University a growing reality. The Vice-Chancellor (Dr. Hetherington), speaking of the faith of those who laid the foundations of the University, welcomed the presence of some who saw and some few who shared in that endeavour, expressed the indebtedness of the University to these teachers who have won for it recognition in the world of scholarship and letters, and to those who have served it in the care of its affairs. Above all others, he recalled in faithful remembrance those who gave themselves in battle that the foundations of the University might not be moved.

Prof. Campagnac, as Public Orator of the University, presented the following recipients of honorary degrees to the Chancellor, and in each case delivered a brief eulogy of their work:—

Doctor of Letters.—The Earl of Crawford and Balcarres (Chancellor of the University of Manchester), Emeritus Prof. Oliver Elton (University of Liverpool), Prof. T. Percy Nunn (Principal of London Day Training College, and professor of education in the University of London).

Doctor of Science.—Prof. John E. Littlewood (professor of mathematics in the University of Cambridge), Prof. Robert Robinson (professor of organic chemistry, University College, London).

Doctor of Laws.—Vice-Chancellor William MacBride Childs (The University of Reading), The Right Hon. H. A. L. Fisher (Warden of New College, Oxford, and formerly Minister of Education), Prof. John W. Gregory (professor of geology in the University of Glasgow), Miss Emma G. Holt (founder of the Liverpool University Hall), Sir Edwin L. Lutyens (in recognition of his services to British architecture), Sir Archibald Salvidge (leader of the City Council of Liverpool).

Doctor of Engineering.—Emeritus Prof. John A. Fleming (for forty-two years professor of electrical engineering in University College, London).

Speaking of them individually, Prof. Campagnac said that the Earl of Crawford had directed his disciplined taste and lent his strong advocacy to preserving what Nature and human effort had produced of fair and lovely in our land. For twenty-five years Prof. Elton, as head of the Department of English Literature, had been to many generations of students, guide, philosopher, and friend, the pattern of exact scholarship, the model of just criticism, and the unbending champion of University liberty. By nature and vocation a teacher of teachers, Prof. Nunn had astounded all by the variety of his learning, in letters, philosophy, mathematics, and music, and by his supreme perfection in administration. The researches in which Prof. Littlewood delights fill the uninitiated with wonder and dread, and provoke, in his peers, reverence and admiration. The learned revel in Prof. Robinson's synthesis of flower pigments and have admired the fertility of his genius. Of the Vice-Chancellor of the University of Reading, he said that in the development of that institution he had acted with courage and wisdom, and had satisfied modern needs by freely interpreting a venerable tradition. As scholar, teacher, historian, and philosopher, the Right Honourable H. A. L. Fisher had shone, but above all he had been the champion of youth, resolute to ensure their inheritance in liberty and discipline. In presenting Miss Emma G. Holt, Prof. Campagnac said that the establishment of colleges in which piety and learning might be sought in cloistered leisure was of old the beneficent labour of royal and generous ladies. Miss Holt had taken up and embellished this tradition by providing in Liverpool a hall which, in beauty and fitness for its purpose, challenges the glory of these houses. As a traveller, Prof. J. W. Gregory had fared far east and west, north and south, over the world and in the realms of thought. His scientific instinct had had the nature of prophecy, and his anticipations boldly made in many fields of inquiry had been fulfilled in as many regions of knowledge ascertained by his labours. In East Africa and Australia, in Chinese Tibet and along the Himalayan system, he had conducted explorations, the results of which are of great social and political importance. He has illuminated some of the most difficult social and racial problems. To the success of Sir Edwin Lutyens in planning a new capital city in India was added the fact that to him Britons had turned when at the heart of their Empire a memorial of the men who had fought and died for home was needed. In presenting Sir Archibald Salvidge, Prof. Campagnac spoke of the encouragement and generous support which the University had received from the City of Liverpool, and of the University's pride in a man for whose heart its prosperity is a passion, and by whose courage, enterprise, and unremitting labour the city has been promoted and advanced. As in great measure responsible for the introduction to this country of the telephone, the incandescent electric lamp, and radio telegraphy and telephony, and as the inventor of such cunning instruments as the thermionic valve, the University sought to honour Emeritus Prof. J. A. Fleming.

In the evening the University, the civic representatives, the honorary graduates, and the University delegates were the guests of the Lord Mayor of Liverpool (Miss Margaret Beavan) at a reception at the Town Hall.

The celebrations ended on the afternoon of Saturday, May 12, with a garden party at the University Sports Grounds at Allerton, at which the Christie Sports were also held.

University and Educational Intelligence.

Cambridge.—The honorary degree of LL.D. is to be conferred upon the Right Honourable Sir John Simon, P.C., M.P.

W. H. McCrea, Trinity College, has been elected to the Sheepshanks exhibition in astronomy.

The General Board of Studies has issued a report giving details of the scheme for carrying out the statute passed by the recent Statutory Commission, which gives University teaching officers a right to be excused from teaching duties during one term in seven. There are financial difficulties in granting this leave generally with full stipend, but the Board hopes that it will be possible to grant two terms' leave of absence with stipend once in every period of seven years. A significant development in University teaching is indicated in the transfer of Mr. W. S. Farren's lectureship from the Department of Engineering to that of Aeronautics.

A syndicate, consisting of the Vice-Chancellor, Sir Henry Miers, Sir William Pope, Sir Ernest Rutherford, Sir William Bragg, Dr. Thomas, Dr. Spencer, Dr. Rastall, Mr. Thirkill, Dr. Harker, Mr. Nicholas and Dr. Rideal, has been appointed to consider the position of mineralogy in the studies of the University. A second syndicate has been appointed to consider plans for the new University Library.

Mr. L. E. S. Eastham, lecturer in advanced and economic entomology, has been appointed to represent the University at the International Congress of Entomology to be held at Ithaca, New York, next August.

Messrs. J. S. Fry and Sons, Ltd., Bristol, offer a post-graduate studentship of £300 a year for two years, tenable at Peterhouse, for research in moral science, law, history, modern languages, economics, and English. The studentship is open to members of any university in Great Britain or Ireland.

Manchester.—The Edmund Mills Harwood Memorial Scholarship, value £50 per annum for three years, is being offered by the Municipal College of Technology. It will be tenable in one of the university engineering courses in the College. Information concerning the scholarship and forms of application are obtainable from the Registrar of the College until June 15.

Oxford.—On May 8, two rival schemes for the extension of the Bodleian Library came before Congregation. The first scheme, which contemplated the building of a large new library at a distance of not more than three-quarters of a mile from the present Bodleian Library, was advocated by Sir Michael Sadler, Master of University College, and Mr. E. L. Woodward. The second plan, which proposed an addition to the Library by building on the site owned by the University on the north side of Broad Street, was supported by Prof. H. W. C. Davis and Dr. A. E. Cowley, Bodley's Librarian. After a speech by Mr. Falconer Madan, a former Bodley's Librarian, who opposed both projects, the two schemes were rejected, the former by a large majority. There is little doubt that a paper put out by the late Warden of Wadham and the Provost of Worcester, urging that Congregation should declare its mind on the general policy of the future of the Bodleian before descending to points of detail, contributed largely to this result.

On June 16, Convocation will proceed to the election of a Chancellor of the University in succession to the late Viscount Cave. It is understood that there will be no official opposition to the nomination of Lord Grey of Fallodon to the vacant office, but nominations will be received at the University Registry up to June 7.

A limited number of grants-in-aid are being offered by the Salters' Institute of Applied Chemistry to young men and women employed in chemical works in or near London who desire to extend their education for a career in chemical industry. The latest date for the receipt of applications by the Director of the Institute, Salters' Hall, St. Swithin's Lane, E.C.4, is June 9.

The Board of Education is again prepared to receive applications for full-time studentships from teachers desiring financial assistance in order to attend approved full-time courses of advanced instruction or research at universities or other institutions at home or abroad. The amount of grant cannot exceed £100 for an academic year. The Board is prepared to consider proposals for carrying out research involving travel or the practical study of industrial conditions connected with the teaching of technical subjects. Teachers must have had not less than five years teaching experience and may be serving in any type of a school or institution recognised by the Board. Applications for the year 1928–29 should be made as soon as possible, and in any event not later than June 30. Further information and application forms can be obtained from the Board of Education, Whitehall, London, S.W.1.

The report of the Principal of the University of London (Dr. Franklin Sibly), read on Presentation Day (May 9), records 9119 admissions to the University in 1927–28, compared with 3852 in the last year before the War. Of these, 6545 entered through the ordinary matriculation examination and 426 as graduates of other universities. In 1927 there were 3325 candidates for first degrees and 529 for higher degrees, these figures showing slight decreases compared with the previous year. Of the candidates for degrees, 2283 were internal and 1571 were external, contrasting with 900 and 907 respectively for the last year before the War. The roll of internal students now comprises 9556 names. The outstanding event of the past year was the completion of the purchase of the Bloomsbury site for the new University buildings. New scientific developments include the institution of a chair of dietetics, at present a part-time appointment; and a chair of highway engineering. The Vice-Chancellor (Sir William Beveridge), in an eloquent address on the same occasion, referred to the reconstitution of the University now in progress, which, he expected, would be completed in a year's time "On the old examining university," he said, "had been successfully grafted a new teaching and researching university." The new constitution will give to the Colleges of the University for the first time an organic place in its structure and government. Development of the Bloomsbury site awaits only the passing of the Bill now before Parliament for closing the streets and making the site "a self-contained plot," and he promised that the new buildings would be worthy of the greatest city in the world—the University dared not build anything "mean or cramped or ugly." That enclosure of great courts and green spaces and great libraries and halls of learning in a market-place of nations would be a thing of beauty to which the thoughts of all its children of all races from all lands would turn continually, a visible sign to all men of the academic faith—of the learning that knew no frontiers, of the contemplation that alone gave eyes to action, of the calm that should be the centre of man's being.

Calendar of Customs and Festivals.

May 20.

THE DIVINE SACRIFICE IN MEXICO.—On the first day of the fifth Aztec month, a date of which the exact incidence is uncertain, though it has been fixed conjecturally at various times between Easter and May 20 by different authorities, the festival of Toxcatl, the most important of the Mexican year, took place. The great god Tezcatlipoca was sacrificed in the person of his human representative, a man who had been feasted and worshipped during the whole of the preceding year, and was now succeeded by another who enjoyed divinity for a like period and was then sacrificed in his turn. Twenty days before the god was to die, his costume was changed and four brides were given him. On the last day he embarked with his retinue in a canoe, was ferried across the lake and slain by a priest on a stone altar on the summit of the pyramidal temple. His heart was cut out and offered to the sun. This was said to be a sacrifice for rain, but the names of his brides, for example, "The Goddess of Flowers," "The Goddess of the Young Maize," suggest a general renewal of fertility.

This was one only of a number of occasions on which a man was sacrificed, after living as a god. A human representative of Huitzilopochtli was sacrificed in May after leading dances in which the maidens were decked with maize ears. At Cholula, in February, the merchants sacrificed a slave who was the god Quetzalcoatl, after a ceremonial lasting forty days. The victims of human sacrifice were not men only. Women were also made to personate a female deity and were then sacrificed; for example, the Goddess of Salt, Huixtocihuatl, the sister of the Rain Gods, was personated for ten days by a woman who wore her clothes and led the dancers, until on the last night she danced to the point of exhaustion and was sacrificed in the morning in the same manner as the men by having her heart cut out.

May 21.

ST. BARIND (sixth century), patron of Kilbarron, Co. Donegal, is said to have been the first European to discover America. He gave St. Brendan an account of his adventures on the Western Ocean before the latter set out on his seven years' voyage in search of the Land of Promise. References to a legendary country lying to the west of Ireland are frequent in early Irish tradition.

The story of the voyage of Brendan, extremely popular in the Middle Ages, includes many marvels—visits to an Island of Birds, an Island of Sheep, and an Island of Fruits, an encounter with a sea monster so huge as to be mistaken for an island, fire-drakes, and the like. The parallels to be found in the voyages of Sindbad and other early travellers are obvious. It has therefore been suggested that incidents of an oriental origin have been grafted on to an Irish version of the Land of the Blessed. The description of the Island of Fruits suggests that the West Indies may have been reached, and the story of the island of which the inhabitants cast molten iron at the voyagers might well be an account of a violent volcanic eruption in that area.

May 26.

ST. AUGUSTINE (A.D. 605).—After the conversion of the Saxons to Christianity by St. Augustine, bitter racial quarrels broke out between Saxon and Briton, of which the occasion was the divergence between the ancient British and the Roman churches in the date of celebrating Easter. One incident is said to have given rise to the medieval legend current on the Continent that Englishmen had tails. Fisher folk of Dorset attacked St. Augustine and his followers and drove them from their territory, fastening fish-tails to their robes. Another version attributed tails to the men of Kent only, because they had cut off the tail of Becket's horse.

ST. BEOAN (sixth century).—A native of Munster of great sanctity, who was the object of a cult in the parish of Killardry, Co. Tipperary, where, near the church of Kilpeacon, is Peacawn's Well. It is surrounded by a ring of stones, and nearby are a few stones known as 'the Altar,' with an associated legend. This well was much visited by pilgrims until 1830.

MAY MARRIAGES.—The popular belief that May marriages are unlucky is widespread, being found in most European countries. It was also the view of the Romans, who extended the period of ill-luck to the first half of June. The aversion is sometimes explained as due to the connexion of the month with the Virgin Mary; but this must be regarded as an attempt to justify the retention of a pagan observance. Other periods have also been regarded as unlucky or as forbidden; for example, Lent, and the period between the Rogation Days and the first Sunday in Trinity; August in Sicily and France, and July in Sardinia; between Passover and Pentecost among Jews. Marriage in the month of Moharram in Morocco and Egypt might entail death or madness.

Certain days were also to be avoided. Marriage on the Sabbath was forbidden among the Jews, on Friday in the Mohammedan world; while in popular belief certain days of the week were to be avoided; among others, Thursday in England because of its connexion with Thor, Tuesday and Friday in Italy because curses are peculiarly efficacious on those days. Yet among Teutonic peoples Tuesdays and Thursdays were favourite days for weddings, because they were connected with the deities Ziu and Donar. The Romans did not marry on Kalends, Ides, and Nones, or on the *Dies Parentales* (Feb. 13-21).

Friday is almost universally regarded as unlucky in Christian countries. The avoidance in the north of Scotland of a waning moon, which will lead to a barren marriage, or a falling tide, is due to an obvious association of ideas; while the Irish disinclination to marry in harvest, as the time of binding, points to the widespread popular belief in the efficacy of the knot in the magical prevention of consummation.

Among people of lower culture, marriage is regarded as a time of peculiar danger, and it is a widespread practice to secure by means of consultation of omens that it shall take place at an auspicious time. On the other hand, the occasions on which marriage is regularly avoided are those which are regarded as especially critical, that is, when the powers of evil are peculiarly potent. The Moslem's belief that an evil spirit may enter into the body of the woman at consummation serves to indicate how such an idea becomes operative. Witches, too, may interfere by the knotting of a string, causing impotence, or otherwise. For this reason marriage is avoided in Macedonia between Christmas and Epiphany. The month of May, although the month of fertility and growth, is also the month of the witch. It is the time when the powers of evil are peculiarly active, and the fire festivals of Beltane are called into operation to neutralise and drive them away. At such critical seasons primitive wisdom counselled continence.

Societies and Academies.

LONDON.

Physical Society, April 27.—**Will C. Baker**: Experiments with mercury jets and the phenomena exhibited at their impact with steel and glass. As a light sphere is retained in a vertical jet of fluid in virtue of the change of momentum of the fluid produced by its adhesion to the sphere, it was thought that a steel sphere would not be retained in a vertical mercury jet, as there is no 'wetting' of the steel by that fluid. Experiment showed that a given bicycle ball might or might not be retained by such a jet, as the speed of the jet (at a given angle of incidence) rose above or fell below a critical value for that ball. Conditions were simplified by the use of cylindrical and of plane surfaces of steel, and an approximately constant time of adhesion between mercury and steel was found for various speeds of impact. This led to the explanation of the phenomenon in terms of the well-known instability of jets.—**E. P. Perman** and **W. D. Urry**: The elastic constants of glass. The coefficients of compressibility of soda-glass and Jena 16^{III} glass have been determined at six temperatures ranging from 30° C. to 80° C. From experiments on the effect of external pressure only, Poisson's ratio has been determined, and hence the modulus of rigidity and Young's modulus.—**G. Eric Bell**: A valve-maintained high-frequency induction furnace and some notes on the performance of induction furnaces. In Part 1 the electrical design is given of a valve-operated high-frequency induction furnace; in Part 2 a theory of the behaviour of induction furnaces in general is developed.

Society of Public Analysts, May 2.—**A. L. Williams**: Locust kernel gum and oil. Locust kernel gum has recently been used as a thickening agent for sauces. Its reactions with tannin, borax, and Fehling's solution are the most characteristic. So little as 1 per cent. of the gum may be separated from sauce or jam by treatment with tannin. The constants of the kernel oil have been determined (iodine value, 98·4). The oil gave a negative result in the antimony trichloride test for vitamin A.—**W. R. Schoeller** and **E. F. Waterhouse**: Investigations into the analytical chemistry of tantalum, niobium, and their mineral associates. (12) Observations on the pyrosulphate hydrolysis method. The pyrosulphate hydrolysis method does not effect a quantitative separation of the earth acids from zirconia. At best, a decrease in the quantity of zirconia co-precipitated is achieved, at the cost of slightly incomplete earth acid precipitation.—**F. W. Toms** and **C. P. Money**: The separation of lead tetra-ethyl from solution in petroleum spirit. The method depends on the separation of lead ethyl sulphinate on passing sulphur dioxide into 'ethyl petrol,' and conversion of the deposit into lead sulphate.—**B. S. Evans** and **S. G. Clarke**: New precipitation method of determining vanadium and its application to steel analysis. The method is based on the precipitation of vanadium as ferrocyanide and eventual determination of the vanadium present by titration with potassium permanganate. Vanadium ferrocyanide is insoluble in mineral acids of quite high concentration. In applying the process to steel analysis, the iron is quantitatively converted into ferrocyanide by reducing it from the ferric condition in alkaline citrate solution in the presence of cyanide, and the resulting ferrocyanide then acts as the reagent for the vanadium.—**P. Houseman**: The examination of liquorice mass. Stick liquorice adulterated with starch is now extensively sold in England, and a test to detect this adulteration has been devised. Occasionally the added starch is boiled so as to destroy the individuality of the granules, but usually it is possible to discover a few granules that have escaped disintegration.

PARIS.

Academy of Sciences, April 11.—**A. Lacroix**: The composition of the basaltic lavas of Indo-China.—**Charles Nicolle** and **Charles Anderson**: The presence in Morocco of the spirochæte of recurrent Spanish fever. The Spanish and Moroccan varieties of spirochæte must be considered as belonging to the same species: the Moroccan strain is perhaps somewhat more virulent to the guinea-pig than the Spanish.—**R. Coenen**: The mean geodesic curvature.—**G. Vranceanu**: Some tensors in the non-holonome varieties.—**Edward Stenz**: Observations of solar radiation and of atmospheric opacity made at Jokkmokk during the solar eclipse of May 29, 1927.—**Ch. Jacquet**: Experimental researches on the magnetisation of the volcanic rocks of the Department of Puy-de-Dôme.—The coefficients of magnetisation determined varied from 9·2 to less than 3 (magnetite, 92·7). Determinations of the variation of the magnetisation with the temperature showed that all the specimens examined the magnetisation of which was above 4 units, gave a Curie point of 550° C., near that of magnetite. The enclosures gave 580° C., exactly that of magnetite.—**H. Ollivier**: Research on the thermal variation of the magnetic rotatory power, in the case where the magnetisation coefficient is positive and independent of the temperature. For sodium bichromate, the paramagnetism of which is constant, the Verdet constant, referred to the unit of mass, does not vary between 7° and 61° C. by a quantity exceeding the error of experiment.—**A. Boutaric** and **F. Banès**: The immunity of the granule in colloidal solutions. The results of experiments described agree with the views of A. Lumière in that they prove a certain analogy between living cells and colloids in the sol condition, and between flocculated colloids and dead cells.—**Daniel Bodroux**: The condensation of cyclohexene with some aromatic hydrocarbons in the presence of aluminium chloride. Toluene and cyclohexene in presence of aluminium chloride give cyclohexyltoluene. The replacement of the toluene by other aromatic hydrocarbons gives analogous products.—**L. Palfray** and **B. Rothstein**: Some derivatives of quinite. A description of the preparation of acetate and benzoates of quinite.—**R. Morquer**: The systematic value of the genera *Dactylium* and *Diplocladium*, especially *Dactylium macrosporum*.—**A. Sartory, R. Sartory**, and **J. Meyer**: The influence of radium on the production of the zygospores in *Mucor spinosus* (*Zygorhynchus spinosus*). Zygospores were produced in cultures under the influence of the radium radiation: in the absence of radium, no zygospores were obtained by cultivation in the same culture medium.—**E. Brumpt**: The study of autofecondation in the aquatic mollusc *Bullinus contortus*.—**J. B. Abelous** and **H. Lassalle**: The humoral origin of the modifications of excitability of the nervous system in the course of the Wallerian degenerescence of a severed nerve.—**Emile F. Terroine** and **Mme. Hélène Sorg-Matter**: The influence of the magnitude of the consumption of thermogenesis on endogenous nitrogen metabolism.—**Georges Lakhovsky**: The action on living beings of oscillating circuits.—**Em. Perrot** and **P. Bourcet**: A new method of estimating crystallised digitalin.

LENINGRAD.

Academy of Sciences (*Comptes rendus*, 1928, A, No. 1).—**V. Ipatiev, N. Orlov**, and **B. Dolgov**: The preparation of certain α-ω-diphenylparaffins. Diphenylpropane may be obtained by hydrogenating dibenzylketone under pressure in presence of nickel at 210° C., using Ipatiev's high-pressure apparatus. Diphenylbutane may be prepared by hydrogenating unsaturated diphenylparaffins (diphenylacetylene and diphenylbutadiene) under pressure at 210° C. Diphenylpentane can be prepared by hydrogenating dibenzylacetone obtained by distilling calcium salts of phenylacetic and phenylpropionic acids.—**P. P. Sacharov**: The hereditary transmission of the size and weight of flies resulting from inanition. The reduction in size and weight of larvæ, pupæ, and adult house flies resulting from inanition is not hereditary, since the progeny of the smallest flies was larger than that of the normal ones.—**P. Kobeko** and **I. Kurchatov**: The validity of Faraday's law for currents due to ionisation by collision. It has been shown that in an electrical field exceeding 2×10^4 volts/cm., new charges arise due to collision; it has not been ascertained, however, whether the newly formed charges are ions or electrons. The most direct way to solve the question was to test the application of Faraday's law in such conditions. The results of the experiments by the authors show that Faraday's law holds within the limits of errors, and that consequently the charges liberated by the mechanism of collision are ions and, especially in the case of glass, the most mobile, the sodium ions.—**P. Schmidt**: Three rare cat-fishes of the Magdalena River (South America, Columbia). *Doras crocodili* Humb. et Val. is re-described fully, and *D. longispinis* Steindachner referred to it as a synonym; measurements of *Trachycorystes magdalenæ* Steind. and *Pimelodina flavipinnis* Steind. are given.—**P. Tartakovskij**: The scattering of electrons in a thin aluminium foil. Scattering of electrons by the surface of a crystal is accompanied by interference of phase waves. A diagram analogous to a röntgenogram is obtained containing several maxima the significance of which has not been discovered.

Marshall.—The Effect of Changes of the Heart Beat on the Coronary Circulation, Dr. G. V. Anrep and H. Hausler.—A Modified Cannula for Coronary Perfusion, R Rossler.—A Method for Measuring the Oxygen Consumption of the Tortoise Heart, W. Pascual.—An Approximate Method of Determining the Total Lung Ventilation of Small Animals, H Taylor.—Precocious Puberty induced by (a) Oestrin, (b) Anterior Pituitary Extract, Dr. A S Parkes and G. F Marrian.—The Vascular Reaction in Response to Fear of the Denervated Colonic Mucosa in the Dog, H. Florey and A. N. Drury.—Improvements in the Thermal Method for following the Velocity of Rapid Processes, Dr. F. J. W Roughton.—A Method of Measuring the Oxygen Dissociation Curve of Hæmoglobin applicable both to Dilute and Concentrated Solutions, W. H. Forbes and Dr. F J. W. Roughton.—(a) A New High Speed Electrical Recording System; (b) The Shape of the Action Potential Wave Accompanying a Single Sensory Impulse, B H. C Matthews.—(a) Impulse Discharges in Single Motor Nerve Fibres, (b) Sensory Impulses from the Heart, Dr. E. D. Adrian and D. L. Bronk.—A Scheme for Studying the Pulse-Wave, J. C. Bramwell.—Records of the Korotkow Sounds, J. C. Bramwell, G. L. Brown, and R. Ellis.—The Effect of Frequent Bleedings on the Spleen of the Rabbit, T C. Shen.

MONDAY, May 21.

Royal Institute of British Architects, at 8.—H. P. Adams: English Hospital Planning

Royal Society of Medicine (Odontology Section) (Annual General Meeting) (at Royal College of Surgeons), at 8.—Sir Frank Colyer: The Pathology of the Teeth of Elephants.

Royal Geographical Society (at Æolian Hall), at 8.30.—Dr. J. C Shattuck: A Journey in Liberia and the Eastern Congo.

Medical Society of London, at 9.—Sir Archibald Garrod: Lessons on Rare Maladies.

TUESDAY, May 22

Illuminating Engineering Society (Annual Meeting) (at Home Office Museum, Horseferry Road, Westminster), at 6.—D. R. Wilson: Presidential Address.

Royal Photographic Society of Great Britain, at 7.—J A. Chubb. The University of Chicago Epigraphic Expedition, Luxor, Egypt The Photo-Drawing Process of Recording Ancient Egyptian Scenes and Hieroglyphs.

Royal Anthropological Institute, at 8.30.—Prof. J L. Myres: Ancient Greek Physical Types

Institution of Mining and Metallurgy (Special Meeting in Cornwall) (continued on May 23 and 24).—Annual Meeting, to be followed by a discussion on The Illuminating Engineering Movement at Home and Abroad.

WEDNESDAY, May 23.

Royal Society of Medicine (Comparative Medicine Section) (Annual General Meeting), at 5.—Dr. J. P. McGowan. Aplastic Anæmia.

Geological Society of London, at 5.30.—Prof. P. G. H. Boswell. The Geological Features of the New Mersey Tunnel (Lecture).

Folk-Lore Society (at University College), at 8.—Miss Sona R. Burstein: The Harrowing of Hell.

British Psychological Society (Medical Section) (at Royal Anthropological Institute), at 8.30.—Prof. B. Malinowski: The Melanesian Medicine-Man and his Patient.

THURSDAY, May 24.

Institution of Municipal and County Engineers (East Midland District Meeting) (at Council Offices, Hinckley), at 11.15 a.m.

FRIDAY, May 25

Physical Society (at Imperial College of Science), at 5.

Institute of Chemistry and Society of Chemical Industry (East of Scotland and Glasgow and West of Scotland Sections) (Joint Meeting at St. Andrews), at 6 30.—Principal Sir James C. Irvine (Address).

Royal Institution of Great Britain, at 9.—A. C. Egerton. Engine Knock and Related Problems.

SATURDAY, May 26.

North of England Institute of Mining and Mechanical Engineers (at Neville Hall, Newcastle-upon-Tyne), at 3.—R. White: The Use of Carbon Monoxide Masks in Mines.

PUBLIC LECTURES.

MONDAY, May 21.

University College, at 5.30.—Prof. Ross G. Harrison: Modern Trends in the Study of Animal Development.

THURSDAY, May 24.

University College, at 2.30.—Sir Flinders Petrie: Recent Discoveries (also on May 25, at 5.30, and May 26, at 3).

Institute of Pathology and Research, St. Mary's Hospital, at 5.—Prof R H A Plimmer. Some Recent Researches on Vitamins.

Imperial College—Royal School of Mines, at 5 15.—Dr E. M. Kindle: Types of Sedimentation on the Atlantic Coast of N. America. (Succeeding Lectures on May 29 and 31)

CONGRESSES.

May 19 to 26.

Congress of Radiology of the Union of S.S.R (at Kiew).—Subjects of Discussion:—The Consequences of the Changes of Elements of Cells under the Influence of Radiation. Classification and Radiodiagnosis of Diseases of Joints. Functional and Anatomical Changes of the Gastro-intestinal Canal after Operative Intervention. X-ray-therapy of Diseases of the Circulatory System Temporary Sterilisation with X-rays. Radiodiagnosis of Intestinal Diseases.

May 25 to 27.

French Societies of Oto-neuro-ophthalmology (at Marseilles)

SATURDAY, MAY 26, 1928.

Broadcasting as an Aid to Scientific Study.

"THE modern world," wrote the author of "Arnold of Rugby" in a more recent work, "with its democratic temper which holds in small esteem the traditions of a learned caste, realises that the society of a university may embrace many groups within the State who possess capacity and energy for the serious pursuit of knowledge, even though they are not concerned to complete the courses prescribed for degrees. It [the university] thus becomes an organ for extending the resources of science beyond the limits of the school, it becomes 'an instrument of the people,' placing its resources at the disposal of all members of the State who need its aid. No doubt this ideal is easier to describe than to fulfil: the duty is not fulfilled by merely distributing lecturers or books to miscellaneous audiences; still less by offering instruction of an elementary grade, such as the schools should provide; nor is the ideal attained by ministering only to one class of the community, artisan or other, which can make its voice heard. The university of the future will place at the disposal of all classes, for the common benefit, both the methods of study and the result of research which give to it its special character; and it will discover manifold means by which such a purpose can be achieved." When one considers the potentialities of broadcasting, this description of Prof. J. J. Findlay's seems almost prophetic, though he could not have foreseen the possibility of "taking the mountain to Mahomet" when he wrote "The School."

Broadcasting offers unique opportunities for the encouragement of scientific study. In spite of anti-highbrow campaigns in the daily press, there is undoubtedly an audience of some millions who are finding an interest in the broadcast science talks. In some cases it is the professional interest of a garage mechanic in talks on metallurgy, and in others it is a purely intellectual interest, in talks on, say, astronomy. In any event the audience is certainly there, and it is an audience which cannot be reached in the first place by other means. A small proportion of its members habitually buy scientific reference books or go to public lectures, but large numbers can and do listen to the unseen lecturer. This is probably accounted for by reason of the fact that the value of the broadcast lecture lies in its capacity for awakening and sustaining interest rather than its capacity for supplying information.

The exposition of science in popular periodicals and in the daily press has not always been in the right hands. There have been notable exceptions, of course, but many articles appear in print which do little more than appeal to a sense of the marvellous. Scientific exhibits also are often regarded as like unto conjuring tricks; and their meaning is not understood. There is a demand for sensationalism and 'latest theories' from an over-credulous public, ready to believe all conclusions without having any idea of the sort of evidence behind them—the experimental work, etc.—and often without any knowledge of the scientific method. We are living in a new age of faith. As a result the conscientious scientific worker is apt to shrink from popular exposition, and too often others have rushed in where he feared to tread.

From time to time there emerge from amongst workers in science, men who combine scientific ability with a gift for the interpretation of experimental work and its dependent theories, in lucid and non-technical language. Such men are all too rare. A great task confronts them, and no opportunity for the dissemination of their influence should be lost. It is of growing importance that there should be a widespread and intelligent understanding of the work of science. Research work is, of course, often carried out by individuals working at the universities, or in their own laboratories, quite independently of public support. The situation is, however, now changing. The extreme specialisation which is becoming the rule necessitates team work and a multiplication of the actual number of workers. Much work will be needed to consolidate the new ground which has been broken so rapidly of late years, and there are signs that an expansion of the research world is actually taking place. The growth of organised State-aided research work and the foundation of research laboratories by large industrial firms will, before long, make it much to the advantage of science to have a sympathetic electorate. It is important that the public should have a sense of proportion of the utility of research work. Work must not be thought worthless because it has no obvious practical application; nor, on the other hand, must research work in pure science be expected to put atomic energy and the transmutation of metals on an economic basis forthwith. A widespread knowledge of scientific principles would, in addition, be of great value to the community.

There is, then, an important field for broadcast lectures of an introductory character which will awaken interest, give a grasp of the fundamental principles involved, and provide sound guidance for further study of a serious nature.

A considerable number of science talks have already been broadcast, but these have so far been of an experimental nature and were intended to investigate the demand for such talks. In the early days of broadcasting, single talks on a variety of scientific subjects were given, but more recently connected series of six or a dozen talks of a more advanced and serious nature have been the rule. (The names of Sir Oliver Lodge, Prof. H. H. Swinnerton, Prof. W. Cramp, Prof. A. V. Hill, and Prof. C. H. Desch are to be seen in the B.B.C. list of lecturers for the past year.) The number of interested listeners is encouraging and seems to justify the development of regular short courses, in spite of the growing competition for programme space.

In a report on Natural Science in Adult Education (Paper No. 8 of the Adult Education Committee of the Board of Education) the comparative neglect of science in adult education is deplored. The explanation given for this neglect is that, in comparison with subjects such as history and economics, there is a shortage of suitable lecturers that provision for experimental work is always a matter of difficulty; and that in the minds of those attending adult schools science courses savour of technical instruction. When once half hearted classes have discovered that the science course is intimately related to daily life, and that it stimulates their powers of reflection and judgment the success of the course is assured. The report cites the interest shown in broadcast science talks as evidence of the great latent interest which is believed to exist.

Attention has recently been directed in these pages to the teaching of science in schools. It has been said, apparently with considerable justification, that the "teaching of science in our schools is parrot work, confined to special subjects and failing to impart any notion of the scientific method." All the conditions obtaining in the smaller secondary schools combine to produce this state of affairs. The laboratory equipment is inadequate, and there are insufficient supplies to make the construction of apparatus and glass blowing possible. Stereotyped and exacting syllabuses determine largely the scope and character of school text-books and make insistent demands upon the time available for instruction. Yet a large number of pupils who will go on to science courses at a university are trained under these conditions. The state of affairs is due in part to the school certificate and university scholarship syllabuses, and in part to limited finance, which leads to inadequate staffing and equipment. Broadcasting, perhaps, can be of assistance here. Some thousands of elementary schools are finding that their staff can virtually be increased by means of the broadcasts to schools that are given daily from the B.B.C. stations, and this year, as an experiment, the B.B.C., in consultation with teachers, has started to give weekly talks for secondary schools. The talks deal with subjects of general interest, on which it is unlikely that there will be authoritative exponents among the school staff, and in science an attempt is being made to give short courses of an introductory character on subjects which are not normally in the school curriculum. The virtual neglect of all sciences other than physics and chemistry in boys' schools, and botany in girls', is much to be deplored. It is not suggested that a number of branches of science should or could be taught in detail, but it should not be possible for pupils to leave school with no more familiarity with science than accrues from the mechanical performance of the usual experiments in physics and chemistry.

There is no doubt that the distribution of university entrants among the various branches of sciences suffers an artificial bias to physics and chemistry. Undergraduates faced with a choice of subjects are chary of embarking on an unfamiliar science, and frequently do so only to make up the requisite quota enforced by the university regulations. With the view of filling the gap in school science teaching, talks on geology and anthropology have been broadcast during the past term, and various other courses, including biology, are projected for the future. An attempt is made to link up the various courses and show how each branch of science depends on its related branches. The talks are given at 4.15 P.M. after the normal school hours, and it is found that groups of pupils stay behind voluntarily to listen.

The desire for intellectual adventure is characteristic of the adolescent, and broadcasting can give the right amount of guidance for private study without destroying the sense of independence which is such a rich source of energy. Both in adult and in adolescent education, broadcasting has a useful sphere of activity, but the extent to which it can be effective depends upon the co-operation and support given by other educational bodies. We ourselves have no doubt as to its potentialities as a means of creating interest in science among the general public and affording a valuable educational aid to the work of the school.

The Societies of Ants.

The Social World of the Ants compared with that of Man. By Dr. Auguste Forel. Translated by C. K. Ogden. Vol. 1. Pp. xlv + 551 + 10 plates. Vol. 2. Pp. xx + 445 + 16 plates. (London and New York: G. P. Putnam's Sons, Ltd., 1928.) 63*s*. net.

AUGUSTE FOREL is one of the grand old men of science, a survivor from the heroic heyday of Darwinism, and a welcome reminder, in this epoch of specialisation, that a man can excel in several branches of learning. To the general biologist he is known (not to mention his contributions to comparative physiology, such as his "Senses of Insects") as one of the greatest authorities on ants, both their systematics and their behaviour; he was one of the notable pioneers of neurology and brain anatomy (I recollect, when I visited him in his home above the Rhone Valley, his showing me some brain sections: "You see those," he said, "those were the first microscopic sections of the human brain to be made. I made them, in the 'seventies."); to the medical profession he is a very distinguished psychiatrist; to the sociologist, the author of that arresting book, "La Question sexuelle."

The lover of natural history will rejoice to learn that all these activities had their root in Forel's passion for observing ants. At the age of ten he made an interesting original discovery—that certain small ants lived as thieves in the nests of other larger species; and when only seven he had, without knowing of Huber's classic work, gone far towards an independent discovery of the famous slave-making habits of *Formica rufa* and *sanguinea*. Then came the happy accident. His grandmother gave him a book. It was Huber's publication of 1810, "Recherches sur les mœurs des fourmis indigènes"; Huber himself had been an old flame of hers, and had presented it to her! However, as she said, she had never been able to get through the book: "It was not her style"; but the eleven-year-old Auguste devoured it, and it became his Bible.

Out of Forel's passion to know the habits of ants there came the desire to know more of their structure and physiology; this led him to take up the study of biology; from this in turn he was led to medicine, and thence (with his love for studying behaviour) to psychiatry.

The English-speaking world will be grateful to Mr. Ogden for translating Forel's summary of his main life-work, and to the publishers for the admirable way in which it is turned out. For it is indeed a classic. W. M. Wheeler's "Ants" is the only book with which it can be compared, and that is perhaps, for all its fascination, a shade stiff for the non-biologist. This is not to say that the layman will by any means always find Forel's pages easy going; but the personal touch and the enthusiasm with which the book is written will carry him over many hard passages.

The whole ant-world is here: and a strange world it is. Here is a classification of the five thousand or so ant species, with the fossil record and probable evolutionary history of the ant stock. Here is their geographical distribution, their anatomy, the physiology of their senses. But more than two-thirds of the two volumes is taken up, as is fitting, in describing and discussing their ways of life—their nest-building, their nuptials and the founding of new colonies, their daily routine, labour and sleep, toilet and games, feeding and language. Then come their diverse specialisations, how some tend cattle, others store grain, others make of themselves living honey-pots, others use child-labour in building their nests; how some are thieves, and others parasites, some predatory nomads, and others base their communities on slavery. Then there is an admirable résumé (Wheeler has put it vividly before us already in his "Social Life Among the Insects," but it is good to have another survey at a somewhat different angle) of the food-economics of the ant-community and of the extraordinary guests and parasites of ants, which include several thousand species of animals not found elsewhere than in ants' nests, some of them with habits unparalleled in strangeness in the whole of the rest of the animal kingdom, save perhaps in man alone. The perversion of instinct occasioned in the ants by the secretions of some of these guests, sometimes leading to the neglect of the ants' own brood, has its only parallel in the abuse of alcohol and other drugs by human beings.

Nor finally must we omit to mention the valuable appendix by Prof. Bugnion on "The War between the Ants and the Termites"—a most interesting study of the competition between the two different types of terrestrial social insects. There will be no biologist who will not gain new facts, new ideas, and new points of view from this storehouse of first-hand knowledge on the most successful type of invertebrate organism; it has obvious interests for the sociologist, for the psychologist, and the student of the origin of language; and it will well repay the general reader.

It would be both impossible and impertinent to attempt any detailed criticism of the book in such a review as this, and I propose to confine myself to some general reflections, inspired by the author's epilogue and the translator's foreword.

Mr. Ogden begins his preface with the words, "There are scientists who hold that in due course Man will yield to the Ant the mastery of a planet grown less hospitable to the relatively idle and unorganised." The author near the close of his work writes, on the resemblances and differences between ants and man, "Among ants we find weavers, butchers, cattle-rearers, masons, road-makers, harvesters, bakers, mushroom-farmers, excellent nurses of various kinds, gardeners, warriors, pacificists, slave-makers, thieves, brigands, and parasites; but we find no professors, orators, governors, bureaucrats, or generals, nor even corporals, nor do we find capitalists, speculators, or even swindlers. Think carefully about that, dear reader, and it will give you the key to the mystery."

The key to the mystery is of course, as Forel points out a few pages later, that, in spite of their antennal language, ants have no tradition in the broad biological sense, no transmission of experience from generation to generation, no real education; and this because their whole behaviour and existence is on a different plane from ours, being based primarily on instinct, while ours owes its distinctive qualities and its biological success to the capacity for conceptual thought or reason, and to the power of rapid learning. Once this is grasped—and, in spite of the lucubrations of non-scientific popularisers, of whom Maeterlinck on Termites is a recent flagrant example, there is no doubt of the reality of the difference and of its fundamental biological significance—it is difficult for anyone, scientist or no, to believe that man will yield his supremacy to ants unless there were to be some very radical and peculiar changes in the conditions of this planet.

Consider the vital differences which this one original difference brings in its train. Man, through tradition, is capable of rapid change in the organisation of his societies, rapid improvement in his control over Nature: ants are confined to the slow changes of random variation sifted by the wasteful hand of natural selection. Man can consciously envisage improvement in his conditions, and deliberately set about the control of his racial destiny; ants can do nothing of the sort. Ants have probably been in existence since the Secondary period; since the Oligocene, perhaps fifty million years ago, they have not progressed or even changed in any essentials: man did not become man until the Pliocene at earliest, and even since that time, first he and then his societies and traditions have been evolving at an ever-accelerated rate, which shows no sign of slowing down. His species is thus still in its youth, while ants have long reached evolutionary stability. Then there exist some five thousand quite distinct species of ants, biologically separate and mutually sterile: man exists in but one species, whose races are all fertile *inter se*. Man has the longest infancy and the longest period of dependence and education of any organism: ants, after their larval existence as 'growth-machines,' followed by the radical remodelling of their passive pupal period, emerge fully-formed, ready at once to undertake their most elaborate actions, and never grow or moult again. A society of men is based primarily upon a common tradition, and is built round a scaffolding of authority and obedience: a society of ants is based primarily upon a differentiation of instincts, and lacks any central government or system of authority, the obedience of ants being obedience to their own instincts instead of to leaders. The patriotism of men is based upon ideas and tradition: the patriotism of ants is based upon smell.

Finally, and perhaps in a way most striking, the division of labour in human society depends chiefly upon learning to use different tools and technical methods, and there is no structural differentiation into well-marked castes; while that in ant communities depends upon differences present from the moment of emergence, differences not only in the structure of the brain and consequently in the instincts, but also in the general structure of the body. The ant-soldier hatches predestined from its cocoon, with head and jaws already turned into weapons; the human infantryman, however, is not born with one hand in the form of a rifle and the other in that of a lance, but weapons have to be manufactured for him by society, and he has to learn their use. Again, the range of size in normal human adults, including pigmies, is from about 50 lb. to 250 lb. But there are ants (*e.g. Carebara*) in which the members of one caste—the queens—are at least 2000 times as bulky as the worker individuals.

The ants were already in their present position of dominant land invertebrate in the Oligocene. But they were powerless to prevent the evolution of the higher mammalia and of man, or man's subsequent rapidity of progress. There seems no reason whatever why they should, after so long a stable period, re-acquire the capacity for rapid evolutionary change, or suddenly succeed where they have previously failed.

If we ask what is the secret of this failure to attain complete biological dominance, in spite of such large measure of success, the probable answer lies in their small size. This is inherent in the very nature of insectan organisation. The arthropods in general are limited to sizes far below those attained by cephalopods and vertebrates, owing to the necessity of shedding and re-forming their skeleton in order to accomplish each step in growth. The insects are limited to a much smaller maximum size, as Mr. J. B. S. Haldane has pointed out, owing to their system of respiration. The transport of air direct to the tissues by tracheal air-tubes is extremely efficient for small organisms; but it depends upon diffusion, and diffusion will not be efficient in tubes of more than a certain length. No insect attains more than an ounce or so in weight; and the more active ants are mostly far smaller. This small size limits the number of cells in the brain, and this in turn limits the development of mental faculties; for it appears to be necessary to have many more cells to be capable of rapid learning than for even the most elaborate of instinctive reactions. Had ants been capable of attaining the size of dogs, or even of rats, the course of evolution might well have been very different. . . .

It is to be regretted that Forel has not kept in touch a little more with recent work in heredity, sex, and kindred subjects, for some of his generalisations and explanations are marred by being quite out-of-date: we may cite particularly his discussion of sex-mosaics among ants. In evolutionary theory, he attempts to combine natural selection with Lamarckian views based on Semon's "Mneme." But, as Bateson once put it, to explain heredity by memory is to attempt an explanation of the less in terms of the more complex—as well, be it added, as having no foundation in experimental fact. He asserts with extraordinary dogmatism (vol. 1, p. 15) that those who claim that the castes of ants are determined (as he admits is the case in bees) by feeding, are in error. "They are wrong: polymorphism in ants takes place in the egg." But no proof is given of this, and the evidence that does exist is certainly not against that natural hypothesis. Bugnion's assertion, by the way, which Forel cites on the same page, that the *nasutus* soldier of Termites emerges fully-differentiated from the egg, has since been shown to be erroneous, and the Italian school is making it quite possible that even Termite castes owe their origin to diet-differences.

However, these are minor points. The book is a great book, full of the meat of fact and the wine of thought, and fragrant with the personality of the author. We are happy that he has lived long enough to crown his eighty years of labour with this monument. J. S. HUXLEY.

The Almagest of Ptolemy.

Composition mathématique de Claude Ptolémée. Traduite pour la première fois du grec en français, sur les manuscrits originaux de la Bibliothèque Impériale de Paris, par M. Halma, et suivie des notes de M. Delambre. (Réimpression facsimilé.) Tome premier. Pp. lxxvi + 476 + 48. Tome deuxième. Pp. viii + 448 + 40. (Paris: J. Hermann, 1927.) 2 vols., 210 francs.

THE publication of this facsimile of Halma's handsome edition of the Syntaxis of Ptolemy shows enterprise on the part of the publishers and will no doubt be welcomed by mathematicians and astronomers interested in the history of their subjects, as copies of the original book have long been scarce. Until the issue of Heiberg's definitive text in 1898 and 1903, Halma's was the only modern edition of the whole of the Greek text, and it has the merit of containing, in addition to a French translation facing the text, a large quantity of notes by Delambre as well as an elaborate historical introduction. Halma also had only one predecessor, Simon Grynæus, the editor of the *editio princeps*, containing the full Greek text with the commentary of Theon of Alexandria, which was published at Basel in 1538, previously to which date scholars had to be content with translations from the Arabic or epitomes of such versions.

The Abbé Nicolas Halma (1755–1828) studied first at the College of Sedan, his native place, and afterwards at Paris. Besides Greek and Latin, he learned Hebrew, German, English, and Italian; he also studied mathematics, geography, theology, medicine, poetry, and even drawing. Principal of the College of Sedan from 1791 until its suppression, he moved to Paris and, after holding various other posts, became professor of mathematics and geography at the Prytanée in Paris, professor of geography at the École Militaire at Fontainebleau, librarian to the Empress, and her instructor in history and geography. It was Delambre who, knowing that Halma combined with his accomplishments as a Greek scholar the necessary mathematical ability, urged him to undertake a work which would, he knew, be difficult but would be as honourable to him as it would be useful to science. After several years of hard work he produced the first volume in 1813. The times were not propitious, and he had to pay the cost of its production (about 30,000 francs) out of his own pocket. The second volume appeared in 1816; it was dedicated to Louis XVIII., with a preface in which that monarch was compared to Antoninus Pius, the patron of Ptolemy; the Ministry of the Interior subscribed for 225 copies and, with this encouragement, Halma decided to add to his edition certain minor Greek astronomical treatises as well as the commentary on Ptolemy by Theon. Of the latter commentary, however, only two Books actually appeared, in 1821 and 1822.

The *editio princeps* of Grynæus had been based on a MS. of the sixteenth century (Paris. 2393), a copy, at second hand, of another written in the ninth century which is the first of those used by Heiberg as the basis of his text. Halma used Grynæus's text as his groundwork, but consulted, in addition, four of the MSS. which are the main foundation of Heiberg's text. Unfortunately, Halma's philological qualifications were not quite adequate to enable him to produce a really authoritative text; while Manitius, the editor of the German translation of Heiberg's text (Teubner, 1912, 1913), says that in most of the difficult passages the French translation leaves us in the lurch. Nevertheless, with all its faults, Halma's edition will always retain its great historical interest. T. L. H.

Infection and Immunity in the Bee Mite.

L'Infection microbienne et l'immunité chez la mite des abeilles, Galleria Mellonella. (Monographies de l'Institut Pasteur.) Par S. Metalnikov. Pp. iv + 139. (Paris: Masson et Cie., 1927.) 18 francs.

THIS monograph gives an account of researches carried out at the Pasteur Institute over a period of more than ten years on the microscopic infection and immunity in the mite of bees. This insect, which has been of interest to scientific workers since Aristotle, is peculiar in that it is the only known animal which derives its nourishment from wax. The present work, in fact, shows that wax in some form is essential to its life and development. Ordinarily, the night-flying moth deposits its eggs in the hives of bees, where they hatch and pass through the successive stages to the fully-developed winged form. In the larval stage it feeds upon the wax of the bees, and although experiments have been carried on with the insect in all stages, it is upon the larval one that the bulk of the present work has been done.

The author begins with an account of the biology and physiology of the insect. He has successfully cultivated it under laboratory conditions and made a minute study of its digestive apparatus and nutrition. It has, in fact, become in his hands a laboratory animal which lends itself to most types of experiments. Then the question of infection and immunity is dealt with. By injection of small and large doses into the body cavity, he has been able to determine whether and to what degree natural immunity exists. Immunity is hereditary, providing several generations have been immunised. A chapter on phagocytosis describes in detail the types of cells and the part played by each. The reaction is apparently specific for each organism, and is demonstrated by changes within the protoplasm of the cells. For example, an injection of tubercle bacilli brings about in a few minutes the formation of granules, followed in several hours by the formation of a giant cell. The leprosy bacillus, on the other hand, is clumped within single cells, and the cholera vibrion leads to formation of vacuoles.

The part played in immunity by the nervous system is striking. The third pair of thoracic ganglia is intimately concerned in that its destruction results in loss of ability to become immune. The remainder of the nervous system seems to have no such connexion and may be damaged without affecting immunity. A special chapter deals with tuberculosis. The fact that wax in some form is essential to the life and development of the larvæ makes it peculiarly suitable for experiments with the tubercle bacillus. The larvæ, also, have a complete natural immunity to this organism. The defence mechanism is shown to be similar to that of man and the higher animals, except that in the larvæ the process is much more rapidly brought about, being a matter of hours only. This rapid response is thought to be due to a cellular lipase, probably of the same order as that postulated by Metchnikoff and Koch. It is by an increase in this substance that favourable results in clinical tuberculosis are obtained, and, in the author's opinion, proper treatment favours such an increase.

In the final chapters the phenomenon of anaphylaxis and the factors in immunity are discussed. In connexion with the former it is interesting to note that anaphylactic shock cannot be induced by foreign proteins such as horse serum, but is brought about by blood from the same larva or one of the same or related species. The factor involved seems to be the altered state, apparently by oxidation, of the injected blood. In immunity the part played by the cell is stressed throughout as the factor of first importance, that of antibodies being secondary.

The subject is well presented and contains much useful material on a subject of importance to biologists generally. Throughout the monograph references are quoted and discussed.

The Basic Science.

A Short History of Physics. By H. Buckley. Pp. xi + 263. (London: Methuen and Co., Ltd., 1927.) 7*s.* 6*d.* net.

THE degree to which specialisation has been advanced in every branch of science, coupled with the not unnatural desire on the part of university teachers to equip their students with the necessary technical knowledge to encourage further advances in even more specialised fields, tends to discourage students of science from delving into the history of the earlier developments of their particular subject matter, particularly if this knowledge has to be culled from a large number of different works, not always easily accessible. For some time past attention has been given to remedying this defect. The University of London has founded a chair in the 'history of science,' and already several excellent volumes have been published giving a broad survey of the outstanding contributions of scientific investigators to the progress of scientific thought and the harnessing of natural forces in the service of men. The Cambridge University Press and other publishing houses have also printed series of volumes with the same object in view.

This "Short History of Physics" by Mr. Buckley is most welcome. It is to be hoped that he will be encouraged to write a long one, for this is a most stimulating production. Within the small compass of 250 pages the author ranges over the field of physics from the earliest recorded physical observations to the latest developments of the theory of relativity, the quantum theory, and the latest experimental work on the structure of the atom. Most of his chapters are models of compression and clarity, no salient fact escaping his attention, while his selected quotations from the writings of the great ones of physics are the quintessence of appositeness. Possibly he over-emphasises the influence exerted by the Greek philosophers, culminating in

Plato and Aristotle, and under-estimates the effect of great historical events in stemming the advancing tide of learning: but his tribute to the debt which civilisation owes to the Arabs is welcome at a time when we are apt to regard their descendants as crude barbarians.

The last chapters are the least satisfying from the point of view of historical study, though unquestionably of the greatest value to the advanced student of physics. Not that Mr. Buckley can be held responsible. Modern physical theory has not yet reached that stage of perfect clarity which characterised the work of the investigators of the preceding two centuries. Their work could be explained in terms of fairly familiar concepts, whereas some modern theories make almost impossible demands upon the imagination of those without more than a fair amount of mathematical knowledge. Eddington and Jeans, it is true, are making them plainer, but still not plain enough for the average well-educated member of the community to comprehend their full significance. It is interesting to speculate whether the intellectual gulf separating the great physical scientists from the rest of their fellows is not greater now than at any previous period in the world's history; whether they have not usurped the place of the metaphysicians.

A. G. C.

Our Bookshelf.

Müller-Pouillets Lehrbuch der Physik. Elfte Auflage. Herausgegeben von A. Eucken, O. Lummer, E. Waetzmann. In fünf Bänden. Band 5: *Physik der Erde und des Kosmos (einschl. Relativitätstheorie).* Zweite Hälfte: *Physik des Kosmos (einschl. Relativitätstheorie).* Herausgegeben von August Kopff. Pp. xii + 596 + 14 Tafeln. (Braunschweig: Friedr. Vieweg und Sohn A.-G., 1928.) 36 gold marks.

The volume on the "Physik des Kosmos," which forms one number of Müller-Pouillet's "Lehrbuch des Physik," gives an interesting up-to-date account of astrophysics, looked at from the physicist's point of view. It is edited by Dr. Kopff of Berlin-Dahlem, with chapters by different specialists such as Prof. Emden, who writes on "The Sun." The German style is on the whole easy and readable, the descriptions of instruments and methods clear, and the work of a high standard of accuracy. As is perhaps inevitable in a work composed by a number of different authors, there is occasional overlapping and a lack of balance between the different branches of the subject. The work of the English mathematicians is very fully discussed, especially the theories of Prof. Eddington. References are freely given in some chapters, but more might have been given with advantage in other chapters, for example, Chap. iii., especially in the summary of theories of stellar radiation at the end. Many familiar photographs are to be found illustrating the chapters on clusters and nebulæ, two chapters which seem rather long for the scale of the book. On the whole, the book deals rather more with stellar statistics than would seem to be necessary if written primarily for the physicist.

The chapter on cosmogony is interesting. Prof. Kienle is, on the whole, somewhat too content to give the views of others and does not often express his own views. Where he does do so definitely, the reviewer is not generally able to agree with him, but it must be admitted that Prof. Kienle is both fruitful and suggestive in emphasising fresh points of view. The chapter on relativity is interesting both historically and as giving a reasonably short description of both the special and the generalised theories and their applications to astronomy. Very few mistakes have been noted, but the line of unknown origin of wave-length 5316·87 A. has long been known. It may be natural that the English reader and the German writer should feel different needs in the matter of references, but for at least one reader who wishes to go behind the text of the book, its value would have been enhanced considerably by a fuller use of references to original work.

F. J. M. Stratton.

Religious Conversion: a Bio-Psychological Study. By Prof. Sante De Sanctis. Translated by Helen Augur. (International Library of Psychology, Philosophy and Scientific Method.) Pp. v + 324. (London: Kegan Paul and Co., Ltd.; New York: Harcourt, Brace and Co., Inc., 1927.) 12*s*. 6*d*. net.

This treatise on religious conversion by the professor of psychology in the University of Rome is of importance. The author defines conversion as "an exceptional process representing an intellectual and moral regeneration of the person in whom it occurs"; but its etiology is "far too complex to allow us to ascribe it to disease, age, endocrine variations, or the like." Of its psychic antecedents the experience of suffering, whether of illness, domestic misfortune, moral perturbation, or some similar condition, seems the most common. With regard to the suddenness of onset of conversion, this is probably less definite than appears to the patient, since "an emotional shock suffices to blot out mnemonic pictures nearest to the event itself." Yet Prof. De Sanctis does not regard the process as dissociated from the will of the patient. Lasting effects upon the consciousness cannot be produced "unless it has been adapted by preparation and unless it assumes a decisive attitude of action"; and Ruysbroeck's saying is quoted "You are saints according to the measure of your desire to be such."

In short, Prof. De Sanctis does not pay to Freudian theories all that tribute of uncritical respect which has become customary. He uses the happy term 'mutation' to describe the process and results of conversion; old elements of personality are so recombined as to give birth to entirely new quality of life. It will be seen that this involves

the spontaneity of the *psyche*, which is to be regarded as a form of activity *sui generis* "regarding whose essence and origin psychology should remain entirely agnostic." This book displays an independent point of view and will be read with much interest.
J. C. H.

Regeneration und Transplantation. Von Prof. Dr. E. Korschelt. Band 1: *Regeneration.* Pp. xii + 818. (Berlin: Gebrüder Borntraeger, 1927.) 60 gold marks.

PROF. KORSCHELT'S modest book of 1907 is now swollen almost beyond recognition. The second edition of "Regeneration und Transplantation" is a massive volume of eight hundred pages dedicated to the four hundredth anniversary of the University of Marburg. That the work of twenty years should involve the printing of some six hundred additional pages is no doubt evidence of progress; it is also a very depressing fact, for it tends to limit the interest in a definite and fundamental property of living animals to a select band of specialised individuals instead of providing for the needs of a more numerous public. At the same time, an encyclopædia has its uses, and when it is written by Prof. Korschelt, it will long remain a source of accurate information and instruction.

The arrangement of the book is good, and most of the illustrations are new and helpful. Without doubt, the author has provided by far the most comprehensive text-book available, and it is regrettable that some sections are strangely inadequate. The phenomena of autotomy and regeneration in the Crustacea are described as though they were in the same nebulous state as those of other groups. This is unfortunate, for the physiological mechanisms involved are now adequately known, and they should not have been omitted from a work of this nature.

Prof. Korschelt's second volume will deal with the more exciting results of transplantation, and it will be awaited with interest. At present we have to thank the author for collecting into one volume the scattered results of many researches, and for presenting them in a not too forbidding form.

The Journal of the Institute of Metals. Vol. 38. Edited by G. Shaw Scott. Pp. xii + 813 + 59 plates. (London: Institute of Metals, 1927.) 31*s*. 6*d*. net.

A FEATURE of the new volume of this Journal, containing the papers presented at the last autumn meeting of the Institute, is the attention given to the accurate determination of equilibrium diagrams, in which English metallurgists are now taking the lead. Mr. Hume-Rothery has re-determined the system magnesium–cadmium; this system has been included in all text-books on account of its unique constitution, but it now proves to be incorrect, although the system still shows several interesting peculiarities. A revision by Mr. Raper of one of the most discussed portions of the copper–tin diagram again shows the essential accuracy of the original work of Heycock and Neville, modified as it has been in minor details. Several papers deal with ternary systems. A memoir by Miss Gayler on some of the light aluminium alloys is of interest as containing the first determination of the supersolubility curve, as found by Miers in various non-metallic systems, for a series of alloys. It has importance in connexion with the modified structures of such alloys as those of aluminium and silicon. Age-hardening has been measured in alloys of magnesium as well as in those of aluminium, and a paper on this subject is contributed from the Berlin aircraft experimental station, whilst the Royal Aircraft Establishment contributes two papers on the anodic protection of aluminium against corrosion. The standard of the contributions is high. Dr. Aitchison has given an interesting lecture on the use of non-ferrous metals in transport, and the volume contains the usual very thorough abstracts of the literature.

Statistique mathématique. Par Prof. G. Darmois. (Encyclopédie scientifique: Bibliothèque de mathématiques appliquées.) Pp. xxiv + 363. (Paris: Gaston Doin et Cie, 1928.) 32 francs.

THIS is a very readable account of the applications of the theory of probability to statistics. A knowledge of the calculus is assumed. In England the treatment of probability except for specialists has suffered from an excess of amusing but useless developments, and as a reaction against this the subject has lately been neglected. Now that the calculus is learnt at a much earlier stage than was formerly customary, it is possible that an elementary course might be devised which would have its value as leading up to the kind of work dealt with in this volume. Apart from the question of educational value, a knowledge of the elements of probability might serve as a corrective against the extraordinary views held by the man in the street about chance, and the mathematician should not ignore a movement towards the re-introduction of the subject, however unwilling he may be to add to his syllabus.
A. R.

Royal Botanic Gardens, Kew. Popular Official Guide to the Royal Botanic Gardens: including an Historic Notice and Descriptions of the Collections in the Botanic Gardens proper, the Glasshouses, Museums, and Arboretum. Second edition. Pp. 118. (Kew: Royal Botanic Gardens, 1928.) 6*d*. net.

THE plan of this new guide to the Royal Gardens at Kew is well described in the title. The material in it has been thoroughly revised and brought up-to-date and has been set in a new style. The guide contains an interesting account of the history and functions of the gardens, and each section is clearly described and the outstanding species noted. With this guide in hand, the visitor, whether botanist or layman, needs no other directions for an intelligent and profitable tour of the famous gardens. The key plan at the beginning of the book has been done in some considerable detail, and will be useful to those wishing to visit any particular spot or examine particular types of plants.

Letters to the Editor.

X-ray Studies on the 'Nitrides' of Iron.

EXPERIMENTS made by Fowler, Baur and Voermann, White and Kirschbraun, and Tschischewski show that iron 'nitrides' with a maximum amount of about 11 per cent nitrogen are formed when ammonia is led over heated iron. The most favourable temperature for the reaction seems to be about 450° C. Some of the authors are of the opinion that definite chemical compounds, that is, nitrides, are formed, while others consider the products to be solid solutions of nitrogen in iron. Studying the iron–nitrogen system by means of X-rays, I have found the latter opinion to be the correct one.

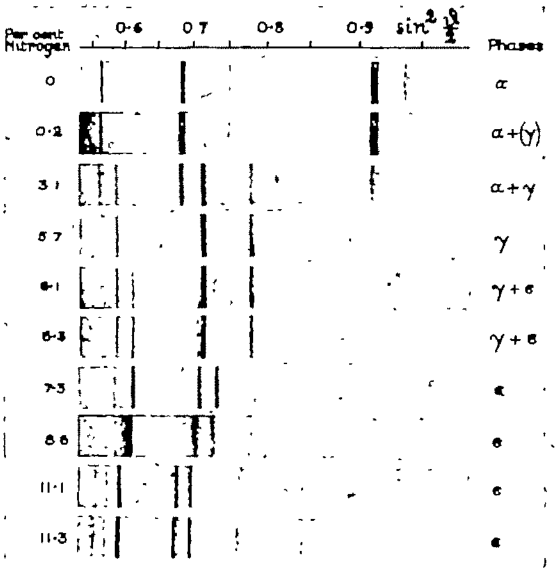

FIG. 1.

Pure iron, obtained by reducing carefully prepared iron oxide with hydrogen, was treated with pure ammonia in a porcelain tube heated in an electric furnace. The temperature was measured with a nickel–nichrome thermo-couple. The chemical analyses of the products were done according to different methods. The maximum amount of nitrogen was found in a preparation containing 11·3 per cent nitrogen. It may be pointed out that no trace of hydrogen could be shown.

The X-ray analyses were carried out by the powder method in three focusing cameras using the *K*-radiation of iron.

The structure of the 'nitrides' was found to be dependent only on the nitrogen content and not on the conditions (temperature, duration of treating with ammonia, etc.) under which the 'nitride' was prepared.

Photograms of the most deviated lines from preparations with different contents of nitrogen are compared in Fig. 1. Already at 0·2 per cent nitrogen very faint lines belonging to a face-centred cubic (= close-packed cubic) phase (γ) appear, and at 5·7 per cent nitrogen all lines of α-Fe have disappeared. The lines of the α-Fe do not change their positions, which shows that its lattice dimensions remain constant. The lines of the new phase also remain fixed with increasing nitrogen content. The edge of the elementary cube is 3·789 A., which is somewhat larger than the parameter of pure γ-Fe (= 3·6 A.), but as the existence range of this new phase at high pressure certainly will join the existence range of γ-Fe, it seems justifiable to give this phase also the denomination γ.

The γ phase is therefore to be considered as a solid solution of nitrogen in γ-Fe. The iron atoms are arranged in a cubical close-packed lattice, and the nitrogen atoms are located in the interstices between them. The distance between the centres of the iron atoms is $a/\sqrt{2} = 2{\cdot}679$ A. Nothing in the photograms indicates regular distribution of the nitrogen atoms.

Between 5·7 and 6·1 per cent nitrogen, new lines belonging to a hexagonal close-packed phase (ε) appear. The new lines are at first fixed, showing the existence of a two-phase range. Between 7·3 and 8·6 per cent nitrogen, however, the lines begin moving inwards, showing an increase in the lattice dimensions. The percentage at which the homogeneous range begins is estimated to lie between 7·5 and 8 per cent nitrogen. The parameters of the ε phase are here, $a = 2{\cdot}695$ A. and $c = 4{\cdot}362$ A. (axial ratio $c/a = 1{\cdot}619$). In this case, when the atoms are not absolutely spherical, one has to distinguish two values of distances between the centres of adjacent atoms. One is $= a = 2{\cdot}695$ A. and the other (the shorter of the two) is $= \sqrt{\frac{a^2}{3} + \frac{c^2}{4}} = 2{\cdot}679$ A. The latter accurately coincides with the shortest distance between the atom centres in the γ phase.

As more nitrogen enters the ε phase, the parameters increase, *c*, however, relatively less than *a*, so that c/a decreases.

In the photogram of the preparation with the maximum nitrogen percentage of 11·3, some of the lines are split, owing to the fact that the preparation consists of two parts with different nitrogen content. As *c* is not very sensitive to changes in the nitrogen content, the lines will be the more split the greater the angle the reflecting net plane forms with the basal plane. In this photogram the part richest in nitrogen has the parameters $a = 2{\cdot}782$ A. and $c = 4{\cdot}419$ A. ($c/a = 1{\cdot}588$).

The ε phase may evidently be considered to be a solid solution of nitrogen in a hexagonal close-packed form of iron, where the nitrogen atoms are situated in the interstices between the iron atoms. No photograms of this phase show any lines indicating a regular distribution of the nitrogen atoms.

There seem to exist several analogies to this type of solid solutions in other systems; for example, the tungsten and molybdenum carbides described by Westgren and Phragmén, the nickel hydride described by Bredig and Allolio, and probably the copper hydride described by Müller and Bradley. The hexagonal close-packed form of chromium which Bradley and Ollard showed in some preparations of electrolytic chromium might also be an analogous hydride.

It is of interest to note that some of the concentration limits of the homogeneous phases lie very close to stoichiometric proportions of iron and nitrogen. Thus, the upper limit of the γ phase, which, as already mentioned, seems to lie between 5·7 and 6·1 per cent nitrogen, might coincide with the formula Fe_4N with 5·9 per cent nitrogen. In the same manner, the lower limit of the homogeneous ε phase, which was supposed to lie between 7·5 and 8 per cent nitrogen, might coincide with the formula

Fe_3N with 7·72 per cent nitrogen. It is also worth mentioning, that all recent investigators of the iron–nitrogen system put the upper limit of nitrogen concentration attainable at atmospheric pressure to slightly above 11 per cent nitrogen, which is close to the formula Fe_2N with 11·14 per cent nitrogen. These coincidences may of course be only accidental, but it is also possible that they are related to certain concentrations of valency electrons.

In recent years the method of treating iron with ammonia has sometimes been used in industry to obtain very hard surfaces (cf. the articles by A. Fry in the *Kruppsche Monatshefte*, 1923 and 1924). With the purpose of showing to what extent an iron surface will be 'nitrated,' a thin iron sheet was heated in ammonia for four hours at 450° C. The thin grey film on the surface caused rather strong γ lines and weak ϵ lines to appear in the photogram.

The fact that the iron 'nitrides' are solid solutions of nitrogen in iron will also furnish a possible explanation of the action of iron as a catalyst in the Haber ammonia process. The catalysing substance is there prepared by reducing iron oxide with ammonia and will therefore consist mainly of iron 'nitride.' The nitrogen dissolved in the iron is probably monatomic, and as such must be expected (cf. 'active' nitrogen) to react easily with hydrogen, forming ammonia.

A more detailed report on this investigation will be published later.

The experiments are being continued with 'nitrides' of other metals.

The Colour of the Peacock's 'Eye.'

I HAVE for some time past been experimenting at intervals on this subject. There has been much debate as to whether the animal colour in this and other difficult cases is due to pigments, or to a structure on a scale comparable with the wave-length of light, which gives colour by interference. It is not proposed here to embark on this controversy, but to mention some observed facts, reserving discussion for the present.

If the feather is exposed to strong ultra-violet radiation from a quartz mercury lamp placed a few inches away, the colours soon begin to alter, for the most part becoming less brilliant. The effect is noticeable after an hour, and conspicuous after several hours. It is convenient to screen half the feather, thus reserving it as a standard of comparison. The various zones of colour are affected in different ways, entirely new tints being produced in certain cases. This shows the complexity of the phenomenon. I am not ready to give a full description at present. The effects are naturally different for the different zones as we go out from the centre of the 'eye,' and depend also on the obliquity or otherwise of the reflection.

The conditions are simpler if we examine the feather through a monochromatic filter. Two striking cases may be mentioned. For the sake of description, I consider the feather as showing four chief zones, disregarding minor and transitional zones of colour. The four are numbered from the innermost.

Examining the feather in sunlight at normal incidence through a red filter, it is found that the second zone is made notably brighter, and the third notably darker than it was before exposure. If we use oblique incidence and a blue filter, it is found that exposure has made the second zone much darker, and the fourth zone, including the straggling outer portions of the feather, much brighter than originally. This observation is most striking if we use a glass mercury vapour lamp as illuminant, because it is rich in blue rays.

Prolonged exposure (hundreds of hours) to the quartz mercury lamp destroys the colour of all the zones entirely, leaving only a black background, on which, however, the position of the zones formerly seen in colour can be distinguished.

Experiments of the same kind have been made on some other cases of brilliant animal colours. It may be mentioned that the colour of the brilliant blue butterflies from Brazil, used in making 'butterfly jewelry,' is almost immediately affected, and after a few hours entirely discharged. On the other hand, the golden beetles, in which I was able to detect interference spectra (*Proc. Roy. Soc.*, A, vol. 103, p. 233; 1923), are entirely unaffected by very prolonged exposure, running to hundreds of hours.

Hardness of Alloys.

IN a letter to NATURE, published in the issue of May 7, 1927, I gave curves showing the hardness of some alloys of copper in terms of the percentage of the alloying metal. I here add similar curves for alloys of lead with antimony, tin, and bismuth (Fig. 1).

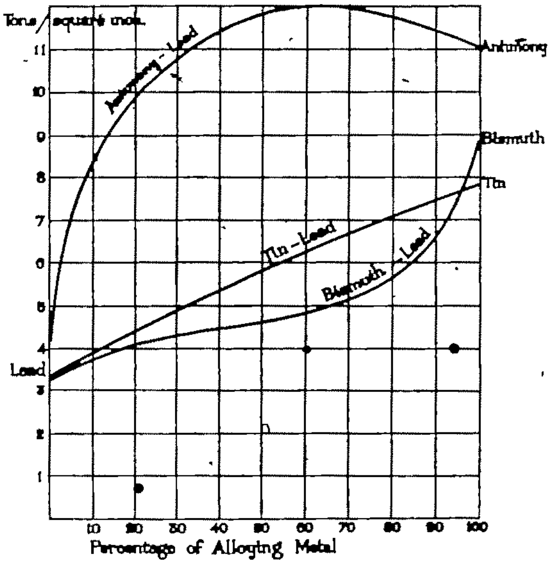

FIG. 1.—Curves showing the hardness of alloys of lead with antimony, tin, and bismuth. The percentages are percentages of volume.

The hardness was measured, as in the former experiment, by pressing with a known force a cone of the metal to be tested against a hard flat surface and taking the area of the flat thus formed at the point of the cone.

There are no special features in the hardness curves of the tin and bismuth alloys, but the antimony alloy shows a not very marked maximum when between 50 and 70 per cent of the volume is antimony.

The Quantum Postulate and Atomic Theory.

Every physicist is greatly indebted both to Prof. Bohr for committing to paper, and to Nature for printing, the admirable account of the new wave mechanics entitled "The Quantum Postulate and the Recent Development of Atomic Theory," which appeared as a Supplement to the issue of April 14. It sets out in an extraordinarily luminous manner the essentials of the new ideas.

Bohr speaks of a 'complementarity,' which is a duality of observed phenomenon and observing mechanism. He points out that in the delicate observations involved in the study of interactions between atoms, or between atoms and radiation, the two are no longer separable but become two aspects of one whole. I wish to suggest that Bohr's complementarity is rather a trinity, of which the third member is the 'conscious' observing mind. It will be seen in the sequel that this leads directly to an explanation of the origin of the quantum.[1] The extension is, indeed, clearly involved in Bohr's statement: the demarcation between subjective and objective disappears, as he says in his conclusion, and the subjective involves at least the living factor, which is a part of consciousness.

The three are one. Consider, for a moment, the observation of a spectrum band (not line) of the hydrogen spectrum, seen by the eye. The energy of the band is contained within a small but finite width: we are accustomed to associate with it a definite wave-length, but such a narrow band, covering a range of wave-lengths, is more properly represented by a succession of wave-groups with indefinite boundaries, following one another with a certain frequency: we may speak of this as a series of 'beats.' The eye must be attuned to the beats and will absorb their energy by resonance: the response of the resonant mechanism, whatever it may be, requires time. The response is thus associated with a quantity of dimensions energy × time, and I suggest that there is a minimum of this 'action,' a *minimum visibile*, a *minimum sensibile*, to which the eye, with the mind behind it, will respond. Quantum theory tells us that this is the same, or approximately the same, for different colours.

Let us accept this suggestion as an hypothesis, and reconsider our point of view. Starting from the observer end of the 'trinity,' what the eye receives is a series of 'beats,' associated with a certain frequency. Tracing the energy back to our conception of a spectrum, we represent this energy by $\int I d\lambda$. λ, the 'line' wave-length, is at once seen to be no longer definite: it is an abstraction, the boundary merely of an integral field. The quantum, which experiment has shown to be constant, is the 'real' thing: its basis is the human possibility of perception. Hitherto, in our conceptions of spectra, we have started from the abstraction, the wave and the wave frequency: we ought to start from the quantum, with its associated beat frequency, dependent on the eye mechanism, and we can, of course, at once reproduce the conception, the wave. The same idea follows through all encounters of atoms and atoms, atoms and radiation, using the method of resolution of the Hamiltonian 'action' into wave-groups, as suggested by wave mechanics.

Every observation is a trinity in unity. Every physical quantity, the result of such observation, is expressed in terms of three units, of length, time, mass, but preferably for our present purpose of length, time, action. Every event perceived involves all three: we can leave out one in our conceptions for convenience, but in any full description of the event, that is, of our perception, all three are involved as part of one whole. We can change the measure of any one with consequent changes in the measures of the other two; but there is a *minimum sensibile* which fixes a limit to the whole, a subjective unit; to talk of its absolute size is meaningless; the measurements in Lilliput would be indistinguishable, save by external omniscience, from those in London.

It will be seen from the preceding paragraph that the limiting velocity of Einstein, the velocity of light, at once follows from the general conception. We never need to use a greater velocity in describing our perceptions. Quantum theory completes and rounds off the theory of relativity into one consistent whole.

The *minimum sensibile* in the above, it will be noted, is a *minimum visibile*. The *minimum sensibile* is not necessarily the same for other sense perceptions.

In "Space, Time, and Gravitation," Eddington wrote: "We have found a strange foot-print on the shores of the unknown. We have devised profound theories, one after another, to account for its origin. At last we have succeeded in reconstructing the creature that made the foot-print. And lo! it is our own." No words more apt could be written in relation to quantum theory.

I wish to say one final word. All the ideas contained in the above are to be found in Bohr's paper. He speaks even of the 'individuality' associated with an event. I have but rearranged the setting of the picture.

The Application of the Irregular Doublet Law to Complex Spectra.

Prof. M. N. Saha and Mr. P. K. Kichlu have recently (Nature, Feb. 18, p. 244) shown that the irregular doublet law, which has been applied by Millikan and Bowen to locate approximately the spectra of elements which are reduced by electric discharge to the same electronic configuration, can also be applied to complex spectra. We have tested this hypothesis by taking the two groups (1) Ne, Na^+, Mg^{++} . . . and (2) A, K^+, and Ca^{++}. In group (1), one of us has already demonstrated the applicability of the law. It now remains to add that the spectrum of Mg^{++} can be predicted with the aid of this law, since the spectra of both Ne and Na^+ are known. A number of strong lines, some of which were previously obtained by Handke and by McLennan, have been located between the wave-lengths $\lambda 2400$ and $\lambda 1800$. This is quite in accordance with the prediction of Messrs. Saha and Kichlu.

In the group A, K^+, Ca^{++}, the spectrum of A is now completely known, thanks to the work of Meissner (*Zs. fur Phys.*, vol. 40). The lines of K^+ have been grouped into energy levels by T. de Bruin (*Proc. Amst.*, vol. 29), though he has not yet attempted the comparison with the predictions of Hund's theory. This can be easily done from his work, and the $5M_2 (N_1 \longleftarrow N_2)$ lines written down. The fundamental difference ${}^3P_1 - {}^1P_1$ comes out to be 2425. As regards Ca^{++}, the spectrum was obtained by Anderson (*Astro. Jour.*, vol. 59, p. 76) by using the condensed discharge in vacuum, and a large number of lines entirely new (about 800) were obtained between the wave-lengths $\lambda 2100$ and $\lambda 4800$. One of us has undertaken the analysis of this spectrum and has been able to identify the group $5M_2 (N_1 \longleftarrow N_2)$. The fundamental difference is ${}^3P_1 - {}^1P_1 = 3766$. The correctness of this difference is shown not only by the fact that it connects a number of the strongest lines given by Anderson, but also by the fact that it is approximately the difference (actual difference is 3804) between the two strongest lines, λ403·8 and λ410·1, obtained by Millikan and Bowen in the hot-spark spectrum of Ca in the extreme ultra-violet. These must be the $^1S_0 - {}^1P_1$, $^3P_1$ lines of transition $5M_3(M_3 \longleftarrow N_1)$. The applicability of the irregular doublet law is illustrated in the following table :

Group I.		Group II.	
$5M_3(N_1 \longleftarrow N_2)$.	$^2P_2 - {}^2\overline{P}_2$.	$6M_3(N_1 \longleftarrow N_2)$.	$^2S_{\frac{1}{2}} - {}^2P_{\frac{1}{2}}$.
A	13987	K	12985
K+	25647	Ca+	25192
Ca++	37194	Sc++	36566
Sc+++	(48600)	Ti+++	47534

A further comparison has been made between the spectra of A and K, K+ and Ca+, Ca++ and Sc++ (*vide* table above). The lines compared belong to the groups $5M_3(N_1 \longleftarrow N_2)$ and $6M_3(N_1 \longleftarrow N_2)$ in each case. The difference is that the second group has only one more electron in the inner M_3-level. The value of $^2P_2 - {}^2\overline{P}_2$ line in group I is almost identical with the value of the $^2S_{\frac{1}{2}} - {}^2P_{\frac{1}{2}}$ line in group II (lines arising out of the transition $6L_2(M_1 \longleftarrow M_2)$). The same analogy has been obtained in the spectrum of the groups Ne, Na, Na+; Mg+; Mg++, Al++.

The analysis of the Ca++ spectrum lends no support to Pannoecock's view that the spectrum of the solar corona is made up of the lines of Ca++. The ionisation potential of Ca++ comes out to be approximately 52 volts, and the excitation required for stimulating the line $\nu = 37194$ would amount to about 53 volts if we start from the neutral state.

Apparent Distortion in Sports Photographs.

IN conversation with various people of some scientific attainments (even with some who have considerably greater technical skill in practical photography than I have myself), I have found usually that not enough allowance is made for the distortions produced by so-called *instantaneous* photographs. In my own Goerz-Anschutz focal-plane camera (some twenty-five years old), the nominal exposure of $\frac{1}{1000}$ sec. is obtained by allowing a slit of about $\frac{1}{25}$ the width of the plate to travel in front of the plate, at such a speed as to cover the whole plate in $\frac{1}{40}$ sec. In later patterns some increase in speed may exist, but the essential idea is the same.

The distortion is illustrated in the simplest possible way by considering a man of, say, 6 ft. to be running at such a speed as to cover 100 yd. in 12 sec., that is, at 25 ft./sec. The photographer will endeavour to place himself so as to get the runner to cover about $\frac{3}{4}$ of the height of the plate; or the slit corresponds to $\frac{1}{25}$ ($\frac{4}{3}$) 6 ft. $= \frac{8}{25}$ ft. at the distance of the runner. Compared with the speed of the runner, this distance would correspond to $\frac{1}{25}$ ($\frac{8}{25}$) sec. $= \frac{8}{625}$ sec. $= \frac{1}{80}$ sec. roughly. But this is very nearly half the time during which the slit falls.

Probably a graphical investigation will help to make the matter clearer: we can simplify our ideas by taking in the first place the effect of, say, 25 strips on the plate, each having (theoretically) *instantaneous* exposures, at intervals of $\frac{1}{1000}$ sec.

In the first strip affected by the runner (some strips will not receive his image at all) there will be a straight line[1]: in the next strip, an equal vertical line displaced a distance to the side. This displacement will correspond to $\frac{25}{1000}$ ft. $= \frac{1}{40}$ ft. at the distance of the runner: and 8 ft. at that distance is represented by the height of the plate. Thus the sideways displacement is $\frac{1}{320}$ of the height of the plate: while each strip is $\frac{1}{25}$ of the height. Accordingly, the general effect is to produce an appearance of the form sketched (Fig. 1):

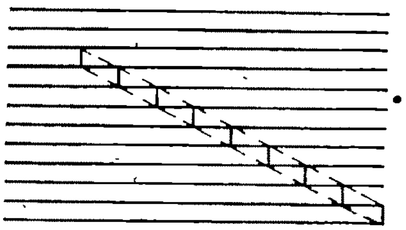

FIG. 1.

where the slanting lines make with the horizontal an angle the tangent of which is $\frac{64}{125} = 0·512$. This angle is roughly 27°.

In the actual case of continuous exposure, a vertical line (moving at right angles to the line of sight) is therefore swung (by the camera alone) through about 63° ($= 90° - 27°$).

No doubt, in few *actual* photographs can such enormous distortion appear: for usually the photographer (from experience of previous bad results) is likely to stand near the finish of a race and to point the camera so that its axis makes an angle of (perhaps) less than 20° with the direction of the race. This would reduce the angle of swing to something more like 25° or 30°; but even this is enough to distort entirely the photographs commonly reproduced in illustrated papers.

Another cause of distortion, perhaps less readily recognised, in (say) a tennis photograph is due to the variations in the distance of different parts of the player (and specially during the swing of the racket) while the slit travels over the plate.

April 21.

The Buoyancy of Whales.

MR. R. W. GRAY's series of letters make interesting reading to one who has been associated with various attempts to enable men to dive a little deeper than usual. From what has been published, and from other documents Mr. Gray has kindly lent to me, the evidence that whales can dive to 500 fathoms and beyond seems good, while it is certain that, after being harpooned, they can remain submerged for 40 minutes, and much longer in the case of the bottle-nosed whale. Since they can exist so long without taking breath at a time when they are exerting their utmost energies to escape, there need be little difficulty in accepting the view that when resting or sleeping (and consequently using oxygen at a slower rate) they can remain under the ice or on the sea bottom for some hours.

I find it difficult to accept the hypothesis that they can regulate their buoyancy by actively compressing the air in their lungs. Raising the intra-thoracic pressure to any useful extent would surely interfere with the circulation, as in Valsalva's classic experiment, which, with Muller's experiment and everyday experience of human divers with various forms of apparatus, impresses on one the fact that the mammalian circulation cannot carry on unless the air in the lungs is kept at practically the same pressure as the fluid environment of the body, whether that be air at atmospheric pressure or water at a hydrostatic pressure many times as great.

---

[1] For simplicity consider the runner as merely a vertical line.

When a whale starts to dive, part of its buoyancy is derived from blubber and part from the volume of air in its lungs, and assuming, as I think one must, that the increasing hydrostatic pressure of the sea water acting through the body walls automatically compresses the air in the lungs in accordance with Boyle's law, it follows that as soon as the whale has reached the small depth of 5 fathoms, the air volume, and consequently the buoyancy, due to it is halved. Mr. Gray has shown that the blubber alone is insufficient to support the animal, so that the descending whale will eventually reach a certain critical depth, probably not a great one, at which the air buoyancy is so much reduced that the density of the whole animal becomes the same as that of the sea water; and if the whale dives below this and dies, it will tend to sink still farther, as in the instances Mr. Gray has described.

In diving to 500 fathoms, the air in the lungs would be compressed to about $\frac{1}{91}$ part of its original volume, and the lungs must shrink to a corresponding degree: it is not surprising, therefore, that anatomists have commented on their remarkable elasticity. Hunter's words (for which I am indebted to Mr. Gray) are that they are so elastic "as to squeeze out any air that may be thrown into them and to become almost at once a solid mass having a good deal the appearance, consistence, and feel of an ox's liver." The human lungs and chest are so formed that (without distortion) they cannot hold less than about $\frac{1}{4}$ of the volume of air contained after a deep inspiration, so that naked pearl divers cannot descend much beyond twenty fathoms.

The appearance of drops of condensed water in the spout of whales in the tropics may be attributed to the rapid expansion and consequent cooling of the air in the lungs as the animal ascends from a great depth.

G. C. C. DAMANT.

Photography of the Infra-red Solar Spectrum.

NEARLY fifty years ago, Sir William Abney (*Phil. Trans.*, Part II., p. 653, 1880, and Part II., p. 457, 1886) photographed and measured fine detail in the solar spectrum out to λ9867. He also recorded, with low resolving power, a few broad absorption bands of greater wave-length, but he evidently observed no individual absorption lines having wave-lengths exceeding that of the line mentioned. It is remarkable that, in spite of some subsequent improvements in equipment, no one has measured lines in the solar spectrum out to the limit reached by Abney. The nearest approach of which I am aware is that of Brackett (*Astrophysical Journal*, **53**, 121; 1921), who measured λ9849 and could see a few more faint lines beyond.

With the aid of plates sensitised by neocyanin, the solar spectrum is now being examined once more, using both prisms and gratings. A filter of iodine in carbon disulphide, described long ago by Prof. Tyndall, is found to be the most efficient means of preventing fog. On the prismatic plates about a dozen lines are observed between λ10,000 and λ10,750, one of which is fully as conspicuous as Hα. It stands clear of the great water-vapour band ρ, and several photographs made at various solar altitudes and on days of very different humidity fail to show any change in its appearance. On spectrograms made with the grating, dispersion 4·7 A. per mm., it appears as a single wide line of wave-length 10049·8 A. The line is clearly of solar origin. Its wave-length, width, and general appearance leave little doubt that it is really the fourth member of the Paschen series of hydrogen, the calculated wave-length of which in air is λ10049·4. Later members of this series fall in the water-vapour band between λ9000 and λ9600, so that they are very difficult to observe. In addition to the lines already mentioned, fifteen others, faint and sharp, have been measured with the grating out to λ10,220.

In spite of this extension of Abney's limit by nearly 900 A., my experience leads to the belief that his emulsion was far more sensitive in this spectral region than any of those now available. He mentions Tyndall's filter, but seems actually to have used copper-flashed ruby glass, transmitting the red as well as the infra-red. Fog due to false spectra and the diffusion of shorter wave-lengths must have caused his failure to observe the lines recorded here.

Observed Relative Intensities of Stark Components of Hα.

BY means of wave mechanics, Schrödinger (*Ann. d. Phys.*, **4**, 80, 437; 1926) has made quantitative calculations of the intensities of Stark components in hydrogen which are commonly considered to be an improvement on the earlier estimates based on the correspondence principle (H. A. Kramers, *D.K.D. Vidensk. Selsk.*, 8, 3, 287; 1919). That this is so in the case of Hβ was shown recently by the writers in a quantitative experimental investigation (NATURE, Oct. 23, 1926).

The greatest variation of the new theory from Prof. Stark's results, however, occurs in the parallel components of Hα. There are three pairs of such components which have been photographed, and in the original experiments, as well as in the older quantum theory, the outside components were found to be the strongest. This is further supported by the recent calculations of Epstein on wave mechanics (*Phys. Rev.*, **28**, 695; 1926). In contrast to these results, Schrödinger finds the greatest intensity for the pair with intermediate displacements (Fig. 1). The difference between Schrödinger's calculations and the observations of Stark is obviously rather large to be considered as an experimental error. Yet this is what it appears to be according to numerous plates obtained by the junior author in an extension to the earlier experiments, the new results being in general agreement with the calculations of Schrodinger.

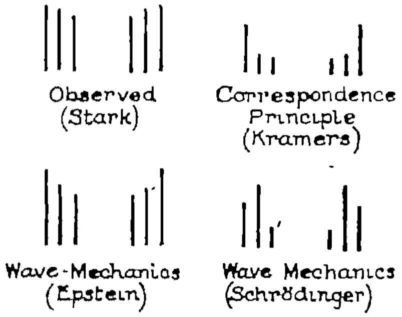

FIG. 1.

The new photographs are taken by the Lo Surdo method, with a tube designed to give components which run parallel for a short distance on the plate. It is not thought probable that this source should produce components with intensities essentially different from those which might be obtained from a canal-ray tube. Its design permits the use of a micro-photometer in the ordinary way. On the plate from which the accompanying curve (Fig. 2) was taken there appears to be a strong undisplaced parallel component, but, in reality, this is due to the overlapping of the images on the slit.

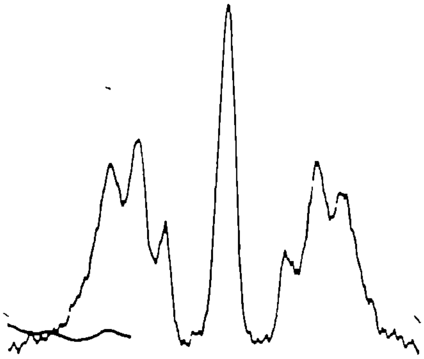

FIG. 2.

Quantitative measurements of the intensities by a wedge method are in progress. The present note is just to state that on this most outstanding point Schrödinger is correct.

Genes and Chromomeres in Flowering Plants.

THE objection to identifying chromomeres with genes was that there were not supposed to be enough chromomeres. In my opinion this supposition was based on post mortem changes, or on too low a working aperture in the microscope. I have studied the pachyphase (pachytene stage) in *Aloe*, *Lilium*, *Kniphofia*, and *Agapanthus* especially. The less the opportunity for change before fixation, the greater the number of cells showing the ultimate chromomeres.

These ultimate chromomeres appear about twice as broad as long, in all positions of the fibre. They differ in size; and sometimes only the scattered largest ones take the stain, and the others are nearly or quite invisible. They show equally well in iron-acetocarmine squeezes, or in smear preparations fixed in chromic-acetic-formol and stained with iron-brazilin. Their lateral extension is due to their composition out of the laterally joined homologous chromomeres of four strands, and the longitudinal divisions can sometimes be made out.

In many pachyphase cells these chromomeres are seen merged into long blocks, or into a continuous thread; but the writer considers this phenomenon to be a post mortem change. In *Aloe purpurascens* an enumeration of the ultimate chromomeres in pachyphase, by an apparently trustworthy method, gave approximately 1250 for the total in the cell. These chromomeres averaged less than a third of a micron apart, and so approached the limits of microscopical separation. At diaphase, and still more at metaphase, the number of separable chromomeres has greatly decreased; but these are obviously compound bodies. Hence a useful working hypothesis seems to be that the ultimate chromomeres are genes.

Milton and Modern Science.

IF Lucretius can be quoted in NATURE as anticipating modern scientific discoveries, perhaps space may be found for a far greater English poet, John Milton.

Are not Millikan's cosmic rays foreshadowed in Bk. IV. of "Paradise Lost"? Eve has just asked (657-8):

> But wherefore all night long shine these? for whom
> This glorious sight, when sleep hath shut all eyes?

Adam replies:

> Those have their course to finish round the Earth
> By morrow evening, and from land to land
> In order, though to nations yet unborn,
> Ministering light prepared, they set and rise;
> Lest total darkness should by night regain
> Her old possession,
> . . . these soft fires
> Not only enlighten, but with kindly heat
> Of various influence foment and warm,
> Temper or nourish, or in part shed down
> Their stellar virtue on all kinds that grow
> On earth, made hereby after to receive
> Perfection from the sun's more potent ray.

Again, Bk. XI., from v. 429 onwards, contains an excellent description of a cinema show, and the chariot of Paternal Deity (vi. 750) is a motor-car. Truly,

> What the sage poets, taught by th' heavenly Muse,
> Storied of old in high immortal verse

("Comus," 517), is well worth rescuing occasionally from the oblivion into which such things fall.

C. L. BARNES.
Manchester, May 13.

Ultra-Violet Transmission of New Glasses.

DR. L. C. MARTIN, in his interesting article in NATURE of April 21, on "The Ultra-Violet Transmission of Transparent Materials," makes a reference to the new glass of the Corning Glass Co., and states that it is not yet available in large pieces.

The chemical composition of this glass undoubtedly involves manufacturing difficulties at present greater than are met with in the preparation of Vita-glass and the newer ultra-violet transmitting window glasses now being marketed in Great Britain, Germany, and America. It may interest readers of NATURE, however, to know that early this year I received from the Corning Co. a sheet of the new glass, known under the name of Corex, of dimensions 8¼ in. × 6¼ in. and 4 mm. thick, a size sufficient for many screening purposes. The sheet appeared to be quite homogeneous and clear. In thickness of 2 mm. it was found to transmit down to 0·212μ and to have the following percentage transmissions: 86·5 at 0·295μ; 66 at 0·250μ; 35 at 0·230μ; and 13 at 0·220μ.

Shipworms in San Francisco Bay.

THE San Francisco Bay Marine Piling Committee was established in 1920 by the American Wood-Preservers' Association, following a serious outbreak of damage by shipworms to timber structures in the northern part of San Francisco Bay. The Committee's work was, almost from the first, associated with the national scheme of research on the same subject begun by the U.S. Forest Service and later co-ordinated by a special committee of the National Research Council. The final report now issued[1] brings together the results of all the researches undertaken. While a good deal of the ground has already been covered by the report of the National Committee published in 1924 (see NATURE, Nov. 22, 1924, p. 744), the fuller account of the local conditions and of the admirable series of biological, hydrographical, and engineering researches carried out at San Francisco is very welcome.

It is now possible to get a clear picture of the succession of events in this region. It is pointed out in the historical section of the report that shipworms have been active at San Francisco at any rate since the days of the gold rush in 1849. By 1857 many wharves were derelict and tottering from their attacks. This was at the water-front of San Francisco itself, just within the Golden Gate, and no doubt the species of shipworm causing most of the damage was *Xylotrya* (now *Bankia*) *setacea*, described by Tryon in 1863. This species is probably indigenous to the Pacific coast, and in San Francisco Bay it is confined to the region of high and constant salinity (not much less than 25 per mille), not penetrating to the northern districts (San Pablo and Suisun Bays) where the salinity is low and fluctuating. An isolated record of the species from San Pablo Bay is considered to be due to the shipworms having been present in the piles before they were driven.

Before the seventies of last century, the Crustacean borer *Limnoria* was unknown at San Francisco, but in 1873 it is mentioned as having "only recently made its appearance in our waters," and it speedily became very destructive. The distribution of *Limnoria* within the bay coincides with that of *Bankia*, and nearly all the damage done in the middle and southern parts of the bay is caused by these two species. In these districts their destructive activities have been long guarded against by the use of piling protected by impregnation with creosote or by other methods.

In the northern districts, where the salinity is greatly diminished by the influx of fresh water from the Sacramento River, no dangerous borers had ever been known to occur, and extensive wharves and other structures were built of unprotected timber. In 1914, however, a species of shipworm, later identified as the European *Teredo navalis*, was found to be causing damage at the Mare Island Navy Yard in San Pablo Bay. No further damage was reported until 1917, when the pest broke out again, and in the following years assumed disastrous proportions. Wharves collapsed on all sides, sometimes carrying buildings with them, until, by the end of 1921, "the bulk of structures with untreated piling had been destroyed," and the total losses were estimated at the enormous sum of twenty-five million dollars. Precautions against the recurrence of such a catastrophe are now taken by using piles of reinforced concrete and by protecting the timber piles by creosoting, concrete jacketing, and other methods.

From the biological point of view, there are several features of interest in this story. It is evident that the special destructiveness of *Teredo navalis* as compared with other species is due to its peculiar adaptability to low and fluctuating salinity. This enables it to take advantage of a favourable season to establish itself in localities where it is not expected and precautions against it have not been thought necessary. At San Francisco, as was shown long ago in Holland, the outbreaks could be definitely correlated with years of reduced rainfall and consequent increased salinity in harbour waters. Once established in the timber, the animals can survive many weeks in water of reduced salinity by closing the mouths of their burrows with the pallets and resume their activity when the salinity rises again. Since the individuals rarely survive for more than one year, a succession of favourable years is probably necessary to cause a severe and prolonged outbreak.

Doubt has been cast on the popular opinion which attributes sudden outbreaks of shipworm to importation from abroad, but in the case of the San Francisco outbreak, at any rate, there is good reason to regard it as justified. Investigations on the shipworms of the bay were made in 1910–11, and again in 1912–13, and no specimen of *Teredo navalis* was recorded. It is just possible that it may have existed in small numbers in some part of the region, but favourable conditions must have occurred many times before 1914 which would have led to its invasion of the northern districts had it been there to take advantage of them. It is much more likely that the species was introduced in some unknown manner in 1913 or 1914. When first discovered, it was described as a new indigenous species, and it was only after prolonged and careful study that its identity with the European species was established.

It is sometimes assumed by practical men that the only help to be expected from scientific research in dealing with marine timber pests is the discovery of new kinds of poison for protecting the wood. Fortunately, the American investigators have taken a wider view. They have shown that detailed studies of the systematics, distribution, physiology, and bionomics of the shipworms and other marine boring animals can yield results that are of immediate practical importance to the engineer.

[1] Marine Borers and their Relation to Marine Construction on the Pacific Coast: being the Final Report of the San Francisco Bay Marine Piling Committee. C. L. Hill and C. A. Kofoid, editors-in-chief. Pp. ix+357. (Berkeley, Cal.: University of California Press, 1927.) 4 dollars.

The Glasgow Meeting of the British Association.

MANY of the senior members of the British Association still carry in their memory pleasant recollections of the last meeting in Glasgow twenty-seven years ago, and of the wonderful excursions by sea and loch and glen of which it was the centre. There have been many changes of personnel since that meeting, when such names as Rücker, Kelvin, Geikie, Lister, M'Kendrick, and Bayley Balfour were conspicuous in the list of members, but there are not a few still in the position of being able to look forward to repeating this year (Sept. 5-12) their experiences of 1901.

The invitation to the Association is again a joint one from City and University. The University, with its spacious premises, is able to exercise the unusual hospitality of accommodating the entire sectional and administrative activities of the Association within one boundary-fence, while the City—Lord Provost, Corporation, and citizens—is leaving no stone unturned to make the meeting a success.

The main activities of the meeting will be concentrated in the University, that impressive pile of buildings—situated on the high right bank of the Clyde valley just where it is cut through by the tributary Kelvin—which looks out from its dominating position across the broad river valley with its alluvial flats now covered in great part by busy streets and docks and shipyards. The great hall of the University—the Bute Hall—will function as Reception Room, with general offices, post-office, bookstall, etc.: the adjoining Randolph Hall will be used as a writing-room; while in close proximity accommodation will be provided for the president and general officers, the secretaries and local secretaries, and the representatives of the Press.

The individual sections will be housed as a rule in the University department devoted to their particular subjects, thus ensuring the availability of suitable furnishings and equipment. In a few cases, to secure greater convenience, this general rule is departed from; thus Section C (Geology) will meet in the old Natural History Lecture Room, E (Geography) in the Department of History, F (Economics) in that of English, J (Psychology) in the newly completed west wing of the main University building, M (Agriculture), and also the forestry sub-section of K, in the new medical block.

Long experience has demonstrated the great practical advantages to be derived from the secretarial staffs of the different sections being housed together in one residence during the meeting. In organising the Glasgow meeting it was found impossible to obtain adequate accommodation for this purpose in immediate proximity to the University, and the secretariat is consequently to be housed in the Training College Hostel at Jordanhill, about two miles to the north-westward. The local committee is, however, providing transport arrangements which will, it is hoped, reduce the practical inconvenience of this arrangement to negligible dimensions.

For the presidential address, the Corporation has placed at the disposal of the Association the finest of its halls, St. Andrew's Hall, with seating for 4000 and admirable acoustic properties. For the evening discourses the governors of the Royal Technical College are giving the use of their great hall.

As regards lodging accommodation, the chief Glasgow hotels are much in demand, so prospective visitors will do well to secure their accommodation as soon as possible. As, however, the meeting of the Association takes place out of term, many of the lodgings normally occupied by students will be available, and the same applies to the various students' hostels. Further information regarding lodging accommodation may be obtained from the Local Secretaries, 30 George Square, Glasgow, C.2.

The attractions of the Glasgow meeting will not be confined to those of a purely intellectual kind. On Thursday, Sept. 6, the Lord Provost and Corporation will welcome the members at an evening reception and dance in the magnificent City Chambers, while on the following Monday evening the hospitality of the Corporation will again find expression when the Kelvingrove Art Galleries will be placed at the disposal of the local committee for a second evening party. At this party, members who slip away for a while from the extensive galleries devoted to the sciences, in which as members of the British Association they are primarily concerned, will have the opportunity of revelling amongst the artistic treasures which form one of the chief glories of Glasgow.

Nor again will the meeting be devoid of tempting distractions outside the city. Even those who are unaware of the charms of Glasgow itself are dimly conscious that it guards the gateway to the wonderful scenic beauties of the western Highlands. Many undoubtedly will see in the Glasgow meeting an excuse for a prolonged Highland holiday either before or afterwards. But even those who do not will have the opportunity of devoting the Saturday to one of many excursions which have been organised for that day. Biologists will be drawn towards Millport, with its admirably situated and well-equipped biological station, where the Scottish Fishery Board's research vessel *Explorer* is expected to be an object of special attraction. Archæologists will tend to Bute with its ancient remains and modern developments: engineers to the Falls of Clyde and its electric power station. Others will devote the day to recuperation by a long day's sail round Bute and Arran and Ailsa Craig or round the various sea-lochs, or by an expedition by land to the Trossachs and Loch Katrine and Loch Lomond, or farther afield to Aberfeldy and Loch Tay. Other interesting excursions will be to the

Burns Country, and to Peebles and its neighbourhood.

Saturday is, as usual, devoted entirely to excursions, but in addition there will be numerous half-day and afternoon excursions during the week. Many of these will be of special sectional interest, or will be devoted to visits to particular works and industrial centres. That great achievement in applied science, the Port of Glasgow, with its quays and docks and shipyards, will, of course, be of special interest to many visitors, and to facilitate its inspection the Clyde Trustees are generously proposing to place their steamer *Comet* at the service of members of the Association.

The Harvey Tercentenary.

THE place that William Harvey occupies in the development of modern physiology and medicine can only be properly appreciated when his work is viewed in the light of the current scientific knowledge of the seventeenth century. Like many other great discoveries, that of the circulation of the blood owed something to the work of previous observers, but all the more honour is due to Harvey for proving experimentally beyond the shadow of a doubt that the blood circulates, when others had approached the truth but had failed to draw the correct inference from the facts available, and had not devised experiments to test the correctness or otherwise of this deduction.

Ever since the time of Galen, it had been held that some of the blood must pass from one side of the heart to the other through the wall or septum separating the two ventricles: in the earlier part of the sixteenth century, the anatomist Vesalius proved that there was no direct communication between these two chambers of the heart, but such was the force of tradition that he did not directly deny Galen's teaching, the difficulty being surmounted by assuming that the blood passed through invisible channels in the muscle. At about the same period, Servetus described the circulation through the lungs, but failed to correlate this observation with the circulation of the blood through the rest of the body.

Harvey studied at Cambridge and at Padua: at the latter University he came under the influence of Fabricius ab Aquapendente, who published at about this time—in the first few years of the seventeenth century—a treatise on the valves in the veins, which was probably the starting-point of Harvey's discovery. It is easy to demonstrate in the human arm that the blood in the veins can only flow towards the heart owing to the existence of these valves. During the next ten years Harvey was working at the problem arising from these facts: and in 1616 he was lecturing before the College of Physicians in London on the circulation of the blood. Accepting the truth of the facts previously demonstrated, he saw that the only explanation possible must be that the blood reaching the right side of the heart from the veins, was pumped by the right ventricle through the lungs, returning to the left side of the heart, whence it was pumped to all other parts of the body. By animal experiment he was enabled to demonstrate the truth of the conclusion drawn from the anatomical data at his disposal. The work was not published in book form until 1628, when the first edition of "De Motu Cordis (Exercitatio anatomica de motu cordis et sanguinis in animalibus)" was printed by Wilhelm Fitzer of Frankfurt-on-Main.

Harvey may be truly described as the founder of modern physiology and scientific medicine: he refused to be bound by tradition, yet, whilst discarding traditional teaching for which he could find no basis in fact, he paid honour to the earlier workers: above all, he always insisted on testing the truth of inferences and on seeking the explanation of observed facts by means of animal experiments, not excluding observations on man himself.

The celebration of the tercentenary of the publication of the "De Motu Cordis" was arranged by the Royal College of Physicians of London: delegates attended from nearly thirty different countries. The celebration took the form of orations to Harvey's memory, a reception of the delegates by the King, and scientific demonstrations and visits to places and institutions especially associated with Harvey.

The proceedings commenced on May 14, when the delegates were received by the King at Buckingham Palace, being introduced by Sir John Rose Bradford, president of the Royal College of Physicians. Harvey, as a physician, was closely associated with both James I. and Charles I., and accompanied the latter to Oxford: King Charles always supported Harvey's experimental work so far as he was able. In the afternoon, the delegates were welcomed at the Royal College of Physicians and presented their addresses from universities and learned institutions throughout the world. The rare honour of honorary fellowship was conferred upon Lord Balfour, Sir Ernest Rutherford, Prof. I. P. Pavlov, of Leningrad, and Prof. K. F. Wenckebach, of Vienna. Eulogies of Harvey were delivered by Sir Charles Sherrington, Prof. Chauffard, of Paris, and Dr. Keibel, of Berlin.

Sir Charles Sherrington said that the Renaissance occurred first in letters and scholarship, then in the physical sciences, but last in the study of living animals. Harvey was really the first to investigate their function, as distinct from study of their outward form. It is experiment, together with observation, which is at the basis of medicine as we know it to-day. Prof. Chauffard compared the period of twelve years during which Harvey continued his investigations before the "De Motu Cordis" was published with the same period Francis Bacon required for the maturing of his work, and with the twenty years which elapsed between the time Newton and Darwin began their work and their dates of publication. Perhaps the most striking characteristic of Harvey's work is its modernity: the outlook and the methods are those of to-day.

On May 15 the delegates visited St. Bartholomew's Hospital, where Harvey was physician for twenty-one years: after lunch, Sir Wilmot Herringham gave an account of Harvey's connexion with the hospital and paid a tribute to his memory. On May 16 the delegates were entertained at dinner at Guildhall by the president and fellows of the Royal College of Physicians. In connexion with the celebrations, demonstrations and exhibitions of objects of interest at University College and at the Royal College of Physicians were also arranged. The celebrations were concluded by visits to Merton College, Oxford, of which Harvey was warden, on May 17, and on May 18 to Caius College, Cambridge, from which Harvey graduated.

In connexion with the tercentenary, Dr. Geoffrey Keynes has published an attractive little bibliography of Harvey's writings.[1] The text is illustrated with reproductions of the title pages of certain of the editions, two portraits of Harvey, and several prints illustrating the valves in the veins. Although the "De Motu Cordis" is the best known of Harvey's writings, he published also two short essays on the circulation of the blood in 1649, addressed to John Riolan the younger, professor of anatomy at Paris, in answer to certain criticisms of his work, and two years later his "Exercitationes de Generatione Animalium" appeared. Although the latter has been somewhat neglected, it is almost as great a contribution to science as the "De Motu Cordis," and reveals the master mind of the Father of modern physiology.

Chemical Industry in Modern Life.

WHEN public attention is from time to time directed towards the great scientific achievements of the age, the seeker after the mysteries of Nature is assured of the respectful praise and admiration of modern British men and women as he displays the results of his labours, whether his audience understand their significance or not. It is probably true to-day to say that there is in all civilised countries a keen appreciation of such successes, and a general desire that they shall be acknowledged by public honour, equally, for example, with the no less worthy achievements in the realms of art and literature.

Chemistry, however, and its sister sciences, have now reached a stage of development in which they operate so profoundly on the course of human affairs, and especially on national health and safety, that it becomes necessary to put clearly and frequently before the public such facts as will lead to a proper recognition of the magnitude of the issues which exercise the minds of scientific men. It becomes necessary, for example, to present what may be described as interim non-technical reports exemplifying the progress that is being made in preserving the general well-being of the community and in meeting the demands of modern conditions of existence, and indicating the broad lines along which—perhaps not without public support—development can from time to time be foreseen. The Chemical Industry Conference, organised by the Society of Chemical Industry in co-operation with its London section and Chemical Engineering Group, and with the Institution of Chemical Engineers, which was in session in London on May 11-15, was not intended to introduce new technical data to a technical circle; its function was rather to present such general reports primarily to its members and guests, and also to the Press, and hence to a far wider audience. Such a conference, apart from the offer of opportunities of personal contact and discussion, performs the valuable service also of bringing the labours of one group of workers more vividly before the minds of other groups than is possible through the medium of technical publications.

The conference opened, on its professional side, with an address by Mr. F. H. Carr, president of the Society of Chemical Industry, who dealt with some chemical engineering aspects of the fine chemical industries. Sir Arthur Duckham, the first president of the Institution of Chemical Engineers, contributed an important paper on the fuel industries and the work of the chemical engineer, emphasising the necessity for practical training, and for closer contact between the university and the factory. He confessed that, with ever-widening experience, he became more and more convinced of the great scope which exists for improvement even in our latest methods, and of the splendid prizes still to be won by application of technical knowledge, imagination, and driving force to the daily problems of industry; he put the matter in a nutshell when he stated that the basic need in industry is to get exact knowledge of what we are doing.

Lieut.-Col. G. P. Pollitt described developments in the heavy chemical industry, pointing out that we are at the beginning of a period of replacement of natural products by products made by synthetic and partly synthetic processes, and that what is a 'fine' chemical now may well become 'heavy' in a few years' time. In this paper the general effect of the War on chemical manufacturers was summarised, and the principal differences between pre-War and post-War practice were indicated; recent achievements, such as the synthesis of ammonia, the hydrogenation of coal, and the artificial silk industry, were also passed under review. Prof. G. T. Morgan's contribution was an account of a chemical study of low-temperature tar, a material the investigation of which has been carried out chiefly since the War. All these papers thus dealt with matters of the highest technical importance, and gave some idea of the responsibility that rests on the chemical engineer in transferring successful laboratory processes to the domain in which mechanics and economics occupy so dominating a position.

Other papers were more general in their appeal. Sir Alfred Mond, as was to be anticipated from the title of his paper, "Scientific Research as applied to Industry," delivered a most inspiring and convincing address on the broad questions at issue. He was rightly insistent, in the first place, that science is not national, but human, and that little is therefore to be gained by attempts to nationalise it. He was also anxious to remove the widespread impression that chemical industry and the manufacture of dyes are synonymous terms, and incidentally showed that the obstacles which in the past have stood in the way of rapid development of that branch of the industry within the shores of Great Britain are to be sought in the patent laws rather than in any deficiency in British technical capacity. Indeed, it was most encouraging to hear him—a man of great experience and responsibility—declare that in Great Britain we have now, and probably always have had, the right kind of men who can be entrusted with the care of our important chemical industries, and that we can claim a superiority in this respect over other countries. Further, although the ability for original inquiry is inborn, and hence not to be acquired to order, the spirit of research and the intelligent, courageous application of new knowledge should permeate the factory; conversely, of course, practical considerations must always occupy a prominent place in the field of vision of the researcher. One might, indeed, go further, and say that the diffusion through civilised communities of such a spirit, call it what one may, is one of the prime factors in our progressive attempts to make the world a better place to live in.

Sir Alfred has had unique opportunities of estimating the cash value of research, and he sees in large industrial combinations the opportunity of making the best use of specialised talent and new possibilities. His statement that the leaders of chemical industry nowadays are the guardians of the nation's defence and prosperity could have encountered no lurking doubts in an audience of men and women acquainted with some of the relevant facts; the dependence of a cheap and plentiful food supply on cheap synthetic or artificial fertilisers, and the possibility of the economic conversion of coal into fuel oil, are but two examples of the vital considerations which were evidently in his mind.

Sir Ernest Rutherford, under whose chairmanship Sir Alfred Mond was speaking, amplified the discussion by pointing out that at the foundations of the applied research which means so much for industry are the labours of those devoting themselves to 'pure' science, and he exemplified the manner in which apparently academic or unpractical investigations may in a surprising way lead to applications of the greatest significance.

Water supplies formed, under Lord Desborough's chairmanship, the subject of another session of the conference. An abundant supply of pure water, especially in urban areas, is now so universal and commonplace a service that few other than those directly concerned give a thought to the extent to which its provision draws on our resources of scientific knowledge and invention, and—in average seasons, at any rate—how it depends on considerations of fluctuating supply and demand. As Lord Desborough showed, the question is not altogether devoid of anxiety, and the matter requires constant skilled and highly organised supervision. Sir Alexander Houston gave a most interesting account of the various ways in which London's water supply is purified before it reaches the consumer, and expressed some apprehension concerning the possible pollution of water supplies by gulls. Mr. J. H. Coste discussed more fully the pollution of tidal and non-tidal waters by house rubbish and sewage, and by the waste products of trades, whereby a pleasant river may be rendered unsavoury or unsafe, and normal life in it, of fish in particular, may be degraded or destroyed. Mr. Coste referred to the nature and movement of the pollution, discussed the causes of the unfitness of water for fish life, the standards applicable to, and treatment of, works' effluents, and the legal and administrative steps that have been taken to protect streams from unnecessary pollution.

The scientific assistance which can be afforded to agriculture was represented by Sir John Russell's paper on the part played by British workers in the application of fixed nitrogen to the soil. In the unavoidable absence of the author, the paper was read by Dr. B. A. Keen, who said that in agricultural chemistry two main considerations are in the foreground, namely: "What is 'quality'?" and "What is the detailed effect of fertilisers on yields?" The paper presented a concise, yet informative, account of experiments which have been carried on for many years at Rothamsted Experimental Station, Harpenden. Such a mass of data has accumulated from these continuous field experiments that the application of modern and newly devised statistical methods has been necessary in its interpretation. These new methods have paved the way to a study of the effect of soil and climatic conditions on the effectiveness of fertilisers. The investigations indicate the possibility that, if the general character of a season could be predicted, appropriate manurial schemes could be drawn up for mitigating its bad features and utilising to the fullest extent all its good ones. Alternatively, it would be possible to construct tables of expectancy of crop yield, on the basis of which large fertiliser combines could insure farmers using recognised fertiliser mixtures against getting less than an agreed yield per acre. If it is true that 1400 million people till the soil in order to feed and clothe 1800 million inhabitants of this planet, could science be applied in any more vital interest?

News and Views.

PROF. J. W. GREGORY has received a cable from Sir Edgworth David announcing the discovery of a rich fossil fauna of ancient annelids and arthropods throughout the whole of the Adelaide Series which lies at the base of the Cambrian System in South Australia. The appendages are excellently preserved. Sir Edgworth David considers the age probably Lipalian, but possibly Lower Cambrian. The newly discovered fossils extend from 2000 ft. to 12,000 ft. below the fossiliferous Cambrian beds. The Lipalian is the name given by Walcott to a division of time a little lower than the Cambrian. This discovery, amongst its many other bearings, may be expected to throw important light on the age of the ancient glacial deposits of South Australia which have been assigned either to the Cambrian or to the pre-Cambrian.

AFTER an interval of more than six years, the non-magnetic sailing ship *Carnegie*, of the Carnegie Institution of Washington, set out on May 1 on another scientific world cruise. The scientific and navigating staff of the yacht numbers eight men. The cruise is intended to cover three and a half years; the places to be visited, in order, are England, Germany, Iceland, the West Indies, Panama, the South Pacific (the Society Islands, Easter Island, Peru), Japan, California, Honolulu, Samoa, New Zealand, Cape Horn, South Georgia, South Africa, Ceylon, India, Western Australia; across the South Pacific again and around the Horn to Buenos Ayres, Argentina, St. Helena, Azores, Madeira, and back to Washington. The first object of the cruise is to take magnetic observations, in order to determine the secular variation without which the magnetic charts, used nowadays for aerial as well as ocean navigation, cannot be kept up-to-date; atmospheric electric observations will also be made, as on the preceding cruise. In addition the staff are taking up new work of three kinds: the investigation of radio-propagation, in accordance with a programme of transmission and reception arranged with the Washington Naval Research Laboratory; the investigation of the sedimentary deposits on the ocean bed; and the mapping of the sea bed by sonic depth-finders. The *Carnegie* is due to arrive at Plymouth on May 26, and will be there until June 8. During her stay at Plymouth, Capt. J. P. Ault and his staff will welcome visits from scientific workers anxious to see the vessel and examine her equipment.

THE expedition organised by the British Association Great Barrier Reef Committee will leave England for Brisbane by the R.M.S. *Ormonde*, which sails from Tilbury on May 26. The party, which is now fully constituted, will consist of the following: Leader, Dr. C. M. Yonge, Balfour Student in the University of Cambridge; second in charge and leader of the boat party, Mr. F. S. Russell, assistant naturalist at the Plymouth Laboratory; leader of the reef party, Dr. T. A. Stephenson, lecturer in zoology, University College, London; chemist and hydrographer, Mr. A. P. Orr, chemist, Marine Station, Millport; phytoplankton worker, Miss S. M. Marshall, assistant naturalist, Marine Station, Millport; botanist, Mr. G. Tandy, Department of Botany, British Museum (Natural History); zoologist and leader's assistant, Mr. G. W. Otter, University of Cambridge; medical officer, Mrs. C. M. Yonge. Mrs. Russell and Mrs. Stephenson will accompany the party. There will follow later, Mr. J. A. Steers, fellow of St. Catherine's College, Cambridge, and Mr. M. Spender, of Balliol College, Oxford, who will carry out geographical work under the auspices of the Royal Geographical Society, and also Mr. J. S. Colman, of New College, Oxford, who will assist Mr. Russell in his work on the distribution of zooplankton. Valuable assistance is expected from Australian sources. With the exception of Mr. Russell, Mr. Tandy, and Mr. Steers, who will be in Australia for six months only, the members of the expedition will carry out continuous observations for a period of about thirteen months.

A GREAT quantity of apparatus is being taken by the Great Barrier Reef Expedition, for the object aimed at is a repetition under tropical conditions of the standard observations, chemical and planktonic, made in temperate seas, so that not only will the results obtained give new and much-needed information about the conditions prevailing in tropical waters, but also they may throw considerable light on conditions in temperate seas when the results of parallel observations in the different localities are compared. The conditions underlying the formation of coral reefs will, naturally, receive the greatest attention, the nutrition and calcium metabolism of corals and associated organisms being one of the chief objects of the expedition, while the many economic possibilities of the Great Barrier Reef will be fully explored. The total cost of the expedition will be some £10,000, of which about £8000 has been received to date, the money having been provided by the Empire Marketing Board, the Commonwealth Government, the British and Australian Associations for the Advancement of Science, the Australian Great Barrier Reef Committee, the Royal Society, the Royal Geographical Society, the Zoological Society, and a number of private individuals. The committee hopes to raise the remaining £2000 during the coming year, and any subscriptions towards this would be welcomed by the committee, the chairman of which is the Right Hon. Sir Matthew Nathan; the treasurer, the Hon. J. Huxham, Agent General for Queensland; and the secretaries, Prof. J. Stanley Gardiner and Mr. F. A. Potts, Zoological Laboratory, Cambridge.

VERY hearty congratulations are extended to Sir Daniel Morris, K.C.M.G., botanist, and Col. R. E. Crompton, C.B., electrical engineer—two octogenarian men of science—who celebrate, respectively, their eighty-fourth and eighty-third birthdays on May 26 and May 31. Sir Daniel Morris was born at Loughor, Glamorgan, and was educated at Cheltenham and

Trinity College, Dublin. Early in his career Sir Daniel's particular studies and efforts were directed towards promoting the economic resources of tropical parts of the British Empire by means of scientific exploration and research. Appointed Director of the Royal Botanic Gardens, Ceylon, in 1877, he afterwards became Director of the Botanic Department, Jamaica, vacating this post on his appointment as Assistant Director of the Royal Botanic Gardens, Kew. Here he remained for twelve years (1886–98), becoming then Imperial Commissioner, West Indian Agricultural Department. From 1908 until 1913 he was scientific adviser in tropical agriculture to the Colonial Office. Sir Daniel was president of Section K (Botany) at the Bournemouth meeting of the British Association in 1919.

COL. CROMPTON, the distinguished engineer, who forms one in a still living group of veterans in that branch of science, is a Harrovian. After leaving school he began training as a mechanical engineer, but for family reasons entered the army and for some years served with his regiment in India. Whilst on the Commander-in-Chief's staff at Simla, he persuaded the Governor-General, Lord Mayo, to promote the first large-scale road-transport experiment. Returning to England in 1876, Col. Crompton engaged in electrical engineering, founded the firm of Crompton and Co., and remained its managing director for nearly thirty years, a period of unceasing application to electrical undertakings at home and abroad. For long Col. Crompton rendered unstinting service to the National Physical Laboratory in a consultative capacity. He has been twice president of the Institution of Electrical Engineers, and he was, in 1926, awarded the Faraday medal of the Institution. Still actively engaged, he is a member of council of the Institution of Civil Engineers, and representative of that body on the official Advisory Panel (Ministry of Transport).

A CONVERSAZIONE was held at the East London College on May 15 to commemorate the twenty-first birthday of the College as a 'school' of the University of London. The College has, however, provided education of university type for more than forty years, and for eighteen years has participated in the Government grant to university colleges. His Majesty the King is Patron of the College, and the King and Queen visited it five years ago. On the present occasion the Duke and Duchess of York were distinguished guests, and, with the Masters and Wardens of the Drapers' Company, the Vice-Chancellor and the Principal of the University of London and more than 2000 others, were received in the Queen's Hall by the Deputy Chairman of the College Council, Sir Lynden Macassey and Principal Hatton. After the presentation of the members of the College Council, of the Academic Board and of the officials of the Students' Union to the Duke and Duchess, their Royal Highnesses made a tour of the laboratories, in which about 150 experiments had been arranged and were demonstrated by the staff or the students. Short lectures on broadcasting, television, and noctovision, and on other subjects were given by Capt. P. P. Eckersley, Mr. J. L. Baird, and members of the staff.

A FEATURE of the laboratory exhibits, somewhat unusual at a conversazione, was the amount of apparatus and the number of experiments representing research either completed or in progress in East London College. As examples may be mentioned: in the physics laboratories, the elasticity of metals and experiments on sound; in the geology laboratory, the photomicrography of rocks; in the botany laboratory, the exhibit by Dr. W. A. Goddyn of Leyden, illustrating natural hybrids between plants and between humans, and that of mosquito larvæ and their food; in the electrical engineering laboratory, the investigation of the electrical field about high-voltage apparatus and of the three-carbon arc; in the mechanical engineering laboratory, the researches on the temperature distribution in a dual cycle oil engine and that on the application of the principle of similitude to earth pressures; in the chemical laboratories, the furnace for specific heats of gases at 1500° C. and the apparatus for measuring heats of solution; and in the zoology department, the specimens illustrating species. The fine library on the lines of the British Museum reading room, with its large collection of books relating to Shakespeare from the library of the late Sir Sydney Lee, provided interest for the literary guests, while the dancing to which the Queen's Hall was devoted after 9.30, kept many of the students and guests until nearly midnight.

THE annual general meeting of the Institute of Physics was held on May 15, when the following officers were elected for the year 1928-29: *President*, Sir Frank Dyson; *Vice-Presidents*, Dr. Alexander Russell and Mr. C. C. Paterson; *Honorary Treasurer*, Major C. E. S. Phillips; *Honorary Secretary*, Prof. A. O. Rankine. Sir Ernest Rutherford and Sir Richard Glazebrook were elected honorary fellows of the Institute. The president, in moving the adoption of the Report of the Board for the year 1927, referred to the substantial additions to the membership of the Institute during the year, and to the increased activities which coincided with the transfer of the offices to South Kensington. The Royal Meteorological has been added to the list of participating societies. The report affords evidence of the progress made by the *Journal of Scientific Instruments*, which now, at the close of its fourth annual volume, may claim to be firmly established. The journal has become a recognised medium for the publication of papers dealing with the instrumental aspects of scientific work. An important announcement in relation to the journal, of interest to present and future members of the Institute, was made at the meeting, namely, the decision of the Board that, commencing in January 1929, the journal is to be distributed without charge to fellows, and at a small charge to associates. Dr. C. V. Drysdale's resignation from the editorship, largely on account of ill-health, has been accepted by the Board with great regret; the secretary of the Institute, Mr. Thomas Martin, has been appointed his successor.

At the close of the annual meeting of the Institute of Physics, Sir Frank Dyson gave his presidential address, taking as his subject "Physics in Astronomy." Among the developments of astronomy and astrophysics in which physics has played an important part are the successive improvements in the construction of clocks which have led to accurate timekeeping. The independence of the 'judiciary' and the 'executive,' that is, of the pendulum and the clock train, is largely secured by Riefler's work. The latest solution of the difficulties, resulting in a nearly perfect timekeeper, has been made by Mr. Shortt in conjunction with Mr. Hope Jones of the Synchronome Company, in the clock they have produced. Sir Frank Dyson also referred to the work of astronomers in ensuring uniformity of timekeeping by the distribution of time signals, from the dropping of the time-ball by hand, which was instituted by Pond at Greenwich at the commencement of the last century, to the final stage in which wireless is used in the co-operation of Greenwich with the British Broadcasting Corporation. Increase in the size of telescopes has called for the assistance of the engineer and physicist in the provision in the observatory of driving clocks and electric motors for moving the instrument and turning the domes and shutters; while the manufacture of optical glass has provided one of the principal and most important fields for the practice of physical science in the service of the astronomer.

Prof. S. Langdon's summary of the sixth season's work of the Oxford-Field Museum Expedition's work at Kish, which appeared in the *Times* of May 17, serves to emphasise once more the remarkable additions to our knowledge of the early age of metal which have been made by the excavations in Mesopotamia of the last few years. In the past season this expedition has been engaged under its field director, Mr. M. F. Watelin, in the excavation of a mound to the north-west of the great stage tower of Hursagkalamma. After laying bare to a depth of 25 feet, the ruins of a temple of Sargonic times, dating from about 2700 B.C., over an area of 300 yards square, beneath a sterile stratum 7 ft. thick was reached a continuous red earth stratum of five feet in thickness which extended over the whole area and represented the temenos platform on which the stage tower and three great temples of Kish were erected. This represents plain level. At this point there is a definite break between the objects of the red stratum and those of the earlier civilisation beneath, which yields, as Prof. Langdon points out, "a most valuable chronological and archæological criterion in the evolution of ancient civilisation." In this earlier stratum excavations were carried down 25 ft. below plain level. Here were found a long series of brick-vaulted tombs with true arches, in which the bodies were laid upon boards resting on layers of potsherds. Inscribed cylinder seals and tablets cease at this level, and the funerary equipment is entirely different from that of the later strata. Stone bowls and spouted painted pots characterise the cemetery. Two of the tombs contained two- and four-wheel chariots mounted in bronze and with the bodies of the oxen. It would appear, therefore, that the custom of sacrificing oxen and attendants to accompany their master was practised. The overlying red layer is definitely dated as preceding 2900 B.C. Prof. Langdon dates this pre-Sumerian culture at about 1000 years before the oldest Sumerian inscriptions which can be translated. Prof. Langdon concludes by announcing that Dr. Rushton Parker has generously offered to give to the funds of the expedition 10 per cent of the total amount of any contributions received before Oct. 1 next.

The Huxley-Wilberforce debate at the Oxford meeting of the British Association in 1860 has come to be regarded as a classic encounter in the progress of modern scientific thought, typifying the overthrow of rhetorical distractions, prejudice, and intolerance in face of cool reason. On all hands the effectiveness of Huxley's closing words were admitted, and it is strange that in spite of this unanimity, no member of that memorable audience could recollect the exact terms of his overwhelming retort to the Bishop of Oxford. Prof. E. B. Poulton's contribution to the *Jesus College Magazine* Lent Term number, therefore, makes some welcome additions. He shows that Huxley was present at the meeting against his own inclination, and quotes several versions of the encounter, revealing that the article in *Macmillan's Magazine* for October 1898 was written by Mrs. William Sidgwick. But the most accurate account is that contained in the letter from J. R. Green, who had just graduated B.A., to his college friend, now Sir William Boyd Dawkins. (It is amusing to picture this doyen of British prehistoric archæologists 'chucking' a snowball through the glass of Green's window, as he confessed to the author he had done.)

Green's letter was written three days after the meeting, and Prof. Poulton prints a communication from Huxley himself, written less than a year before his death, stating that in his opinion its account, with one emendation, was accurate. "I asserted, and I repeat, that a man has no reason to be ashamed of having an ape for his grandfather. If there were an ancestor whom I should feel shame in recalling, it would rather be a *man*, a man of restless and versatile intellect, who, not content with [an equivocal] success in his own sphere of activity, plunges into scientific questions with which he has no real acquaintance, only to obscure them by an aimless rhetoric, and distract the attention of his hearers from the real point at issue by eloquent digressions, and skilled appeals to religious prejudice." We have placed in parentheses the words which Huxley considered he did not use. Sir William Boyd Dawkins has expressed his intention of presenting the letter from which the above is a short extract, together with others of the deepest interest, to the archives of Jesus College, Oxford.

A cuneiform tablet of Rusa I. of Chaldæa (733–714 B.C.), found by the Armenian scholar Avdalbegian in July last at Nor-Bayazet in Armenia, proves to be of considerable historical importance. It definitely identifies the Velitkukhi region with the district of

Nor-Bayazet, confirming the indication of another tablet of King Rusa in which Velitkukhi is mentioned among twenty-three countries conquered by that king. Some scholars identify Velitkukhi with Colchis, thus extending the Chaldæan conquests far into the north. The inscription is cut on a massive basalt slab, apparently the corner stone of some edifice, and consists of eight lines. An illustration, with translation, appears in the *Weekly News Bulletin* of Feb. 4 of the Russian Society for Cultural Relations with Foreign Countries.

The *Eugenics Review* begins its twentieth volume in a new dress, in accordance with its increasing importance as a periodical dealing with everything that concerns eugenics or racial welfare. It is edited for the Eugenics Society by Mr. Eldon Moore. The current number contains the annual Galton Lecture by Dr. C. J. Bond, on the causes of racial decay. Mr. W. T. J. Gun replies to Prof. Raymond Pearl's rather hasty conclusion that great men have usually sprung from mediocre families, and Miss M. C. Buer discusses present and past birth- and death-rates in a review of Griffith's "Population Problems of the Age of Malthus." Other short articles are on "The Cost of a Child" and "Temperament and Social Class." The remainder of a number containing 74 pages is devoted to notes, book reviews and notices, and current periodicals. The net is spread widely, and everything bearing on the current problems of eugenics finds a place. The journal is valuable to all those interested in the problems of sociology, medicine, anthropology, and heredity applied to man.

The popular interest taken in evolution in America is shown by a new monthly journal called *Evolution*, published in New York. A recent number has on its front page the "Family tree of Man," in which the relationships of the various types of human, pre-human, and anthropoid ape skulls are diagrammatically shown from an exhibit in the American Museum of Natural History. The nature of the contents of the number can be judged from some of the titles, which include "Thomas H. Huxley and Peter Kropotkin," "How Man differs from the Ape," "X-rays stimulate Variation," "Evolution and the New Perspective of Life Purposes," "How old is the World?" The editor does not deal gently with the Fundamentalists. The result should be to spread a more rational and unprejudiced attitude to the whole subject of man's origin and development.

In September next, the Folk-Lore Society, which was founded in 1878, will celebrate its fiftieth anniversary. The occasion is to be marked by an International Jubilee Congress of Folk-Lore which will be held in London on Sept. 19–25. An influential advisory council is in process of formation. Among those who have already intimated their willingness to serve are: Sir James and Lady Frazer; Prof. R. M. Dawkins, president of the Folk-Lore Society; Prof. J. L. Myres, president of the Royal Anthropological Institute; Dr. M. Gaster; Dr. Haddon; Lady Gomme; Prof. Halliday; Sir Everard im Thurn; Prof. Westermarck; Sir Richard Temple; Prof. Sayce; Prof. Seligman; Sir D'Arcy Power; Mr. Henry Balfour; as well as a number of distinguished continental and American folklorists and anthropologists.

In the issue of *Chemistry and Industry* for April 20 is an account of an address delivered by Prof. H. E. Armstrong before the Lancaster Astronomical and Scientific Association. The subject of the address, which was reported in full in the *Lancaster Observer and Morecambe Chronicle* for Mar. 23, was Edward Frankland. Prof. Armstrong was at one time an assistant to Frankland, and he gave an interesting account of Frankland's life as a man, rather than of his work as a chemist, which has been told before. One of Frankland's greatest scientific contributions was his investigation of public water supply and drainage, which led to a great reduction of cholera and typhoid fever during the latter half of the nineteenth century.

The annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 2. The Observatory will be open for inspection by invited guests at 3.30 P.M.

The British Empire Cancer Campaign has received an intimation that His Majesty The King (Patron of the Campaign) will receive the overseas delegates to the forthcoming International Conference on Cancer at Buckingham Palace on Monday, July 16.

A public meeting will be held at King's College, London, at 5.30 P.M. on Thursday, May 31, under the auspices of the University of London Animal Welfare Society, to discuss "Man's Duty to Animals." The chair will be taken by Prof. Hobday, Principal of the Royal Veterinary College, who is president of the Society.

A large earthquake was recorded at Kew Observatory on May 14 at 22 hr. 27 min. 26 sec., G.M.T. The epicentre is estimated to be 5850 miles away in an easterly direction and is probably one of the islands off the Asiatic coast. The main shock was followed by a smaller one at the same distance away on May 15 at 2 hr. 49 min. 00 sec.

By the will of Lieut.-Col. A. J. C. Cunningham, R.E., who died on Feb. 8, aged eighty-five years, the London Mathematical Society will receive £1000 for the improvement of the method of factorisation of large numbers, and £2000 for the publication of Col. Cunningham's unpublished printed mathematical works and the completion and publication of his mathematical MSS., and also his library of mathematical books. The residue of his estate is to be divided as to one-twelfth to the London Mathematical Society, and one-twelfth to the British Association, mathematical subsection, for preparing new mathematical tables in the theory of numbers.

At a general meeting of members of the Institute of Metals, held in London on May 8, an invitation was received from the American Institute of Mining and Metallurgical Engineers to hold a meeting in the United States in 1932. The invitation was accepted, and it is hoped the ample notice given of the proposed meeting will make possible a good attendance. The council of the Institute is endeavouring to arrange for an inclusive fare of about £100 to cover the entire cost of the trip, which will be of about five weeks' duration, and will take place in the autumn, both Canada and the United States being visited.

THE centenary of the incorporation by Royal Charter of the Institution of Civil Engineers will be celebrated on June 3–7. On Sunday, June 3, the president and council of the Institution, with members and delegates, will attend a service at 3 P.M. at Westminster Abbey. On the following day an address will be given by the president, Mr. E. F. C. Trench, at a reception in the Hall of the Institution, and in the afternoon the thirty-fourth James Forrest Lecture will be delivered by Sir Alfred Ewing on "A Century of Inventions." The remaining days of the celebration will be occupied by a conference dealing with railway, marine, hydro-electric, and other aspects of engineering, and with visits to engineering works. Cards of admission to the meetings of the conference can be obtained from the secretary of the Institution by members of other engineering societies.

THE council of the Institution of Electrical Engineers has made the following awards of premiums for papers read during the session 1927–28 or accepted for publication: The Institution Premium to Mr. F. H. Rosencrants; Ayrton Premium to Mr. F. Lydall; Fahie Premium to Mr. B. S. Cohen; John Hopkinson Premium to Mr. D. B. Hoseason; Kelvin Premium to Messrs. T. N. Riley and T. R. Scott; Paris Premium to Messrs. A. H. Law and J. P. Chittenden; Extra Premiums to Mr. E. C. McKinnon, Mr. H. B. Poynder, Dr. T. H. Turney, Mr. P. D. Morgan; Wireless Premiums to Prof. E. V. Appleton, Lieut.-Col. A. G. Lee, Messrs. G. W. N. Cobbold and A. E. Underdown; and Willians Premium to Lieut.-Col. H. E. O'Brien.

THE annual congress of the South-Eastern Union of Scientific Societies opens at Rochester on June 6, and Sir Martin Conway will take as the subject of his presidential address "Mountain Exploration." As a veteran explorer and traveller, his reminiscences on this subject will undoubtedly prove of much interest and importance. The congress will last over four days, and addresses will be given by Prof. E. W. MacBride, Dr. Mortimer Wheeler, director of the London Museum, Dr. William Martin, the well-known London archæologist, Mr. H. B. Milner, of the Royal School of Mines, who will lecture on "Geology from the Air," and others. Visits will be paid to Rochester Cathedral and Castle, Gads Hill and Dickens Land, Blue Bell Hill, where is the famous Kits Coty dolmen and other stone age relics, and other places of interest. Further information can be obtained from the honorary secretary, Mr. Edward A. Martin, St. Lawrence, Isle of Wight.

THE annual free booklet published by Messrs. Burroughs Wellcome and Co. is this year entitled "Pictorial Perfection in Photography," and besides some interesting pictorial illustrations and elementary details of manipulation, includes time and temperature tables for development with the various 'tabloid' developers prepared by the firm, some details regarding enlarging, and colour effects obtained by staining, by toning, and by double toning.

THE February issue of *X-Ray News and Clinical Photography*, published by Kodak Limited, is devoted to the use of X-rays in dentistry. The factors treated of are illustrated by diagrams, photographs, and examples, and include the position of the patient's head, the fixation of the head, the use of a film holder to prevent the film from slipping, the correct angle of the tube, and the exposures necessary for the various teeth under conditions that are given. Extra-oral work is also described showing how to avoid the super-imposition of the image of the anterior jaw on the area under examination.

ON the occasion of the Linguistic Congress at The Hague last month, an International Society of Experimental Phonetics was founded. The following elections took place: *President*, Prof. E. W. Scripture, of Vienna; *Vice-President*, Dr. E. A. Meyer, of Stockholm; *Honorary Members*, Prof. A. Meillet, of Paris, and Prof. L. Zwaardemaker, of Utrecht. The object of the Society is the promotion of scientific research in experimental phonetics. A *Bulletin* will be issued from time to time. The membership fee for 1928 is 5 shillings, or a dollar and a quarter. Applications with fee are to be sent to Prof. E. W. Scripture, Strudelhofgasse 4, Vienna, Austria.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A principal of the Acton Technical Institute—The Secretary, Middlesex Education Committee, 40 Eccleston Square, S.W.1 (May 30). An instrument maker to assist in making and repairing scientific instruments, at the Bradford Technical College—The Principal, Technical College, Bradford (May 31). A part-time lecturer in sociology at Bedford College for Women—The Secretary, Bedford College for Women, Regent's Park, N.W.1 (June 4). An assistant in the mining department of the North Staffordshire Technical College—The Clerk to the Governors, Town Hall, Hanley, Stoke-on-Trent (June 4). A lecturer in architecture in the University of Sheffield—The Registrar, University, Sheffield (June 4). A full-time teacher in the department of mechanical engineering of the Rugby College of Technology and Arts—The Organiser of Further Education in Rugby, 61 Clifton Road, Rugby (June 6). A senior technical officer in the Wireless Department of the Royal Aircraft Establishment, primarily for work on design and development of wireless receivers for use in aircraft—The Chief Superintendent, R.A.E., South Farnborough, Hants (June 9, on form A.258). An assistant lecturer in geography in the University of Birmingham—The Secretary, University, Birmingham (June 11). A lecturer in mechanical engineering and a lecturer in mathematics and physics at the Chesterfield Technical College—The Principal, Technical College, Chesterfield (June 11). A part-time demonstrator in biology at King's College for Women (Household and Social Science Department)—The Secretary, King's College for Women, Campden Hill Road, W.8 (June 16). A reader in chemistry at the East London College—The Academic Registrar, University of London, South Kensington, S.W.7 (June 21). The John Lucas Walker studentship of the University of Cambridge—Prof. H. R. Dean, Pathological Laboratory, Medical School, Cambridge (June 29). A leather research chemist for the New Zealand Tanners' Research Association—The High Commissioner for New Zealand, 415 Strand, W.C.2 (June 30). A dairy bacteriologist, a dairy chemist, two senior plant pathologists, a senior plant geneticist, and a senior plant physiologist, each under the Australian Commonwealth Council for Scientific and Industrial Research—The Acting Secretary, Commonwealth Council for Scientific and Industrial Research, 314 Albert Street, East Melbourne, Victoria, Australia (Aug. 15). A test assistant at the Royal Aircraft Establishment for calculation work in connexion with engine investigations—The Chief Superintendent, R.A.E., South Farnborough, Hants (quoting A.275). A senior research assistant, experienced in the science and practice of poultry husbandry, at the National Institute of Poultry Husbandry—The Director, National Institute of Poultry Husbandry, Newport, Shropshire. Teachers of engineering and of mathematics and a full-time instructor in engineering workshops, with special qualifications in metal plate work, at the Wandsworth Technical Institute—The Principal, Wandsworth Technical Institute, S.W. An assistant in the physics department, Woolwich Polytechnic—The Principal, Woolwich Polytechnic, S.E.18.

Our Astronomical Column.

The Planet Mercury.—Mr. W. F. Denning writes: "A favourable easterly elongation of the planet Mercury will occur on June 3, and this rather difficult object ought to be well seen as an evening star between about May 26 and June 7. At spring elongations, Mercury is usually seen under the brightest aspect a few evenings before the date of elongation. This year the planet sets about two hours after the sun for about a fortnight, and should be distinctly visible to the unaided eye after sunset whenever the west-north-west sky is clear of clouds up to about June 7. The twilight is very strong at this period of the year, but Mercury will be brighter than a first magnitude star, and should be easily distinguishable by persons of ordinary vision. It exhibits a reddish lustre and presents a starlike aspect from the fact that its small disc shows scintillation similarly to that of the fixed stars. The low altitude at which it is usually observed encourages this appearance as the atmospheric effects are more pronounced when objects are near the horizon than when they are at considerable elevations. Were the English climate more favourable for astronomical observations, Mercury would be often seen either before sunrise or following sunset and considered an easy object, but clouded sky at low altitudes frequently prevents the attempts of observers being successful."

Magnetic Storms and Sunspots.—Among the astronomical exhibits from the Royal Observatory, Greenwich, which were on view during the conversazione held at the Royal Society on May 17, there was a series of solar photographs and reproductions of magnetic traces illustrating the frequent coincidence between very large terrestrial magnetic storms and large sunspots. The period represented by the exhibits was 1874–1927. During these 54 years there were recorded at Greenwich 17 large magnetic storms with ranges as follows: Declination 90′, or, Horizontal Force (or Vertical Force) $500\ \gamma$. In 15 of those cases there was, at the time of the commencement of the storm, a large sunspot (mean area 500 millionths of the hemisphere or greater) within 4 days of the sun's central meridian. At the time of one of the two remaining storms there was a smaller spot near the central meridian, but this spot had been a large one in the previous rotation, when it was associated with one of the 15 large magnetic storms. In the case of the remaining storm, there was also no large spot near the central meridian at the time, but possibly it is of significance that one solar rotation (about 27 days) afterwards a large spot originated near the central meridian. The coincidence shown between these very large magnetic storms and large sunspots is strongly suggestive of a relationship between individual spots and individual magnetic storms of a certain magnitude.

A Suggested Cause of New Stars.—M. C. Johnson offers in *M.N.R.A.S.* for March a suggested explanation of new stars. He points out that any acceptable explanation must be adequate to account for the large amount of energy liberated, and must be likely to occur sufficiently often to give two or three novæ annually; this includes the faint novæ that do not attain naked-eye visibility.

Collision of star with star would not occur often enough to be acceptable as a general explanation. The theory that the outburst is due to some sudden change in the star's interior has found favour of late, but we have no data for estimating whether such changes would occur sufficiently often to explain all cases.

We know that gaseous nebulæ extend through vast regions of space, so that the impact of a star with a nebula is not too improbable as an explanation; but the boundaries of nebulæ are so diffused that it has not been considered likely that a collision would give rise to such a sudden outburst as we observe in novæ. Mr. Johnson suggests that the first effect of the entry of a star into a nebula may be to form a blanket round the star which obstructs the output of its heat and so causes a gradual accumulation of heat which culminates in a violent outburst. The suggestion is similar to the explanation of long-period variables by supposing a smoke-cloud to form round them, bottling up the heat, until the latter accumulates and dissipates the cloud.

The author gives reasons for thinking that the entry of a faint dwarf into a nebula would be the most likely to produce the required conditions. It might be in the nebula for two centuries before the outbreak occurred, its light being dimmed by 40 per cent. Its surface temperature, taken as 3000° previously, might then rise to 11,000° for three months or so. Col. F. J. M. Stratton and Prof. E. A. Milne have helped and encouraged Mr. Johnson in this study.

Research Items.

Ghosts in East Africa.—A further contribution to the study of ghosts and devils in East Africa, by Mr. G. W. B. Huntingford, appears in *Man* for May. Among the Bantu, ghosts visit the huts of sick people only. When they appeared it was usual to go to a medicine man for medicine to exorcise them. A goat was killed, some of its blood put in a pot with the medicine, and it was left at some distance for the ghost to eat. The spirits of the dead live in holes in the ground and people in good health do not see them. A kind of evil spirit which is abroad at night takes the form of a black bird. Among the Syan of Bugishu in Uganda it is customary to make yearly offerings of eleusine corn to the spirits of the dead. If anyone neglects this custom the angry spirit comes at night and seizes him by the neck with its hands. In the morning he is ill and cannot eat. He must go at once to a medicine man, who will tell him to make an offering of a goat or fowl and beer. The goat or fowl is put in a tree at some distance, while the beer is put in a hole dug just outside the door of the hut. Certain of the witch doctors are said to turn into hyenas at night and to prowl around the huts of people they do not like, howling like hyenas (the Kitosh of northern Kavirondo). Among the Nilo-Hamitic peoples, the Nandi believe in a devil with one leg, nine buttocks, and a mouth which shines like a lamp, which they call Chemosit. It wanders about at night looking for children to eat, whom it entices by singing. Tobolwa Hill, in north-west Nandi, is said to be haunted. The spirits of people, cattle, and goats may be heard there. While others deny this, it is evident that the hill is not liked, and there are no huts or people anywhere near it.

Paganism in the Churches.—Some interesting examples of survivals of pagan beliefs and practices in early and modern Christianity were cited in an article by Mr. C. E. Lart in the *Hibbert Journal* for April. The Edict of Theodosius of A.D. 380, later ratified by Gregory the Great in his letter to Mellitus, the missionary to Britain, allowed heathen temples to be reconsecrated to Christian use, and sanctioned the continuation of such rites and usages as could be turned to the purpose of the church. This recognised a practice which had already begun in the Church of the Catacombs. As a result, while the Church forbad the worship of sticks and stones, the local god became a saint, the pagan holy stone was sprinkled with holy water and a Latin cross was cut on it. The worship of fire, lighted torches, trees, fountains, wells, and menhirs were forbidden by numerous Church Councils from that at Arles in A.D. 453 down to that at Toledo in 692, and similar practices were forbidden by Charlemagne in 789, including that of beating the bounds. St. Patrick took holy stones into the church after sprinkling them with holy water, one such, covered with gold plates, being preserved in the Cathedral of Clogher until 1498. Traces of sun worship are numerous, for example, in the use of the south side of the churchyard, the north being allotted to suicides. The wedding ring is a symbol of the sun. Monasticism was taken over from Buddhism, and the nun was the vestal, the 'bride of the god.'

The Rodents of Ceylon.—In continuation of his guide to the mammals of Ceylon, W. W. A. Phillips now describes the rodents (*Spolia Zeylandica*, vol. 14, 1928). Greater in numbers than any other mammalian order in the island, with the exception of the bats, they also show more differentiation in structure, as is indicated by the large variety of families, genera, and species. Of the twenty-seven indigenous forms, the majority are squirrels and rats, apart from which there occur only a porcupine and a hare. The specific descriptions contain many interesting notes on habits. It is remarkable to read of the ferocious disposition of the Ceylon gerbil, which has been observed to kill and devour a young rat and a small bat, and to have attacked a small monkey. Seasonal movements, and the control of the balance of Nature, are well illustrated in the succession of events which follow the maturing of the 'nillu' (*Strobilanthes*), a jungle plant common on the hill-sides. As soon as the abundant seed commences to ripen, a local migration takes place, and jungle fowl, bronze-winged doves, and many rats of different species make for the area, and gorge upon the seed. Some of the gourmands eat to death, and others reach the same end by becoming so lethargic that they fall easy victims to the carnivores which have followed hard upon the heels of the first migrants.

The Classification of Spiders.—Twenty-five years have passed since the last volume of Simon's "Histoire Naturelle des Araignées" was published, and in that time the study of spiders has so increased the number of known species and genera, that a revision is welcome. Prof. A. Petrunkevitch, whose preliminary paper on the subject was noticed in these columns four years ago, has now produced a striking and invaluable work—"Systema Aranearum"—in *Trans. Connect. Acad. Sci.*, 29, 1-270. This lists the whole of the 2144 genera established to date, arranged in 55 families. Tables for dividing the families into sub-families are given wherever they are required, followed by the genera of each sub-family, printed alphabetically, with their authors, dates, and types. Finally, there is an alphabetical list of 623 generic synonyms, with their authors, dates, types, and the genera to which they should be referred. It is at present useless to expect complete agreement of all authorities upon every title, and there are a certain number of details which do not conform to the present British custom; but these are small blemishes in a work the importance of which it would be hard to overestimate. After long uncertainty, the order of spiders is reaching a welcome condition of stability.

Stomiatoid Fishes.—The species of the deep-sea Stomiatoid fishes have recently been reviewed by Mr. A. E. Parr as a result of a very rich collection of these fishes made by the *Pawnee* under the direction of Mr. Harry Payne Bingham (Scientific Results of the Third Oceanographic Expedition of the *Pawnee*, 1927. *Bulletin of the Bingham Oceanographic Collection*, vol. 3, art. 2, 1927). More than thirty species were captured, of which twenty-one were new to science, from the waters in the region of the Bahamas. Mr. Parr has grouped the families Astronesthidæ, Idiacanthidæ, and Melanostomiatidæ in a new suborder, the Gymnophotodermi. They are characterised by the presence of highly differentiated luminous organs combined with a primitive (though secondary) nakedness of the skin. The author has not included in this suborder the genus *Stomias* on the grounds that fishes of this genus possess scales that cannot be considered as having been redeveloped from a naked ancestor. At the same time, the genus cannot be regarded as a direct representative of a scale-bearing ancestor of the first Gymnophotoderm owing to the positions of its fins. Regarding *Astronesthes* as the most primitive of the recent Gymnophotodermi, the author traces the probable phylogenetic relationships of the genera of the Melanostomiatidæ. Keys are given to the genera and species, and the new species are described, with illustrations by the author and by Mr. W. S. Bronson.

CHROMOSOMES IN MEIOSIS.—*Thespesia populnea* belongs to a genus of Malvaceæ related to the cottons (*Gossypium*). Youngman (*Annals of Botany*, v. 41, p. 755) finds that it has 13 haploid chromosomes, the same number as the Asiatic cottons, while the American cottons are known from the work of Denham to have twice as many chromosomes. Youngman describes a peculiar behaviour of the chromosomes of *Thespesia* during meiosis. He states that the 13 bodies of the heterotypic prophase become massed together and emerge in the metaphase as an equatorial belt of 8 bodies. This is interpreted to mean that 10 bodies fuse in pairs, leaving 3 unpaired. The latter pass undivided into one daughter nucleus, while the 5 pairs separate. A tetrad results, in which one nucleus has more chromosomes than the other three. The explanation suggested is that transverse fragmentation of certain chromosomes takes place at some stage in the life history. Some of the figures suggest imperfect fixation, but the problem involved is a very interesting one and will no doubt be cleared up by further investigation.

LONG-LIVED PLANT CELLS.—D. T. MacDougall and his collaborators have made some interesting observations regarding certain types of plant cells which seem to show remarkable longevity (*Amer. Nat.*, 60, 393, and 61, 385). Living medullary cells of the tree cactus (*Carnegiea*), well over a century old, have been recorded, and examination of elements of all ages indicates active enlargement during the second half of the century. The melon cactus (*Ferocactus*) has also been found to contain similar medullary cells of great age, the active growth in this case, however, ceasing after the first decade. In all of these cells, the carbohydrate constituents, pentosans and hexoses, progressively decrease with age, while the fatty constituents and nitrogenous materials change much less. Transformation of sugars to wall material with consequent thickening is apparent in *Carnegiea* and in the medulla of *Ferocactus*. It is interesting to note, however, that the disappearance of carbohydrates in the cortical cells of *Ferocactus* extends even to the cell walls, which are thinner after a hundred years than after the first ten years of their life, suggesting the removal and liquefaction of pentosans. Still more recently MacDougall and Smith have recorded living ray cells in the heartwood of *Sequoia sempervirens* (*Science*, vol. 66, No. 1715). The changes in the Redwood are accompanied by the disappearance of starch and protoplasts from all wood parenchyma cells, and the formation of an orange-coloured resin that completely or partially fills the lumina. Similar disappearance of starch from the ray parenchyma cells is not always followed by the death and disintegration of the protoplasts, and a thin layer of cytoplasm and a conspicuous nucleus are sometimes retained. Cells of this kind have been recorded by the authors from places seventy layers deep in the heartwood, and, as the sapwood was about twenty-three layers in thickness, the approximate age of the cells was reckoned at nearly a century.

ON *PALUDINA DILUVIANA*.—With the view of ascertaining which living form is nearest akin to the *Paludina diluviana*, Kunth, V. Franz (*Biblioth. Genetica*, Bd. 11) discusses the whole of the European species of *Paludina* (now better known as *Viviparus*). Following the earlier continental textbooks, the author reverses the names of the two common species, *V. viviparus* and *V. fasciatus*, a fact which has to be borne in mind when studying his paper. Careful descriptions of the shells of the several species with excellent figures and elaborate tables of measurements are given, but no anatomical details. The conclusion reached is that *P. diluviana*, Kunth, stands nearest to *P. pyramidalis*, Crist. and Jan, and belongs to the relatively thermophil group, so that its presence in deposits north of the Alps is thus indicative of warmer interglacial periods.

GEODETIC TABLES.—New geodetic tables for Clarke's figure of the earth of 1880 are published by the Royal Geographical Society (R.G.S. Technical Series, No. 4, 5*s*.). In a preface to the tables, Mr. A. R. Hinks explains that the International Congress of Geodesy and Geophysics at Madrid in 1924 decided to accept not Clarke's, but Hayford's figure of 1910 as the standard figure of the earth. The publication therefore contains also the transformation to the Madrid figure, that is to say, the 1910 figure of Hayford.

SURVEY OF NEPAL.—The General Report for 1926–27 of the Survey of India records that after three years' field work, the first survey of Nepal has been completed. The task was undertaken by the Maharaja of Nepal, who asked for the co-operation of Indian surveyors. The result is that it is now possible to publish a skeleton map of Nepal, a country of about 55,000 square miles, pending the preparation of maps on larger scales. The skeleton map showing the main features of the structure and drainage is attached to the report. Field work was carried out on a scale of 4 miles to 1 inch, and an 8-mile contoured map in three sheets is now being prepared. The new information will afterwards be incorporated in revised editions of the standard 'degree sheets.' The survey presented considerable difficulties by reason of rugged relief and diversity of climate. It is believed, however, that any inaccuracies will be practically inappreciable on the scales to be used. None of the triangulation stations is likely to be so much as 100 ft. wrong in position or 20 feet in height.

THE EAST AFRICAN EARTHQUAKE OF JAN. 6, 1928.—Mr. W. C. Simmons, of the Geological Survey of Uganda, has sent us an interesting account of an earthquake of intensity 10 (Rossi-Forel scale) which occurred on Jan. 6 in the Subukia Valley, thirty miles north of Nakuru, in the Great Rift Valley, Kenya. We regret to be unable to find space to print the communication in full, but the following digest gives some of the points of particular value included in it. The epicentre of the earthquake may be taken as about 0° 12′ N. lat., 36° 15′ E. long. On the eastern side of the Subukia Valley, near the foot of the Laikipia escarpment, a fault-line, indicated on the surface by a small scarp and series of cracks, was traced by Mr. Simmons for about 15 miles, running north-northwest and south-southeast. Where the slope of the escarpment approaches 40°, the fault appears to have a downthrow to the west of as much as 8 feet. The fault was nowhere seen in solid rock, but was always best developed in scree slopes and soil deposits on the hill-sides, so that the apparent downthrow is exaggerated by the slip. Where the fault crosses horizontal ground, it either becomes a crack with little downthrow or a series of anastomosing cracks, or is represented by a mound of soil running in the same direction. There is apparently very little horizontal displacement with the fault. It seems clear that this earthquake was due to the opening up of an old fault, and, as the Rift Valley shows very numerous lines of fault and is itself due to faulting, it is to be expected that earthquakes should occur.

A New Incinerating Furnace.—A furnace which has recently been designed to replace the old-fashioned muffle-furnace for the incineration of samples for chemical analysis is described by Dr. Fortnet of Berlin in the *Chemiker-Zeitung* of April 21. In this furnace the bulky fireclay parts have been very greatly reduced in extent and replaced by tall thin cylindrical shells, in which the air can circulate freely under its own draught round the specimen. Four of such shells are mounted on one base and the simultaneous combustion of four samples can be completed in less than an hour without the addition of oxygen or of solid oxidising reagents; nor does the sample require attention during the combustion. The furnace is supplied by Messrs. Armin Kühn of Charlottenburg.

A Pathological Microscope.—Reference was made in Nature, April 14, to several distinctive features of the Beck Pathological Microscope which has been adopted for use in the laboratories of the London School of Hygiene and Tropical Medicine. A complete description of the instrument has now been included in Messrs. R. & J. Beck's catalogue (Section F). The microscope is of large size, and suitable for advanced students' use and for research investigations in bacteriological, medical, and general work. An important feature is the built-in mechanical stage, which is provided with a special holder to take ordinary slides. This can be easily removed, and the top plate will then accommodate a large petrie dish or culture plate which can still be moved by the mechanical motions. The usual cylindrical fittings of the substage have been replaced by dovetailed slides by means of which the change from one form of illumination to another can be made rapidly, accurately, and with the minimum disturbance of the adjustments of the instruments. The milled heads for the adjustment of the mechanical stage and of the substage have been placed on the left-hand side so as to leave the right-hand side clear for drawing. The fine focussing adjustment is operated by two milled drums, one on each side of the limb. Rotation of one of these moves the body at twice the speed obtained by rotation of the other. An intermediate as well as a fine adjustment is thus provided.

Ruths' Steam Accumulator.—In any industrial undertaking, shortage of steam in any one department has a serious effect on the output. In many cases the steam consumption of the various departments fluctuates widely, and the sudden demands have often no relation to one another. Owing to the limited thermal storage capacity of a steam boiler, it is not suitable to meet wide fluctuations in the load. To get over this difficulty, Dr Ruths invented some years ago a steam storage system which enables the steam to be generated at a constant rate although the load fluctuates between wide limits. His steam accumulators are now in use in several hundred factories, mills, and power stations throughout the world. The system is described in a booklet by A. J. T. Taylor, of Africa House, Kingsway, London, W.C.2. By using a steam accumulator, the requisite number of boilers can be considerably reduced, and yet the plant is able to carry on easily over the peak load. The accumulator is shaped like a very large cylindrical boiler, and special methods are used to ensure its thermal insulation. If the initial pressure of the steam in it is 60 lb. per square inch and the final pressure 10 lb., then the amount of steam produced would be 4·24 lb. per cubic foot of water initially in the boiler. A pressure variation of 50 lb. per square inch would be inadmissible in almost any boiler, but the Ruths' accumulator is specially designed for a large pressure drop. In a typical case investigated, the equalising effect of a steam accumulator due to its thermal capacity was found to be eight times that of a Lancashire boiler and forty times that of a standard water-tube boiler. The thermal loss by radiation from the steam accumulator is about 0·2 of a British thermal unit per square foot of exposed surface per hour per degree Fahrenheit. It is so small that the accumulator can be located outside the building, even when it is exposed to the rigours of a Swedish winter.

Apparatus for use with Metalix X-ray Tubes.—We have received from Messrs. Watson and Son (Electro-Medical), Ltd., a catalogue of their 'Sunic' apparatus specially designed for use with the Philips 'Metalix' X-ray tube. The weight and cost of X-ray apparatus had been gradually increasing as the need for adequate protection was appreciated, until the introduction of the Metalix tube with its self-contained protection enabled apparatus to be made lighter and less costly, but at the same time providing adequate protection. On examining the apparatus described in Messrs. Watson's catalogue, one immediately notices the absence of the large and unwieldy protective box which had become such a familiar feature of most apparatus. As Messrs. Watson remark, though the protection at the tube is all that can be desired, it cannot protect against the scattered radiations from the patient: hence the provision of the usual lead rubber aprons and screens. All types of apparatus for diagnostic work are described and the combined couch and screening stand is of interest. In this apparatus, one tube and its carriage are used for upright screen, over and under couch work, and in addition, the apparatus can be used for tele-radiography, up to more than six feet tube to patient distance. All the tube movements can be made quickly without disturbing the patient. All the apparatus is of excellent quality and construction. A wide range of Metalix tubes is described, and a tube can be found suitable for any apparatus for diagnosis or therapy.

The Detection of Flaws in Castings.—By the use of γ-rays so penetrating that they will pass through pieces of metal fifteen inches thick, the Russian State Radium Institute of Leningrad has effected, according to a *Daily Science News Bulletin* issued by Science Service of Washington, D.C., a marked improvement in the examination of thick metal castings, etc. Examination in this way, when compared with the normal X-ray investigation, possesses several distinct advantages. It is cheaper, since the radium lasts indefinitely: large and expensive photographic plates are unnecessary, since the rays which pass through the metal are detected by a special sensitive electroscope, and an automatic record can be taken which may be filed for reference. Another very distinct advantage is that the time required may be cut down to a couple of minutes for a large casting, whereas with X-rays an exposure of the order of several hours might be required, even when the metal is not much more than two or three inches thick. The apparatus is very simple: a glass capsule with the radium preparation is inserted into a deep hole bored in a large ingot of lead; all rays except the strong, narrow beam passing along the bore are stopped. The beam, after passing through the casting, encounters two filaments electrically charged and enclosed within a copper cage. So long as no ray penetrates the metal the air space between the filaments and the cage acts as an insulator. As soon, however, as the γ-rays get into the cage, the air is ionised and a current flows from the filaments to the cage, then through the galvanometer and back to the battery.

The Royal Society Conversazione.

THE first of the two annual soirées of the Royal Society was held at Burlington House on May 17. Sir Ernest Rutherford, president of the Society, received the guests, who were, on this occasion, supplemented by a number of the delegates attending the Harvey tercentenary celebrations. Fortunately for their peace of mind, visitors to this old-established gathering are under no stress to find the "principal scientific exhibit of the year"; an unwritten law of equality reigns, embracing all the departments of science.

A highly interesting illustration of the changes in crystalline form of ammonium nitrate with change of temperature came from the Explosives Branch, Research Department, Woolwich. The substance may occur in five different crystalline forms, according to temperature. Successive changes during cooling from the molten condition were demonstrated by illumination with polarised light and screen projection. Certain difficulties met during the filling and storage of shell with ammonium nitrate explosives are due to these changes.

Sir William Bragg demonstrated the crispations formed on liquids lying on vibrating surfaces, in the study of which Faraday had originally occupied himself, and described, in 1831. These effects underwent re-examination in 1883 by Lord Rayleigh, who confirmed Faraday's interpretations. The exhibit was a model of careful preparation and successful exemplification outside laboratory confines.

The British Museum (Natural History) provided five exhibits; in mineralogy (Dr. L. J. Spencer), the fluorescence of minerals in ultra-violet rays; in geology (Mr. W. E. Swinton), a model of an armoured dinosaur, but with a conjectural head; in zoology (Dr. Baylis), parasitic infection in a whale; the giant shipworm mollusc, allied to *Teredo*, with its shelly tube (Mr. G. C. Robson); and anatomical preparations of Ratite birds (Mr. P. R. Lowe). Dr. Imms, Rothamsted Experimental Station, suitably illustrated biological control in relation to insect pests and noxious plants. In conjunction with the Cawthron Institute, New Zealand, aided by grants from the Empire Marketing Board, and the Government of New Zealand, experiments are in progress with the view of checking the spread of gorse and the notorious ragwort, by the utilisation of insects. The biology of certain species concerned are being studied at Rothamsted prior to shipment. Mention should be made of an exhibit of marine animals and bottom deposits, obtained by the staff of the recent *Discovery* expedition.

The National Physical Laboratory had two exhibits, a high-temperature electric resistance furnace (Dr. Rosenhain and Mr. Prytherch), and an optical interference method of observing modes of vibration of piezo-electric quartz resonators.

The Royal Observatory, Greenwich, showed a transparency of the total solar eclipse, June 29, 1927, and also solar photographs and magnetic traces illustrating the frequent coincidence of large magnetic storms and big sunspots (*v.* p. 842).

Imperial Chemical Industries sent specimens of new ketone dyes; the British Silk Research Association specimens of fibre and yarn-testing instruments; the Cambridge Scientific Instrument Company an apparatus developed in conjunction with the British Research Association for the Woollen and Worsted Industries, and designed for maintaining constant the humidity of the air in rooms where hygroscopic substances, such as textile materials, tobacco, paper, etc., are being tested or stored.

Sir Robert Hadfield, among other interesting items, showed a machineable non-magnetic steel possessing a high yield point, and also samples of recently developed corrosion-resisting steel, indicating in particular greatly improved resistance to dilute sulphuric and phosphoric acids.

Lord Rayleigh demonstrated and offered interpretations of the fading of peacock's feathers in ultra-violet light, described by him in a communication in our correspondence columns (p. 827), and Prof. C. V. Boys exhibited solid dipleidoscope prisms, by means of which an object seen by external reflection from one face may also be seen in the same direction by light which has made two internal reflections.

The International Standard Electric Corporation sent an ingenious machine, though of strange and complicated make-up (of the kind that would have delighted Lord Kelvin) designed for the production, distribution, and analysis of artificial telephone traffic. Where automatic switches are arranged in simple groups, the quantities required to ensure a given grade of service can be determined from curves based on the theory of probability, but to test the efficiency of more complicated switch arrangements it has been necessary to resort to artificial traffic experiments, impracticable by mathematical means.

The Royal Botanic Gardens, Kew, sent examples of grasses used as cereals by African natives; and plants yielding an oil coming into repute in the treatment of leprosy. The species are tall trees occurring in the dense forests of India, Burma, and Siam. The Marine Biological Association showed Dr. Poole's submarine photo-electric photometer apparatus, as used on the Association's trawler. The photo-electric current is measured by a potentiometer, using an interrupter, condenser, and amplifier, with a telephone to indicate the null point.

Mr. J. Reid Moir exhibited limestone implements found at Coney Island, Rosse's Point, and Ballyconnell, Sligo, Ireland, which have been the subject of much discussion. The specimens, which are of limestone and exhibit early Mousterian forms and technique, were found by Mr. J. P. T. Burchell; and they are regarded as important evidence in support of the view that Lower Palæolithic man inhabited Ireland.

From the Pharmaceutical Society's School of Pharmacy came specimens of the animal materia medica of the seventeenth century. At this period entire animals, as well as parts and excretions of animals, were largely used medicinally.

An exhibit from the British Mosquito Control Institute, Hayling Island, shown in the principal library, occasioned much interest. With the projection on a screen of living larvæ and pupal stages, it proved highly instructive. The exhibit was arranged by the director of the Institute, Mr. J. F. Marshall, whose work in mosquito control has had important practical issues.

Among the general exhibits was a theodolite made in 1574 and signed by Humphrey Cole, the Elizabethan craftsman, described by Mr. George H. Gabb as the oldest known instrument of the kind; and there was shown, by Capt. R. Berkeley, a portrait of Sir Isaac Newton, which, although itself of considerable artistic merit, was somewhat unconvincing as regards recorded lineaments.

In the meeting room Dr. Stanley Kemp gave a short lantern lecture on the whaling industry in the Antarctic, which proved attractive and informative.

Oilwells in Great Britain.

IT will be recalled that during the late years of the War, a determined effort was made by the Government to locate oilfields in Great Britain, unfortunately without any commercial success. Of the eleven wells put down at the time, only two can be said to have given technically favourable results; one at Hardstoft, in Derbyshire, the other, the Darcy Well, near Edinburgh. Since that time, in the absence of any striking developments, interest in British oil possibilities has naturally waned, and most people are probably unaware that Hardstoft No. 1, first brought in on May 27, 1919, is still contributing its mite to the world's annual production.

Between that date when it was brought in and the end of last year, this well yielded 2500 tons of oil, about 17,500 barrels, equivalent to an average of just under 6 barrels per day. This oil is of good quality, and in many respects resembles some of the best Pennsylvanian crude. The gravity is 0·823 and, according to Hackford's analysis, the oil yields on refinement 7·5 per cent motor spirit, 39 per cent kerosene, 20 per cent gas oil, 30·5 per cent lubricating oils, 0·26 per cent sulphur, and 3 per cent of paraffin wax. In colour it is dark brown, with green fluorescence, has a setting point of 0° F., and viscosity at 100° F., Redwood 48 seconds. In common with Pennsylvanian crude, the Hardstoft oil possesses in its lubricating fractions a high percentage of oils suited to steam cylinder lubrication, which makes the analogy between the two crudes a still closer one.

The well is situated on a subsidiary anticline of the Pennine system, actually on a local dome developed on this fold, striking north-west–south-east; the folding is accompanied by much faulting. The well is drilled 3070 feet in a sandy limestone near the top of the main carboniferous limestone, though there seems to be some difference of opinion as to the precise horizon responsible for production.

Interest in Hardstoft has been reawakened by Dr. A. Wade's recent paper on this and two subsequent oilwells at Hardstoft, read before the Institution of Petroleum Technologists on April 3. The wells are on the Duke of Devonshire's property, and his agent, Capt. J. D. Penrose, has been instrumental in preserving detailed records and history of operations, without which many of the facts would have been lost to the public.

Hardstoft No. 2 was started on May 16, 1924; its location was chosen about 600 feet west of No. 1, and it was drilled 3125 feet without any other success than a good oil show at 760 feet (a 10-gallon sample after the well had stood for 24 hours), and 20,000 cubic feet of gas at 370 lb. pressure from 1620 feet, afterwards utilised as fuel for the boilers. This well went ultimately to water, and with 2800 feet constant head in the hole, which could not be reduced by bailing, it was abandoned on Mar. 24, 1925.

Hardstoft No. 3 was selected 600 feet north of east of No. 1 well and was started on Aug. 5, 1925. In results it was as disappointing as No. 2, though it was carried much deeper (to 3825 feet), being finally abandoned in a bed of lava on June 8, 1926. In this hole, shows of oil were struck at 1900 and 1978 feet, and a gas show at 1812 feet.

While it is evident that the general geological structure of the district is comparatively determined, the results of these three borings, with their contrasted logs and behaviour, show clearly that the subsurface structures are far from being understood, largely, no doubt, due to the extensive faulting prevalent. We are not aware of what particular methods were employed for subsurface correlation of the well-samples, whether, in point of fact, anything more than casual logging by the drillers was carried out. In any case, the very remote possibility of finding a commercial oil-pool in this area, or in any other in the British Isles for that matter, warrants further drilling neither in Derbyshire nor elsewhere, and although these three wells furnish a pretty problem for the oil geologist, they and their predecessors serve as a warning of what awaits further search for petroleum in Britain.

The Iron–Chromium–Carbon System.

AN important paper on "The Structure of the Iron–Chromium–Carbon System" was presented by Messrs. Westgren, Phragmén, and Negresco at the May meeting of the Iron and Steel Institute (May 3). As a result of the X-ray determination of the lattice dimensions of various iron–chromium alloys, it is shown that there is a progressive change from end to end of the system, confirming the general view that these metals form with each other an unbroken series of solid solutions. Three carbides of chromium have been detected in the chromium–carbon series, one, cubic, with a probable formula Cr_4C, a trigonal one Cr_7C_3, and an orthorhombic carbide Cr_3C_2. In the ternary system containing iron, cementite, which may contain chromium to the extent of rather more than 15 per cent, is also present.

For each of the chromium carbides substitution of iron for chromium may to some extent take place. In the cubic form the chromium may be replaced by iron up to about 25 per cent: in the trigonal carbide the iron content may rise to 55 per cent, but in the orthorhombic carbide only a few per cent of chromium can be replaced by iron. No definite double carbide, the presence of which would necessitate the presence of both iron and chromium atoms, is found.

In annealed chromium steels containing only one or two per cent of chromium, the only carbide found is cementite, the iron of which is partially replaced by chromium. The difference of distribution of the carbide in such steels appears to be due not to any definite difference of composition, but to something of the nature of segregation. The carbide in stainless steel is the cubic one saturated with iron. In a steel containing about 1 per cent of nickel, 11 per cent of chromium, and 2 per cent of carbon (used for dies), the trigonal carbide occurs, rather more than half of the chromium of which is replaced by iron. Sections through the ternary solid model show that as the chromium content is raised the area of the γ-iron phase is gradually reduced and finally disappears: the eutectic occurs at a lower carbon content than in iron–carbon alloys, for example, at about 3·7 per cent with 15 per cent of chromium.

The solubility of the carbide in austenite is reduced as the chromium is increased, and the cementite line consists of two distinct portions corresponding to the solubility of different types of carbide. With 3 per cent chromium, for example, the lower portion of the curve represents the solubility of the trigonal carbide, and the higher temperature region the solubility of cementite. With 15 per cent of chromium the lower temperature portion gives the solubility in the γ-phase of the cubic carbide, and at higher temperatures of the trigonal one.

University and Educational Intelligence.

CAMBRIDGE.—Sir Richard Threlfall, Gonville and Caius College, has been appointed to represent the University on the Grand Council of the World Power Conference's Fuel Conference. The Committee of the Privy Council for scientific and industrial research has appointed Mr. H. T. Tizard as a member of the University Committee for Magnetic Research.

EDINBURGH.—At the meeting of the University Court on Monday, May 14, Dr. F. A. E. Crew was appointed to be professor of animal genetics and director of the University Department of Research in Animal Breeding. The chair, which is to be known as the Buchanan chair of animal genetics, was founded by a donation from Lord Woolavington, supplemented by a grant from the International Education Board, New York.

LONDON.—Dr. Geoffrey Hadfield has been appointed as from May 1 to the University chair of pathology tenable at the London School of Medicine for Women.

Dr. Percival Hartley has been appointed as from Aug. 1 to the University chair of biochemistry tenable at the London School of Hygiene and Tropical Medicine. Dr. Hartley was educated at the Technical College, Bradford, and the Yorkshire College, Leeds. From 1909 until 1913 he was physiological chemist to the Imperial Bacteriological Laboratory at Muktesar, United Provinces, India, and in March 1913 he was appointed first assistant to the head of the Biochemical Department at the Lister Institute; from 1919 until 1921 he was head of the Biochemical Department of the Wellcome Physiological Research Laboratories, and since 1922 he has been on the staff of the National Institute for Medical Research, Hampstead.

Dr. C. B. Fawcett has been appointed as from Aug. 1 to the University chair of economic geography tenable at University College. From 1906 until 1911 Dr. Fawcett was geography master in the Derbyshire County Secondary School at Long Eaton, near Nottingham, and from 1911 until 1913 he worked in the School of Geography at Oxford, obtaining the Diploma in Geography with distinction and the B.Litt. degree as a research student. Later he was lecturer in geography at University College, Southampton, and worked part-time in the Ordnance Survey Office during the War, while since 1919 he has been lecturer, and later reader, in geography in the University of Leeds. Dr. Fawcett was editor of the "General Handbook" for the Leeds meeting of the British Association, for which he wrote two sections.

The title of professor of experimental pathology in the University has been conferred on Dr. Archibald Leitch, in respect of the post held by him since 1921 as Director of the Research Institute at the Cancer Hospital.

The title of reader in pathological chemistry in the University has been conferred on Dr. C. R. Harington, in respect of the post held by him since 1922 as lecturer in pathological chemistry at University College Hospital Medical School. Dr. Harington is known for his work on the chemistry of thyroxine and related subjects, published chiefly in the *Biochemical Journal*.

APPLICATIONS for grants from the Chemical Society Research Fund, made upon forms obtainable from the Assistant Secretary, Chemical Society, Burlington House, W.1, must be received by, at latest, June 1.

THE Committee of Leplay House E. T. A. has organised the following tours for those interested in historical, geographical, and social studies: (1) To south Sweden, visiting Gothenburg, Stockholm, afterwards going to Lappland; (2) to Aldrans, above Innsbruck, in the Austrian Tirol; (3) to St Peter in the Black Forest, 'students' camp.' Particulars of these visits can be obtained from Miss Margaret Tatton, Leplay House, 65 Belgrave Road, S.W.1.

DR. DU BOIS, a Swiss biologist of the University of Geneva, recently working with Prof. Caullery in Paris, has been awarded a Junior Fellowship in Science (£250) by the International Federation of University Women, to enable her to continue her research in Berlin. This is the first of a series of fellowships for graduates wishing to carry on research in a country other than that in which they have previously worked, for which an endowment fund is being raised.

APPOINTMENTS to the twenty fellowships awarded by the Commonwealth Fund and tenable by British graduates in American universities for the two years beginning in September 1928, include the following: Mr. R. H. Angus, of Sydney Sussex College, Cambridge, to Stanford University, in electrical engineering; Dr. G. A. Cumming, of St. Andrews, to the California Institute of Technology, in geology; Mr. Cyril D. Forde, of University College, London, to the University of California, in anthropology; Dr. Norman P. Inglis, of the University of Liverpool, to the University of Illinois, in engineering (metallurgical); Dr. J. M. Robertson, of the University of Glasgow and the Royal Institution, London, to the University of Michigan, in chemistry; Mr. Robert Spence, of Armstrong College, University of Durham, to Princeton University, in physical and engineering chemistry; Miss C. S. Steele, of St. Andrews, to the University of Illinois, in organic chemistry.

THE Association of Teachers in Technical Institutions is holding its annual conference this year at Bradford Technical College, May 26–29. Among the resolutions to be discussed at the conference is one relating to the social applications of biological science. It expresses agreement with the spirit and intention of certain resolutions of a conference of the British Social Hygiene Council and representatives of education aiming at the adoption by health, education, and labour authorities of practical measures for dispelling the prevalent ignorance of elementary biology. "In order to provide a foundation on which an adequate sense of racial responsibility may be developed," biology teaching ought, it is urged, to be extended to all schools, the type of teaching being in each case such as to fit the ages and circumstances of the pupils. Attention is directed likewise to the urgent need of such further education for adolescents between fourteen and eighteen years of age as "would encourage a sense of individual responsibility in the science and art of healthy living." Another resolution signifies approval of the action taken by the President of the Board of Education as a result of the recommendations of the Emmott Committee. The first-mentioned resolution stands in the names of Mr. J. Wickham Murray, secretary of the Association, and Mr. A. E. Evans, of the Battersea Polytechnic, honorary secretary, on behalf of the Association's executive committee. The address of the new president, Mr. W. W. Sirman, of the Technical College, Handsworth, will be delivered on May 28, and there is to be an address on the following day by Mr. Arthur Greenwood, M.P., followed by a visit to the research station of the British Research Association for the Woollen and Worsted Industries.

Calendar of Customs and Festivals.

May 27.

WHITSUNTIDE.—Whitsuntide observances bear a close resemblance to those of Mayday. This is clearly seen in the custom of decorating an individual with green boughs, who, it may be inferred, represents the spirit of vegetation, and occasionally of subjecting him or her to some form of indignity or horseplay which it is not far-fetched to regard as a survival of a sacrifice. The leaf-clad man may be drenched with water, or thrown in a brook, when he scatters water on the bystanders, thus distributing his own 'virtue'; his head may be cut off, or he may be stabbed. Frazer, in "The Golden Bough" (vol. 2, pp. 89 *sqq.*, etc.), quotes a number of instances of this observance at Whitsuntide, among them a Russian example in which a young birch tree is dressed up in female clothes and brought to the village, where 'she' remains as a guest for three days in one of the houses and is then thrown into the water.

In England various Whitsuntide observances have been recorded. None is perhaps in itself so clearly indicative of the nature of the Whitsuntide ceremonial as the central European customs quoted by Frazer, but taken as a whole they point to its origin in a seasonal festival.

One trace at least of its character as the opening of the year survives in the custom of hiring farm servants at this season, the engagement being for the whole of the succeeding year. A similar practice obtains in November, which survives from the Celtic custom of beginning the year at this date. At Whitsuntide it was customary for the hired servants to return to their homes for a week's holiday. It is probably to this interval that we owe the survival of a considerable number of Whitsuntide customs, especially the itinerant performance of Morris dances and the practice of holding sports and contests of the familiar winter versus summer type. Races were one of the features recorded in connexion with Maypole and other Mayday observances.

WHITSUN ALE.—In many parishes throughout the country it was customary for a collection to be made just before or at Whitsuntide. This was expended on the provision of cakes and ale for a feast which was held at the church house. Wardens were elected for the purpose of making the arrangements, and any surplus funds were afterwards reserved for extraordinary parish expenditure. The well-known Eton Montem, which was sometimes attended by the reigning monarch and his consort, was of an analogous character. A procession of Eton scholars in military or fancy dress marched in procession to a mound on the Bath Road, where they took up their position, and then exacted a toll of money 'for salt' from all present and from all travellers passing. Sometimes as much as £1000 or more was collected.

After the Whitsun Ale feast, the afternoon was usually devoted to sports. That this feast was originally of a sacrificial character is indicated by the record of a curious custom at Kidlington, Oxford, on the Monday after Whitsun, when the maids in the town, with their thumbs tied behind them, ran after a lamb, which they tried to catch with their teeth. When it was caught, the successful maid became the 'lady of the lamb,' the animal was dressed and carried in procession on a long pole before the lady and her companions, accompanied by Morris dancers. On the following day the lamb was eaten at the 'lady's feast,' when the lady sat at the head of the table.

In several localities, for example, Heybridge, Essex, Monk Sherborne, Hants, and Herefordshire, rushes were strewn in the church or sprigs of birch were attached to the pews as decorations. Sometimes, as in Northampton, there was a maypole at the Whitsun Ale, as well as a Lord and Lady. At a fair held on Whitsun Monday at Hinkley, Leicestershire, an elaborate procession of the trades took place, which included several grotesque characters, such as Baron Hugo and his lady, the Baroness Adeliza. In Shropshire a 'boy bailiff' was elected for Whitsun week. He was accompanied by a retinue of men and boys mounted on horseback, who carried wooden swords at their right sides. They first rode round the whole franchise and then were met at the Guildhall by the civic authorities. An elaborate Court of Array was held at Litchfield, in which Morris dancers, the bailiffs and city officers, and the members of the trades and guilds with standards or posies took part. The posies afterwards become implements of trade or mere puppets or garlands borne upon halberds, which nevertheless were received as they visited each ward with a volley from the men-at-arms. These last also fired over each house at which they received money and liquor from the inhabitants.

Immediately after the annual hirings were completed, it was customary for the men and women to hold a dance, in which the men chose their partners in a more or less recognised manner which suggests a forgotten ritual of pairing. In some parts of Wales it was indeed the custom for boys and girls to retire, each sex apart, to a wood, when individuals in each party elected or declared the choice of a partner from the opposite sex. On their return to the dancing place, each had to take his declared partner, under a penalty in case of default.

THE MORRIS DANCES.—A regular feature of the Whitsuntide observances was the Morris dance. The name Morris was generally derived from the word *Morisco* =Moor, and it was said that the dance came from Spain. More probably, however, the name itself is derived from the fact that the dancers once used to black their faces, and although dances of a similar character are even now regularly performed in elaborate form, including a bear dance, in the Pyrenean area, similar dances are too widely distributed to warrant a Spanish or Hispano-Moorish origin. The dance, it is scarcely open to question, is a survival of a ritual dance, representing the primitive vegetation spirit ceremonies. This was the view suggested by the late Mr. Cecil Sharp. It is a survival of the sacrifice of the vegetation spirit and the subsequent meal in which the worshippers took part. In the related sword dance the knotting of the swords clearly represents the killing of one of the dancers, and although the Morris dancers carry handkerchiefs and not staves, Mr. Sharp's suggestion that the handkerchief is a survival of the sword is probably correct. It is to be noted that in more than one of the Whitsuntide ceremonies, not the dances, it is recorded that those who took part wore wooden swords. In some of the Morris dances a cake is carried on a sword decorated with ribbons and flowers before the six dancers. This may be all that survives to indicate the sacrificial meal, or victim. At Kidlington, however, the lamb, as mentioned above, was actually carried on a pole at the head of the procession before it was eaten. Finally, the religious character of the Morris is indicated by the fact that in some villages the dance took place in the church tower, whither it must have been relegated from the chancel, where in the early Christian church the dances absorbed from paganism used to take place until they were forbidden.

Societies and Academies.

LONDON.

Linnean Society, May 3.—**G. S. Carter**: The swamps of the Paraguayan Chaco. The Paraguayan Chaco is a plain stretching westwards from the Rio Paraguay towards the Andes. A belt within 100 miles of the river consists partly of grassland, in the more open parts of which are large areas of shallow swamps. During the summer months the climate is tropical, and the nature of the water most largely influenced by the amount of the rainfall. The most striking result of the analyses was the evidence that they gave of the small amount of oxygen present in the water at all times. The co-operation of several conditions, such as the absence of disturbance and the large amount of decay in the water, produces this result. The oxygen-content plays a determining part in the control of the fauna, which includes many forms adapted to life in a medium poor in oxygen. This was especially clear of the fishes and the oligochætes.

Royal Meteorological Society, May 16.—**Sir Gilbert T. Walker**: On periodicity and its existence in European weather (*Memoir*, vol. 1, No. 9). When examining the amplitudes of a number p of the periods that can be derived by analysing a series of numbers, it is important to know how many of these are independent. Further, we must compare the biggest amplitude found with the probable biggest that would be produced by purely random figures, and in order to estimate this we want to know how many of our p amplitudes are independent. This is determined as the number of Fourier frequencies, corresponding to submultiple periods, each of which has one or more of the calculated frequencies nearer to it than to any other Fourier frequency. Applying this to European weather, it is concluded that the periods in temperature of 12¼ and 13 months, apart from the annual period, may be regarded as real. Under ordinary conditions it is sufficient if, instead of the accurate figures to be analysed, we use group figures of which the interval is as large as a third of the standard deviation.—**D. Brunt**: Harmonic analysis and the interpretation of the results of periodogram investigations (*Memoir*, vol. 11, No. 15). The paper collects together for convenience of reference the formulæ used in harmonic analysis. In a general discussion of periodogram results, it is shown that Walker's method of deriving the 'probable greatest amplitude' is faulty. Discussing the periodogram of London temperatures, it is shown that only a very small part of the variations of temperature from month to month can be accounted for by the periods the amplitudes of which are equal to, or greater than, 0·39° F.—**C. E. P. Brooks**: Periodicities in the Nile floods (*Memoir*, vol. 11, No. 12). The paper analyses a series of records of Nile floods extending from A.D. 641 to 1451, by means of the 'difference-periodogram.' Nineteen periodicities are determined, ranging from 1·91 to 76·8 years in length, with mean amplitudes up to 16 9 cm. (the standard deviation of the Nile flood is 56 cm.). The majority are submultiples or multiples of 22·12 years. The lengths undergo a fairly regular variation with a cycle of about 500 years, the cause of which is not known.

CAMBRIDGE.

Philosophical Society, May 7.—**J. Taylor**: On the action of the Geiger α-particle counter. The action of the counter, its partial reversibility, and its self-restoring properties are considered as a general problem of intermittency in discharge tubes and explained on three bases: the threshold current hypothesis, the shape and significance of the volt–ampere characteristics, and the photo-electric theory of sparking potentials.—**J. Taylor** and **W. Taylor**: The high-frequency electric discharge at low pressures. Some new forms of the well-known high-frequency electric discharge at 4×10^7 cycles per sec. are studied at very low pressures (10^{-3} mm. and less) and the presence of more than one type of discharge is demonstrated.—**E. J. Williams**: Some applications and implications of Duane's quantum theory of diffraction. The quantum theory of diffraction is applied to the reflection of electrons by crystals and to the spatial distribution of photo-electrons and fluorescent radiation from a crystal. The extent of coherent scattering of X-radiation by a crystal is also considered.

PARIS.

Academy of Sciences, April 16.—**H. Deslandres**: A new comet discovered at the Paris Observatory. This comet was observed by M. Giacobini on Mar. 17, and was again seen on Mar. 23. Positions are given for Mar. 17 and 28, the latter from photographs by M. Mineur.—**Charles Moureu**, **Charles Dufraisse**, and **Louis Girard**: Researches on rubrene. New experiments with rubrene peroxide. Crystallised from various solvents, the crystals always contain solvent of crystallisation. The dissociation of the peroxide by heating gives as the only gaseous products carbon dioxide and oxygen; the latter corresponding to from 74 to 80 per cent of the total oxygen present in the compound.—**H. Douvillé**: Concerning ophite.—**André Blondel**: The adaptation of bifilar oscillographs to the study of triode valves. The bifilar oscillograph in its usual form is not sufficiently sensitive for recording the variable currents in triode valves. Various modifications are suggested, that involving the use of a specially designed transformer proving to be the best.—**Alexandre Pantazi**: The extension of a theorem of Čech on projective applicability.—**Mandelbrojt**: The singularities of Dirichlet's series.—**Michel Broszko**: The yielding of prismatic bars compressed axially.—**Charles Volet**: A new method for the absolute determination of gravity by the pendulum. In the method proposed, all the measurements are made with the same knife-edge submitted to a constant load: the time of oscillation is varied by displacing a mass on the rod. Some advantages over the usual method are claimed.—**R. de Mallemann**: Calculation of the rotatory power of quartz.—**Mlle. M. Hanot** and **H. Guillemet**: The laws of photographic blackening: the case where the source of light is a series of electric sparks. From the results of the experiments described, it is concluded that in researches in photographic photometry with sparks, such as the study of a spark spectrum, the factor of contrast of the plate may be determined either with a continuous or intermittent source.—**Victor Henri** and **Svend Aage Schou**: The absorption spectra of formaldehyde and carbon monoxide. Close relationship between the two molecules. Analyses of the absorption spectra show close analogy between carbon monoxide and formaldehyde. The latter is a bivalent molecule having a system of triplets with the same separations as carbon monoxide. Moreover, in the absorption spectrum of carbon monoxide, the intercombination bands $^1S-{}^3P$ are found as in the case of bivalent atoms.—**G. Denigès**: The rapid estimation of the phosphate ion in soils and manures by means of molybdenum blue.—**Bodard**: The volcanic activity of Rakata.—**Ch. Jacquet** and **H. Bellocq**: Magnetic measurements in Corsica and Charente. Results of work done in 1926 at 56 stations, 24 of which are new.—**P. Idrac**: The registration of submarine currents of the Straits of Gibraltar. A change in the direction of the current was proved at a depth of 200 metres.—**Antonin Němec**: Determination of the requirements of the soil in phosphoric acid according to the soluble silica.—**H. Bierry** and **Max Kollmann**: The mode of action of vitamin B. From the experimental results described, it is concluded that the stimulating action of the water-soluble vitamin B acts both on the glands with internal secretion and those with external secretion.—**Auguste Lumière** and **Mme. R. H. Grange**: The comparative toxicity of the serum of arterial blood and that of venous blood. Venous blood serum is always much more toxic than the serum from arterial blood. This is in agreement with the authors' hypotheses on the mechanism of the toxicity of the sera from mammals for animals of another species.—**A. Policard**: The study, by micro-incineration, of the amounts of mineral matter fixed by various parts of the cell. The methods described in an earlier communication have now been applied to animal cells.—**E. Nicolas** and **K. Katrandjieff**: The antigen character of albumens modified by heating and their specific differentiation by precipitating sera. The authors regard their work as solving the problem of the specific differentiation of cooked meats.—**Costantino Gorini**: Climbing culture and microbial dissociation.—**S. Nicolau** and **Mlle. E. Mateiesco**: Septineuritis of the rabic virus. Proof of the centrifugal course of the virus in the peripheral nerves of rabbits.

April 23.—**Pierre Termier** and **Eugène Maury**: New geological observations in eastern Corsica. The radiolarites. The radiolarite abounds in eastern Corsica. It appears, with the same petrographical characteristics, in two kinds of layers, those of the Apennine type, with non-metamorphosed limestones and clays, and in deposits of the Pennine type, with limestone schists much metamorphosed. In the layers of both types it is connected with the green rocks, and there is no essential difference between the two ophiolithic series.—**Louis Roy**: The equations of elastic surfaces with three parameters.—**E. Mathias**: Magnetic measurements in the Allier and the Puy-de-Dôme. These measurements form part of the new magnetic network of France and were carried out in 1925, with the assistance of grants from the Loutreuil Foundation. Elements are given for 37 stations, 28 of which are new.—**L. Féraud**: Surfaces admitting a finite group of projective deformations.—**V. Hlavatý**: The second fundamental form relative to the geodesic curves of a V^*_2 in V^*_3.—**Serge Bernstein**: The polynomials of Jacobi.—**de Possel**: The prolongation of the surfaces of Riemann.—**J. Delsarte**: Certain groups of non-Euclidian functional rotations.—**André Roussel**: A generalisation of the notion of primitive.—**Al. Proca**: Further reflections on dynamics. Interferences.—**F. Margond**: The general equations of a synchronous machine, not saturated, outside the normal regime.—**C. Chéneveau**: The magnetic susceptibility of aluminium. Measurements were made on a specimen of aluminium purified by Hoppes' method (iron 0·06 per cent) and on the commercial metal (iron 0·5 per cent). There appears to be no simple relation between the proportion of iron present in the metal and the magnetic susceptibility of aluminium.—**Mme. Ch. Lapp**: The measurement of the true specific heats of nickel by a direct electrical method. The changes in the specific heat of nickel with the temperature were measured over the temperature range −175° C. to +460° C. The point of discontinuity found at 357·6° C. agrees with the point of magnetic discontinuity (Curie point).—**Y. Rocard**: New diffused radiations. A theoretical explanation of the experimental results of C. V. Raman.—**J. Gilles**: The structure of the second order spectrum of sulphur (S II).—**Maurice Lambrey**: The absorption spectrum of nitric oxide.—**J. Cabannes**: The theoretical calculation of the diffusion of light in a fluid.—**J. F. Saffy**: Profound alteration of a copper-nickel alloy by the action of steam superheated to 350°-400° C. The alloy containing nickel (68·6 per cent), copper (28·9 per cent), manganese (1·6 per cent); it showed great resistance towards a series of corrosive reagents and kept its mechanical properties after seventeen months in steam at 150° C. But this alloy suffered marked change, losing its mechanical properties after a month in superheated steam at 375° ± 25° C.—**Pierre Jolibois**, **Henri Lefebvre**, and **Pierre Montagne**: The decomposition of carbon dioxide at low pressure under the action of the electric current. The tube containing the gas had its electrodes connected with a source of continuous current with several megohms resistance in series. For currents varying between 0 and 2 milliamperes the final dissociation equilibrium was independent of the current intensity, but this equilibrium was reached more rapidly with the larger current. The amount of gas dissociated increases as the pressure of the gas is lowered.—**M. Guichard**, **Clausmann**, and **Billon**: The expansion in hydrogen of metals and alloys containing a little oxide.—**F. Bourion** and **Ch. Tuttle**: The cryoscopic determination of the molecular equilibria of resorcinol and pyrocatechol in aqueous solution.—**R. Cornubert** and **H. Le Bihan**: Attempts at the benzylation and phenylation of α-methylcyclohexanone.—**P. Brenans** and **Ch. Girod**: Bromoiodo-phenols obtained with the 5-bromo- and 3, 5-dibromosalicylic acids.—**Ch. Mauguin** and **L. Graber**: The study of micas containing fluorine by means of the X-rays. A lepidolite containing 6·82 per cent of fluorine has exactly the same parameters as a lepidolite containing only 1 per cent of fluorine. The number of atoms of fluorine and of oxygen is variable in different minerals, but their sum is constant, and it appears that one or more atoms of oxygen can be replaced by the same number of atoms of fluorine in the crystalline network.—**Duboin**: The reproduction of tenorite, oligist iron, and cobalt oxide as crystals. The crystals are formed by the prolonged action of fused potassium fluoride (two or three days at a red heat).—**H. Parent**: A Pyrenees irregularity on the edge of the Maurettes.—**Pierre Viennot**: The extrusions which mark the edge of the French Pyrenees.—**J. Repelin**: The tectonic of the hills forming the southern edge of the Marseilles basin (Carpiagne).—**J. Thoulet**: The Humboldt current and the sea of Easter Island.—**Lucien Daniel**: The variations in calcium oxalate in certain grafted plants.—**Michel-Durand**: The physiological rôle of the tannins.—**Jules Amar**: The water united with colloids.—**Philippe Fabre**: The comparison of the parameters of muscular excitability by the microscopic examination of the reactions.—**J. Risler**, **A. Philibert**, and **J. Courtier**: The photobiological action of radiations. The light emitted by the instantaneous volatilisation of an aluminium wire by a continuous current has high penetrative power and its bactericidal power is greater than that of any other source of light hitherto studied.—**W. Arciszewski** and **W. Kopaczewski**: Microbial antagonism and the problem of cancer. The antagonism between *B. tumefaciens* and *Streptococcus erysipelatus* appears to be a biological fact capable of physico-chemical explanation. A real and strong physico-chemical antagonism appears to exist between *B. prodigiosus* and the bacterial agent of erysipelas. Biologically, the introduction of this organism in the treatment of tumours of plants by the Streptococcus is without effect.—**Et. Hubault**: A bacillus parasite of the caterpillars of *Dasychira pudibunda*. A detailed morphological and biological description of this parasite is given: its virulence and toxigenic power are under examination.—**E. Brumpt**: A new trypanosome pathogenic to cold-blooded vertebrates, *Trypanosoma parroti* from *Discoglossus pictus*.

Haveg Chemical Plant. Pp. 16. Rotameter. Pp. 4. (London: Trost Bros.)

Diary of Societies.

SATURDAY, MAY 26.

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (at Neville Hall, Newcastle-upon-Tyne), at 3.—R. White: The Use of Carbon Monoxide Masks in Mines.

TUESDAY, MAY 29.

ROYAL PHOTOGRAPHIC SOCIETY OF GREAT BRITAIN, at 7.—Demonstrations of New Apparatus.

WEDNESDAY, MAY 30.

BRITISH ASTRONOMICAL ASSOCIATION (at Sion College, Victoria Embankment).

THURSDAY, MAY 31.

ROYAL SOCIETY OF MEDICINE (Laryngology and Otology Sections) (continued on June 1 and 2).—Laryngological Papers by Dr. Watson-Williams, L. Yates, Sir StClair Thomson, A. J. Wright, Mr. Rake, and W. McKisson.

Friday, June 1.—Otological Papers:—Prof. O. Mayer: The Pathology of Otosclerosis.—H. Kisch: The Use of Temporal Muscle Grafts in the Radical Mastoid Operation.—D. Guthrie: Fat Grafting.

Saturday, June 2.—W. S. Sharpe: The Influenzal Ear.

INSTITUTION OF MUNICIPAL AND COUNTY ENGINEERS (Scottish District Meeting) (at The Hydro, Peebles) (continued on June 1 and 2).

FRIDAY, JUNE 1.

PHILOLOGICAL SOCIETY (at University College), at 8.—C. T. Onions: Paper.

ROYAL INSTITUTION OF GREAT BRITAIN, at 9.—C. L. Woolley: The Results of the Further Excavations at Ur.

PUBLIC LECTURES.

TUESDAY, MAY 29.

MIDDLESEX HOSPITAL MEDICAL SCHOOL, at 5.30.—Dr. J. Mason: Graves' Disease. (Succeeding Lectures on May 30 and 31.)

UNIVERSITY COLLEGE (in Anatomy Theatre), at 5.30.—Prof. G. Elliot Smith: Elephants and Archæology.

GRESHAM COLLEGE (Basinghall Street, E.C.2), at 6.—A. R. Hinks: Gresham Lectures in Astronomy. (Succeeding Lectures on May 30, 31, and June 1.)

THURSDAY, MAY 31.

INSTITUTE OF PATHOLOGY AND RESEARCH, ST. MARY'S HOSPITAL, at 5.—Dr. G. V. Anrep: Pathology of Conditioned Reflexes.

KING'S COLLEGE (University of London Animal Welfare Society), at 5.30.—Addresses on Man's Duty to Animals by Rabbi S. Daiches, Rev. R. G. Bourchier, Rev. Father C. C. Martindale, Lt.-Commissioner L. Unsworth, Prof. The Rev. W. R. Matthews. Chairman: Prof. F. T. G. Hobday.

UNIVERSITY COLLEGE, at 5.30.—Prof. Max Bodenstein: Chemical Kinetics. (Succeeding Lectures on June 1 and 4.)

FRIDAY, JUNE 1.

KING'S COLLEGE, at 4.—l'Abbé H. Breuil: Les Industries préhistoriques par rapport à la Géologie.—At 5.30.—Dr. J. Krzyzanowski: Polish Culture in the Middle Ages: Secular Literature and Science.

UNIVERSITY COLLEGE, at 5.30.—Prof. C. Spearman: The Psychologist in the School.

SATURDAY, JUNE 2, 1928.

Arctic Aviation.

THE development of aviation, which may already be regarded as a safe means of transport for even comparatively long distances, promises before long to bring the realisation of the sixteenth-century dreams of the north-west and north-east passages and the transpolar routes between Europe and Pacific lands. For three centuries the polar ice has baffled man, but at length the aeroplane and airship have shown him how to avoid it. In 1919, Dr. W. Bruns suggested a series of transpolar commercial routes for airships, and a few years later Mr. V. Stefansson pointed out the advantages that the Arctic offered for flying. Plans for Arctic exploration by air were further discussed at a representative meeting in Berlin in November 1926, which led to the formation of the Internationale Studiengesellschaft zur Erforschung der Arktis mit dem Luftschiff, under the presidency of Dr. F. Nansen. The second general meeting of the society is to be held at Leningrad on June 18-23, when a long programme of papers on Arctic problems will be discussed.

Polar exploration by ship and sledge has made slow advances in recent years. A new method of attack on the inaccessible inner regions of the Arctic Sea is desirable if the remaining problems of the Arctic are to be solved. It was Dr. Nansen who, in defiance of all the accepted canons of polar exploration of the day, introduced the novel idea of a drifting ship in his journey in the *Fram* in 1892–95. At Berlin he dwelt on the value of the airship as an improvement on other means of transport. The new international organisation, of which several well-known British meteorologists are members, aims at raising funds for systematic polar exploration by air, and incidental to that work, the institution of meteorological and magnetic observations in high latitudes. In furtherance of the Association's aims, a quarterly journal entitled *Arktis* (Gotha: Justus Perthes) is being published. The first number, containing several valuable articles on polar work in German, French, and English, has just appeared. It contains also the constitution and membership of the Association, which, for convenience sake, is known as Aeroarctic.

International co-operation in polar exploration is not a new idea. So long ago as 1882–83 eleven States co-operated in a scheme for thirteen Arctic and two Antarctic observatories. The results of that one year's work was the basis of much of our knowledge of Arctic meteorology. To-day there are permanent observatories in west and east

Greenland, Jan Mayen, Spitsbergen, Novaya Zemlya, Siberia, Alaska, and Arctic Canada, but more are needed, and the task of founding and maintaining stations should not prove so arduous as it was forty-six years ago. Northern Greenland, Ellesmere Island, Wrangel Island, the New Siberian Islands, and Nicholas (Northern) Land are among the obvious sites. They could also serve as biological stations, since many of the biological problems of polar regions can be studied only on the spot. At present the Danish station at Disko in Greenland is the only Arctic biological laboratory. Some of the stations might serve as air bases for exploration of the surrounding area. It is important that such stations should be permanent. The intermittency of observations lessens their value. Since the whole of the Arctic regions is now within the nominal political jurisdiction of Denmark, Norway, Russia, the United States, and Canada, it is to be hoped that these States will regard exploration as one of the obligations of sovereignty. To a great extent this has been done already. Arctic sovereignty is no idle claim in Alaska, Arctic Canada, Greenland, Spitsbergen, and Novaya Zemlya.

At the meeting in 1926, when Aeroarctic was founded, discussion favoured the airship rather than the aeroplane in polar exploration. Capt. Amundsen had already used both, and been successful with the airship. The advantages of the airship lie in its great cruising radius and carrying capacity. General Nobile believes that an airship could be constructed to make a non-stop flight of ten days at a speed of 50 to 60 miles an hour; that is to say, it could explore a zone 15,000 miles in length. When he flew with Capt. Amundsen across the Pole, the distance was only 2300 miles, which were covered in 72 hours. Such an airship would obviously be valuable in carrying the materials for establishing a scientific station in regions otherwise poorly accessible. Furthermore, the airship has the advantage over the aeroplane in its powers of going at a low speed or even standing in the air provided the atmosphere is calm. It is said to be possible to land and pick up personnel from an airship. This greatly increases its value in exploration. On the other hand, there is the danger of ice incrustation during fog. However, Capt. Amundsen and Gen. Nobile found this to be less serious than they had anticipated, except when falling pieces of ice were hurled by the propeller against the envelope. The flight of the airship *Norge* in 1926 and *Italia* this year have shown that strong winds can safely be weathered, but it is doubtful if similar craft could face the sudden and incredibly fierce blasts of the Antarctic blizzards.

The aeroplane has been used successfully in the Arctic by Capt. G. H. Wilkins and Com. R. E. Byrd, following on some experimental flights by Mr. G. Binney and others in Spitsbergen and a daring but unsuccessful attempt by Capt. R. Amundsen to reach the Pole in 1925. Compared with the airship, it has the advantage of speed and is less influenced by weather conditions, but its cruising radius is limited by its comparatively small carrying capacity. It has value, however, in reconnaissance work, and might be used for survey of rugged inaccessible country near a convenient base, as in eastern Greenland.

Opinion differs among Arctic airmen as to the use of pack-ice for landing. Capt. Wilkins, from his wide experience, believes that ninety per cent of pack-ice is too rough, but that the remainder is smooth enough to afford frequent landing-places. North of Bering Strait, in 1927, he landed safely on the pack and rose again, and in his long flight across the Arctic Sea this year he saw numerous landing-places, although he had no occasion to use them. Com. Byrd suggests water surfaces as being more useful than ice, but Capt. Amundsen in 1926 nearly lost his hydroplanes in a lead in the pack, and, after extricating one with great difficulty, had to abandon the other. Antarctic pack certainly offers little likelihood of landing-places, while the low air temperatures in the south, even in the height of summer, would increase the danger of alighting on water by ice forming and adding to the weight of the machine. A better knowledge of Arctic meteorology may increase the flying season, but owing to the prevalence of fog in summer, April and May are now regarded as the best months. The disadvantage of that season is that the winter snow still lies and obscures underlying surface features.

All countries will benefit from the work proposed. A fuller knowledge of Arctic meteorology and magnetism will have universal value. There can be no national boundaries in scientific research. The Arctic flights that have so far been made have contributed little to our knowledge of the Arctic, although they have shown the skill and daring of the navigators and pilots. They discovered no new land where none was expected. Capt. Wilkins had fog in the one area where land might have been found. That is no reason, however, why other flights should not have important results. For example, a course from Spitsbergen eastward to Nicholas Land and the New Siberian Islands, which Gen. Nobile has followed, will have interesting results even if they are negative in the discovery of land. In a few hours of flying instead of weeks or even months of laborious sledge travelling, the limits of Northern Land will be defined and the mystery of Sannikov Land solved. Apart from weather, success depends on mechanical efficiency, but the risk is no greater than that of failure of human endurance in the old methods of travelling. The full value of polar flying, however, will not be reached until the problem of voluntary descent and ascent is solved. Ground observations are essential. Without them the work is incomplete; but this difficulty will no doubt be overcome. The Internationale Studiengesellschaft zur Erforschung der Arktis deserves encouragement in its endeavour to make use of new scientific applications in the solution of old problems.

A Frazer Anthology.

Man, God, and Immortality: Thoughts on Human Progress. Passages chosen from the Writings of Sir James George Frazer. Revised and edited by the Author. Pp. xvi+437. (London: Macmillan and Co., Ltd., 1927.) 15*s.* net.

"ALL that I have attempted in the present volume is to crystallise, as it were, the results of my studies into an optic glass which may afford the reader some momentary glimpses of the long march of humanity on the upward road from savagery to civilisation." So with characteristic modesty, but not unfairly, Sir James Frazer defines the scope and object of this last published of his books. It is an anthology which is virtually a statement of his position as a philosopher and a student of certain phases of human evolution. It brings together within the compass of one volume the more general conclusions of his published works. Except for the slightest of revision, the change of a word here and there to fit the new setting, the original wording of the passages chosen remains unchanged. For their selection and the order in which they appear, M. Pierre Sayn has been responsible; but the compilation has been made under the direction of the author.

The contents have been classified into sections. The first deals with "The Study of Man," in which are embodied the author's pronouncements upon certain of the more general methodological problems of anthropological science. Part II. deals with "Man in Society"; Part III. with "Man and the Supernatural"; and the final section with "Man and Immortality." Few of the passages exceed three pages in length and each is complete in itself, except that in so far as it is the conclusion of an argument, or an inference from previously recited data, the evidence upon which it is based has been omitted. In a book of this character that is not to be imputed as a fault, but is merely an essential part of the general scheme. The reference to the source from which each extract is taken guards against any misunderstanding on the head of dogmatism or the nature of the premisses upon which the argument depends.

In publishing abridged editions of "The Golden Bough" and "The Folklore of the Old Testament," Sir James Frazer conferred a great boon upon his public. For while the complete works will always be indispensable to students and for use in reference, the abridged form, contrary to the general rule, conveys the greater pleasure to his readers. It contains proportionately more of Sir James Frazer. But this can be said even more emphatically of the present book. Here we have the author entirely to himself in extracts from the whole of his works and not from two only, and unadulterated with quotation from the work of others. For we venture to differ from the author when he expressed the opinion that if his work survives to posterity, it will be on account of his record of quaint and savage customs which will then have long passed away. If for no other reason, it will endure as a monument of pure, lucid, and flexible English of never-failing charm.

There is, however, little danger that Sir James Frazer's work will survive only as a storehouse of anthropological facts, or as a model of scholarly and graceful writing. In the course of his extensive studies there is scarcely a problem in social anthropology, in the comparative study of religion, in fact, in the whole range of the evolution of the mind of man, upon which he has not touched, and, it must be admitted, whether we agree with his conclusions or not, which he has not illuminated. In fact, so comprehensive in its scope is the present volume, and so versatile is the mind of which it is the offspring, that it might well serve as a guide, if not as a text-book, for the student in the mazes of what is admittedly one of the most difficult subjects of study.

It is not unfair to say that Sir James Frazer has sometimes been represented by those who do not accept his position, as if he wrote in the spirit of a partisan incapable of appreciating the force of an argument contrary to his own views. Nothing could be further from the truth, yet this imputation may have been made perhaps for the very reason of his essential fairness, and his aversion from anything that is controversial in tone. Yet if readers will turn to those passages in this volume which deal with evolution and diffusion in culture, we venture to think they will find no clearer grasp of the problem, no more concise and well-balanced discussion of it, and no more logical conclusion free from prejudice in the whole of anthropological literature. It would be possible to cite instance after instance in the passages included here in which highly controversial problems are discussed in the same philosophical spirit, even if the conclusions are not always equally convincing.

It may be inferred from what has been said that this is a book that is of interest only to the anthropologist and the student. On the contrary, and perhaps even more than the works from which its material is drawn, it is essentially a book for the intelligent public, especially at the present moment. Questions relating to totemism, marriage, and the organisation of early forms of society may be passed over as more highly technical in interest. When Sir James Frazer deals with the form and history of religious beliefs, and the survival of primitive modes of thought in civilised communities, he is handling topics of vital interest to modern society. A study of his penetrating and logical examination of the development of man's attitude of mind in the past is a valuable preparation for clarity of thought in dealing with the problems of to-day.

This is not the occasion to enter upon a detailed and critical study of Frazer's work, although the issue of this compendious volume might seem a challenge. From the present writer, after reading and re-reading, it calls for nothing but respectful homage to a great work and a great thinker.

The Polychæta.

(1) *British Museum (Natural History). British Antarctic (Terra Nova) Expedition, 1910.* Natural History Report. Zoology, Vol. 7, No. 2: *Polychæta.* By Prof. William B. Benham. Pp. 47-182 + 6 plates. (London: British Museum (Natural History), 1927.) 12*s.* 6*d.*

(2) *Faune de France. 16 : Polychètes sédentaires ; addenda aux errantes, Archiannélides, Myzostomaires.* Par Prof. Pierre Fauvel. (Fédération française des Sociétés de Sciences naturelles : Office central de Faunistique.) Pp. 494. (Paris : Paul Lechevalier, 1927.) 75 francs.

(1) PROF. BENHAM'S memoir of the Polychæta of the Antarctic (*Terra Nova*) Expedition, and on those of New Zealand, is important not only for the number of species (88), but also from the novelty of many and the able treatment by the experienced author. As shown in a former paper, the most numerous species are Terebellids, closely followed by the Syllids, then the Phyllodocids, Aphroditids, Sabellids, and Ampharetids. Of the total number of species, 33 were obtained off the northern coast of the North Island of New Zealand during the work of the *Terra Nova* there.

Amongst the Antarctic Syllids, the author was fortunate in procuring the epigamous condition of the large band-like *Trypanosyllis gigantea*, and he combats Fauvel's view that this species is either *T. tæniæformis*, Haswell, or the *T. richardi* of Gravier. He adds the genus Eurysyllis to the fauna, with the 'polybostrichous' condition of *Autolytus maclearanus*. Of the Aphroditids, *Laetmonice producta*, Grube, a widely distributed species, is the only one met with; whilst amongst the Polynoids a new form, *Lepidasthenia antipathicola*, merits special mention, since it inhabits a latticed tunnel formed by the serrated branches of an antipatharian (*Parantipathes tenuispina*), the living tissues of which accommodate themselves to the tubular home of the annelid. The Polynoids and Phyllodocids are well represented; whilst the Lopadorhynchids embrace *Pelagobia viguieri* of Gravier, and *Maupasia cæca*, Viguier. The Nereids include the curious *Cheilonereis peristomialis* of the author, with the hood or collar. The Onuphids have a new sub-family, Aotearinæ, a group with the general facies of *Lumbriconereis*; but whilst the upper jaw-plates are of unequal number as in Eunice, the anterior series are in line as in Lumbriconereis. The Terebellids include the fine *Pista mirabilis* of the *Challenger* Expedition, which stretches from Valparaiso to Graham and Adelie Lands, Gravier's *Lanicides vayssierei*, *Lanice flabellum*, *Amphitrite kerguelensis* and various other members of the group. The author discusses at length his reasons for uniting the *Leæna wandelensis* of Gravier and the *L. arenilega* of Ehlers described two years later. The striking *Hauchiella tribullata* has a distribution ranging from European waters to New Zealand.

The author founds a new genus, Melinnoides, for a species—*M. nelsoni*—from McMurdo Sound. It has only two pairs of gills in a transverse row, and there are neither dorsal crest nor post-branchial hooks. He differs from Augener as regards the relationships of *Travisia olens*, Ehlers, and *T. kerguelensis*, McIntosh, which the first-mentioned author united. Prof. Benham finds, after a careful survey of many examples, that these forms essentially differ.

The addition of a species of Euchone (*E. pallida*, Ehlers) to Antarctic waters is noteworthy, since the genus is characteristically Arctic and northern. The finding of the tubes of the ubiquitous *Sepula vermicularis* L., broken into lengths of 1 in. to 2 in. 30 ft. above sea-level on the Drygalski glacier at Evans Cove, Victoria Land, is an interesting observation. Two new species of Vermilia, a new Zopyrus, and a new genus, Chitinopomoides, are described, the species *C. wilsoni* having an operculum approaching that of Mercierella and allied forms, and probably presenting similar blood-spaces on section. The author rightly groups the various varieties of Filograna under the single species, *F. implexa* of Berkeley—from *Protula Dysteri*, Huxley, to the Salmacinas of subsequent authors; and it may interest some to know that Prof. Huxley in July 1865 spontaneously admitted to the writer that his species was only *F. implexa*, a form which stretches over a wide area. The author met with an interesting case of a tube of this species budding at the tip into two tubes which he figures. Species of Protula and Apomatus from New Zealand complete the series.

Besides the intrinsic value of the memoir as an able contribution to the polychæts—to which it adds three new genera and sixteen new species—it affords another example of the extensive distribution of many of the group almost from pole to pole and from the Atlantic to the Pacific Ocean. It is illustrated by six quarto plates of carefully drawn figures by the author, which bring out striking features like the structure of the bristles and hooks, as well as such unique formations as the spiral ridges of sand-grains bristling with sponge-spicules on the tubes of *Leæna wandelensis*.

(2) Prof. Pierre Fauvel, whose wide experience of the group ranges over both European and distant waters, continues his task in this volume with the "Polychètes Sédentaires" of the shores of France, though under this head are included those of the Mediterranean, North Africa, and one or two other regions. Unlike Prof. Benham, who follows his own classification, he for the most part stands by that of Malmgren.

Each species is defined and its important parts figured with great care by the author or others, so that his successors will reap the benefit of his unwearied labours. The method of illustration adopted (apparently lithographic ink) is prone to make the long bristles somewhat uneven, but on the whole they are helpful outlines. Occasionally inferior figures, as in Magelona, have been selected instead of more accurate representations, but generally the author has given his own figures or those of competent workers. He has a table of the families and of the genera and species in each case, and as there are, for example, in Polydora no less than a dozen species, the author's task has been no light one.

Under the family of the Cirratulidæ are the curious *Ctenodrilus serratus* of O. Schmidt, so common in aquaria, Zeppelinia, which reproduces by scissiparity, and Raphidrilus. Prof. Ashworth's Asclerochilus is mentioned under the Scalibregmidæ, and Ardwisson's work under the Maldanidæ. Under the Arenicolidæ he gives *Arenicola Claparedii*, an Atlantic and Pacific form, notwithstanding Prof. Ashworth's proof in the British Museum Catalogue that it is *A. pusilla*, De Quatref. Again, he adheres to Claparède's species *A. Grubei*, which, after careful study, Prof. Ashworth and the writer consider to be *A. branchialis*, Aud. and Ed. The Sabellariidæ are followed by the Sternaspididæ, a group formerly placed under the Gephyrea, and still open to controversy as to its place amongst the polychæts. Under the great family of the Terebellidæ, Prof. Fauvel follows the reviewer in considering that the proposal of Hessle to classify them chiefly on their nephridia is more or less impracticable, and he prefers the arrangement of Malmgren—giving six sub-families. Notwithstanding his objections, *Amphitrite gigantea*, Mont., stands, as also does the union of the two forms *Nicolea venustula* and *N. zostericola*, as well as the distinctions between *Chone Fauveli*, *C. Duneri*, and *C. Rayi* in the Ray Society's monograph.

The author gives a useful classification of the Serpulidæ, under which *Serpula concharum* Langerhans, and various species of Hydroides seem to be in want of further investigation. Moreover, he adheres to the old view in regard to Filograna and Salmacina, even citing Prof. Huxley's *S. Dysteri* as a species. An appendix contains a few additions to the errant group, besides the Archiannelids and the Myzostomes.

This volume forms an important contribution, by an able investigator of the polychæts, to the fauna of the shores of France, and will be welcomed elsewhere by all students of the subject. W. C. M.

Modern Organic Chemistry.

Lehrbuch der organischen Chemie. Von Prof. Dr. Paul Karrer. Pp. xxi + 884. (Leipzig: Georg Thieme, 1928.) 34 gold marks.

THIS is a comprehensive text-book planned on a somewhat rigid classificatory basis. The historical introduction is limited to three pages, and except for an equally brief note on the evolution of organic chemical formulæ, most of the remaining historical allusions are confined to a bare mention, usually undated, of names of leading investigators in the various fields which come successively under review. The treatment of aliphatic compounds (including methods of molecular diagnosis) occupies the first 361 pages; of carbocyclic compounds (including pyrones, indigotin derivatives, and certain other heterocyclic types), 342 pages; and of heterocyclic compounds, 137 pages. In a series of tables, filling the final 17 pages, a good deal of information of statistical and scientific interest is summarised. Useful bibliographies are appended as footnotes to leading sections of the book.

The general plan has necessarily entailed a dispersion of matter which in British text-books is usually assembled under special headings. Thus, the student of stereochemistry, tautomeric change, or valency, will need to collect his information from divers sections of the book, which may often suggest themselves only to the sophisticated reader. His task will be rendered still more difficult by the nature of the index, which is essentially an alphabetical list of names of compounds; the absence of an index of authors is an additional handicap.

These are inconveniencies; but the work may be commended to teachers and advanced students of organic chemistry as affording an excellent and up-to-date German text, dealing with the subject from the viewpoint of molecular constitution. Questions of structure, synthesis, and interrelationships of structural types are handled in a clear and workmanlike manner, and due regard has been paid to the current biochemical trend of organic chemistry. On the whole, recent developments have been well covered, but in a book of this size one is surprised not to find adequate references to modern ideas and investigations on such important subjects as the genesis and transmission of orienting effects in the benzene ring, applications of electronics to organic chemistry, tautomerism, glutaconic acids, the constitution of urea, the menthone chemistry, carene, hydroxymethylenecamphor, squalene, insulin, the production of acetic acid from cellulose by anaerobic fermentation, lead tetraethyl, dichlorodiethyl sulphide and phenarsazine. However, a text-book of organic chemistry offers a broad target to the arrows of detailed criticism, and it is unnecessary to empty the quiver. Suffice it to say, in conclusion, that both author and publisher are to be congratulated on a useful and well-printed addition to the literature of this flourishing branch of science.

J. R.

Our Bookshelf.

The Flora of Oxfordshire: a Topographical and Historical Account of the Flowering Plants and Ferns found in the County; with Biographical Notices of the Botanists who have contributed to Oxfordshire Botany during the last Four Centuries. By George Claridge Druce. Second edition (rewritten). Pp. cxxxi + 538. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 30*s*. net.

WE congratulate Dr. Druce on this, the latest addition to the series of county floras to the preparation of which he has devoted so much time, study, and investigation in the intervals of a busy life, for more than forty years.

Compared with the original edition of 1886, the book has much increased in size. Both the form and number of pages are larger. The 'botanologia,' or biographical notices of botanists who have contributed to our knowledge of the flora, has more than doubled in extent, while the flora proper, now limited to the seed plants, ferns, and Characeæ, occupies 533 pages as compared with 366 in the 1886 edition. The appendix on mosses and Hepaticæ, supplied by Henry Boswell in 1886, and the lists of fungi and lichens, have been omitted.

The extensive introduction deals briefly with the topography, soils, elevation, and geology of the county, followed by a more detailed account of the characteristics of the botanical districts, of which seven are recognised based on river drainage (by some oversight, a map included in the former edition has been omitted), and a short section on meteorology (by F. A. Bellamy); the second half of the introduction is taken up mainly by the botanologia. The plan of the systematic portion is similar to that of other county floras by the same author,—references are given to the "Flora of Berkshire" for additional synonymy and bibliography.

From the summary we learn that the flora comprises 1061 species, including denizens and colonists, as compared with 1091 in Berkshire and 1027 in Buckinghamshire. Adventives (450), hybrids (79), and varieties and forms (781) bring the total up to 2371, and there are also eight species now regarded as extinct. Two species, *Orchis Simia* and *Stachys germanica*, appear now to be confined to the county. More than thirty species are mentioned as remarkable absences for which special search should be made.

A. B. R.

The Bread of our Forefathers: an Inquiry in Economic History. By Sir William Ashley. Pp. xii + 206 + 4 plates. (Oxford: Clarendon Press; London: Oxford University Press, 1928.) 12*s*. 6*d*. net.

ALTHOUGH at first sight of purely antiquarian interest, the question of the kinds of grain our forefathers used for breadmaking proves on examination, to be "intimately bound up with some of the most fundamental problems of our economic and social history." By the end of the eighteenth century, wheat was firmly established as the universal bread grain in England, at a time when the commoners of other northern races still ate rye.

The main transition to wheat took place during the eighteenth century, and though in earlier times, wheat, rye, barley, and oats were all used as bread corn to some extent, the chief competition always lay between the two former. It is clear from the old records, both civil and ecclesiastical, that wheat and rye bread early became the symbols of social position, rye being the staple food of the commoners, wheat that of the aristocracy or overlords. In some cases bread of different grades was used as currency in payment for services rendered, wheaten bread being given only in very special circumstances.

In England the change in the balance from rye to wheat was much influenced by the interest in the land taken by the lords of the manors. This led to such improvements in agricultural practices as marling and liming, which needed capital expenditure, and steadily improved the land and rendered it more fit for wheat growing. It took centuries, however, for wheat to become the ordinary food of the whole nation. In northern continental countries where the land remained largely in the hands of peasant proprietors, rye growing held its own, and even at the present day forms a staple part of the food of the community.

The rivalry between wheat and rye has always been entirely a question of supply rather than one of cost, because in the early days the price of bread did not affect the bulk of the nation to the degree it now does, as most bread was baked at home. With short supplies, wheat early became a mark of social distinction, and with increasing ambition among the populace, and increasing supplies, it gradually attained the position it now holds as the staple bread corn of Great Britain.

The Soils of Cuba. By H. H. Bennett and R. V. Allison. Pp. 409. (Washington, D.C.: Tropical Plant Research Foundation, 1928.) 6.25 dollars.

A comprehensive survey of the soils of Cuba has been undertaken by H. H. Bennett and R. V. Allison, and the results published in book form. Cuba is still the greatest sugar-producing country of the world, and every effort is necessary to maintain this supremacy. The point of the survey was to investigate the possibility of lowering the cost of production of the raw material in the fields by the use of more modern agricultural methods and the better adaptation of the varieties to the soils on which they are grown.

A general description is given of the various soil series found throughout the island, with complete chemical analyses and physical measurements of some of the more representative types, followed by a detailed survey of middle, eastern, and western Cuba and the Isle of Pines. Some areas are handicapped by the presence of large amounts of soluble salt in the soil, which is so detrimental to sugar cane that the mortality and retarded growth is in some cases severe enough to cause the fields to be completely abandoned. Furthermore, the cane juices obtained from salty areas are of inferior quality for milling purposes. The opinion is expressed that better results would accrue from more intensive cultivation of sugar cane on smaller areas, the poorer and less suitable soils being put down to grass or timber.

The influence of soil is of paramount importance in the Cuba cane fields, and emphasis is laid on the importance of cultivators understanding their soils and learning how to treat them to get the best results, as the behaviour of the soil and subsoil has definite peculiarities in many cases. A large-scale annotated soil map is appended, with brief descriptions of the quality of the soil, the best methods of cultivation and treatment, together with the most suitable crops. W. E. B.

Die europäischen Schlangen: Kupferdrucktafeln nach Photographien der lebenden Tiere. Von Dr. Fritz Steinheil. Siebentes Heft. Herausgegeben von Prof. Lorenz Müller. Tafel 31: *Vipera berus berus* (L.); Tafel 32: *Vipera berus berus* (L.); Tafel 33: *Vipera berus berus* (L.); Tafel 34: *Vipera ursinii ursinii* (Bonap.); Tafel 35: *Vipera ursinii macrops* (Mehely). Pp. 17 + 5 Tafeln. (Jena: Gustav Fischer, 1927.) 6 gold marks.

After an interval of more than twelve years, a further part of Dr. Steinheil's beautiful photographs of European snakes, with the appropriate letterpress, has been published. The issue of the work was interrupted, after the appearance of the sixth part, by the outbreak of the War, and favourable conditions for the continuance of publication did not present themselves until 1926. In the spring of that year, Dr. Steinheil resumed his work, but a return of an old malady necessitated an immediate operation, from which he died in April 1926. His friend, Prof. Lorenz Müller, has undertaken the completion of the work as an act of duty and esteem, and, in a foreword to the present part, pays an eloquent tribute to the memory of Dr. Steinheil and to the value of his work. Dr. Steinheil left behind all the photographs necessary for the completion of his book, and Prof. Müller will write the descriptive text. The seventh part, which is now published, deals with *Vipera berus berus*, *Vipera ursinii ursinii*, and *Vipera ursinii macrops*, and is accompanied by five beautiful copper-plate reproductions of excellent photographs of these forms. This part maintains the very high standard of its pre-War predecessors and, now that publication has been resumed, we shall look for a speedy completion of this valuable work, which Prof. Müller has undertaken as a memorial to his friend.

Introduction to the Calculus. By Prof. William F. Osgood. Pp. xi + 449. (New York: The Macmillan Co., 1926.) 12*s.* net.

In this revision of the author's "First Course," the sets of examples have been improved by the addition of more difficult examples. Even these should be well within the reach of most serious students. The tendency in England in the past has been to include too many examples of the problem type in the introductory course. Nowadays it is recognised that this is a mistake. Nevertheless, it may be doubted whether this course contains enough to extend the abler readers of it. One reason why many teachers are slow to introduce modern text-books is that the older books, however unsatisfactory they may be in some respects, usually have the merit of containing excellent collections of problems for the better students. This is the more necessary in small schools, where it is not possible to grade the real mathematicians into sets by themselves.

In this volume the emphasis is on the applications of the subject, and there is much material which does not usually occur in an English text-book on the calculus. Whether this material is really required depends on what other text-books are being used concurrently, but the book would certainly be suitable for certain classes of British students, for example, those whose main subject is not mathematics, but who wish to acquire some knowledge of the ideas and applications of the subject.

A. R.

Manuel du tapissier décorateur. Par Prof. Lucien Coussirat. (Bibliothèque professionnelle.) Pp. 440. (Paris: J.-B. Baillière et fils, 1927.) 25 francs.

It is always a satisfaction to encounter a work giving evidence, not alone of the pleasure experienced in its preparation, but also of a thoroughness of knowledge and a completeness in execution, such as are too often absent. In writing about 'completeness' it is, of course, not suggested that the whole art and science of decorative upholstery can be embodied between the covers of a book (16mo) of 440 pages with the encroachment caused by 239 illustrations and diagrams. It is rather the completeness that takes a survey of all the *varia* that may be comprehended by the subject matter.

M. Coussirat might have done better to enter more into the class of upholstery that would suit the average purse of to-day; whereas, in fact, his attention is mainly devoted to 'period' furniture and furnishing; this is peculiarly noticeable in Chapter ix. A curious chronological *mélange* occurs early in the book (p. 19) concerning Catherine de Medici, upon which there is no need to enlarge. The chapter on colour is worthy of attention by the student, though there is some confusion created between spectrum colours and pigments. The chapters dealing specifically with upholstering and the cutting-out of fabrics are the most valuable in an interesting work.

P. L. M.

The Story of the Roads. By Cyril Hughes Hartmann. With an Introduction by Lieut.-Col. Alfred Hacking. Pp. xx + 194 + 12 plates. (London: George Routledge and Sons, Ltd., 1927.) 7*s.* 6*d.* net.

Recently there appeared in these columns an article upon road formation, the *raison d'être* being two books, dealing in one case with the scientific aspect of roads, and in the other with the management and methods of concrete highway construction. A passing reference to Mr. Hartmann's "Story of the Roads" will form a fitting corollary. The lively style of diction, in which he displays the history of the island roads of Great Britain from Roman days onwards to the days of gyratory traffic, together with the quaint illustrations, provide a couple of hundred pages of very attractive material. Regarding highway bridges, one might deplore the loss of the original Blackfriars bridge in stone, when viewing the present iron structure.

Apparently the author differs from Mr. Macadam, by lauding the Scotch roads of the eighteenth century to the detriment of those in England. He properly stresses the fact that "the roads must be made to suit the traffic, and not the traffic to suit the roads." It is, of course, a case of pendulum-swinging respecting the former hegemony of the roads being restored after a period of eclipse by the railways. Has the final swing taken place?

P. L. M.

Romance of the Sun. By Mary Proctor. Pp. xii + 266 + 13 plates. (New York and London: Harper and Bros., 1927.) 7*s.* 6*d.* net.

The contents of Miss Proctor's book are not quite so comprehensive as the title would suggest. The first few chapters include an account of the transit of Venus expeditions and Gill's observations of Mars made for the purpose of measuring the sun's distance. Chapters v.-viii. touch upon the sun itself, but almost exclusively on those phenomena—prominences and corona—which are seen at total eclipses of the sun. Chapter ix. gives the author's personal experiences at the eclipses of 1896, 1900, and 1905, whilst the final chapter describes the recent eclipse of June 29, 1927.

Miss Proctor quotes largely from her authorities; indeed, one-quarter of the text is made up of excerpts. Whether so excessive a use of quoted passages is wise in a book of this description is very questionable. But however that may be, an entertaining account is provided of astronomers and their friends in quest of observations which are only possible at rare intervals.

A Manual of Field Astronomy. By Prof. Andrew H. Holt. Second edition. Pp. xiv + 126. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1927.) 10*s.* net.

Prof. Holt's little book is intended for the instruction of those doing field work with theodolites. It contains a theoretical explanation of the heavenly motions sufficiently full to enable the student to follow the formulæ with intelligence. The practical directions are clear and explicit. There is a useful table of formulæ for solving spherical triangles, and some explanation of the solar attachments, which when used in conjunction with a theodolite enable the meridian to be found mechanically. There are tables at the end for the conversion of sidereal to mean time, refraction, azimuth of Polaris at elongation, etc. These tables indicate that the order of accuracy aimed at is the nearest second of arc. An error has been noticed on p. 82. In the equation just above (10) for cos z read cot z.

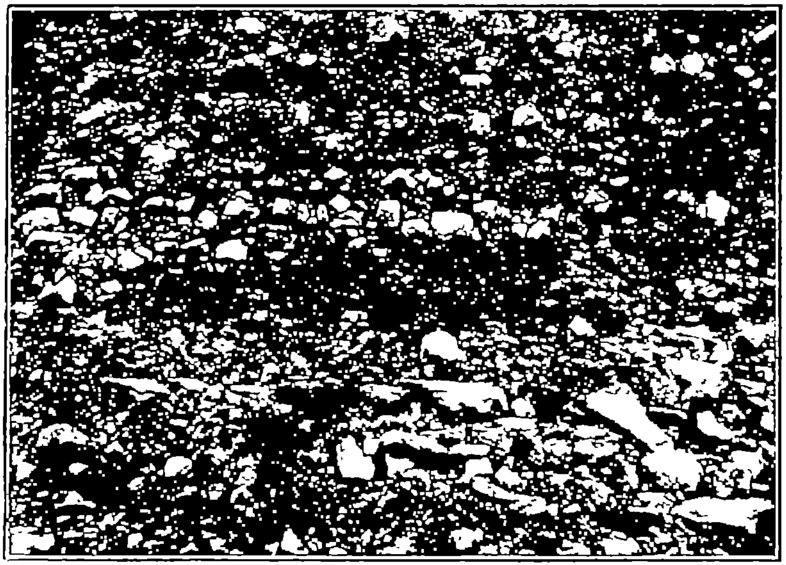
Geological Features of the Sites of the Sligo Implements.

AT intervals from August 1927 to March 1928 there appeared in NATURE a series of letters relating to the discovery of chipped fragments of limestone by Mr. J. P. T. Burchell in the neighbourhood of Sligo. These were claimed by him to be evidence of Palæolithic man in Ireland. Apart from the arguable question of the human character of the flaking of the limestone, Mr. Burchell's statements regarding the geology were disputed by Prof. R. A. S. Macalister, Prof. J. K. Charlesworth, Dr. Lloyd Praeger, and Mr. A. W. Stelfox.

We were therefore requested to assess the geological evidence furnished by the sites, and for this purpose visited the Sligo district at the end of March. We were much assisted in finding the exact sites by the photographs in Messrs. Burchell and Moir's book, "The Early Mousterian Implements of Sligo, Ireland." We have to report as follows :



Photo] [R J Welch

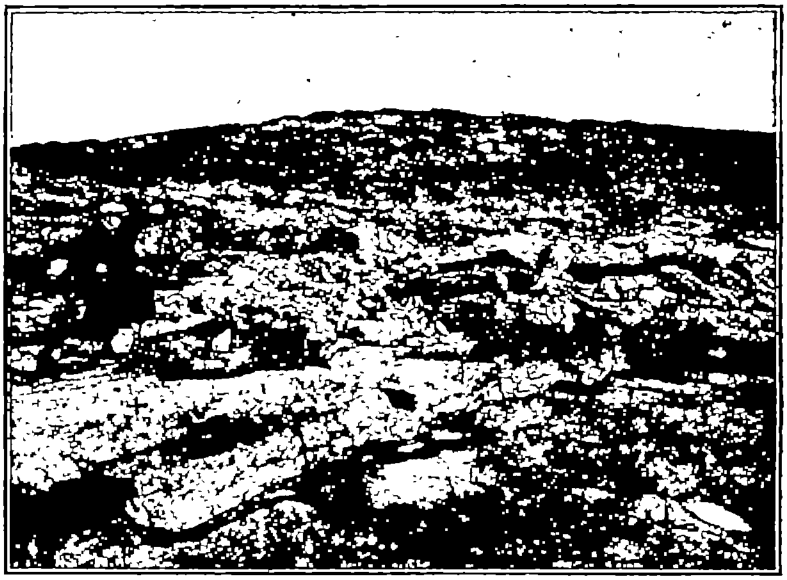
FIG. 1.—Boulder clay at Ballyconnell, showing angular fragments of limestone.

At Ballyconnell, about ten miles north-west of Sligo, is a small bay with two horns, at each of which boulder clay rests upon limestone. There is a place on each of these horns where the boulder clay reaches about the height recorded by Mr. Burchell and where it can be seen lying upon limestone. The 'implements' were obtained from an 'implementiferous layer' a few inches above the base of the section. The boulder clay of the two promontories contains an astonishing number of angular limestone fragments of all shapes and sizes, and near the base the limestone beds can be traced breaking down into angular pieces, similar to those incorporated in the boulder clay (Fig. 1). The edges of the limestone visible just beneath the boulder clay have been flaked and shattered. We understand that Mr. Burchell devoted some weeks to seeking the 'implements' in this section, and we understand also that he found two or more 'implements,' of which the human workmanship is not so enthusiastically and generally accepted as in the case of the Rosses Point finds. Among such myriads of angular limestone fragments, it would be surprising if in the course of some weeks, two or even more pieces simulating human workmanship could not be found. If the 'implements' are *beyond question* of human origin, there is certainly a case for the existence of man before the boulder clay of the region was formed. If, however, there is any doubt about the workmanship, the 'implements' from Ballyconnell are of no value as evidence of Palæolithic man in Ireland.

At Rosses Point, Mr. Burchell claims to have discovered a rock-shelter of high antiquity, the roof of which was formerly in place but was broken down, as he suggests, under the load of the advancing ice which deposited the boulder clay. At the most, the rock-shelf (the 'shelter') was not higher than a table, and at present there is very little overhang of the 'roof' (Fig. 2). One would expect that if a rock-shelter collapsed under these conditions, the collapsed fragments would consist of roof-blocks, whereas in point of fact we counted 26 (out of a total of 36) large slabs, having an aggregate area of about 180 square feet lying above H.W.M. of ordinary summer tides, which were unmistakably derived from the 'floor,' being of limestone of different character from that of the 'roof,' and easily distinguished from it. These 26 blocks have been lifted to a height of at least 5 ft. above the level of the floor by the waves during storms. Whatever, therefore, may be the position as regards the human origin of the flakes found beneath the loose blocks, it is improbable that a 'shelter' could have existed there in Palæolithic times. It might even not have been there a hundred years ago.

The supposed raised beach is neither more nor less than sand and shells which have been blown up and plastered against the face of the boulder clay cliff behind. That boulder clay also is crammed full of angular fragments of limestone, which seems to be a feature of the boulder clay of the district. Mr. Burchell refers in one of his letters to the fact that he hurled blocks of rock about on the site "in the way in which some people imagine the sea to have done." It is easier to contrast than to compare the hurling of blocks by a human being and the action of the sea during winter storms on the Atlantic coasts. The fact that limestone blocks from the floor of the supposed shelter are now found in abundance above the level of that floor, and that one of them was, in fact, imbedded in the soil and grass well above H.W.M., proves conclusively that the storms on the very exposed coast near Sligo are capable of lifting and hurling at each other very large blocks of limestone.

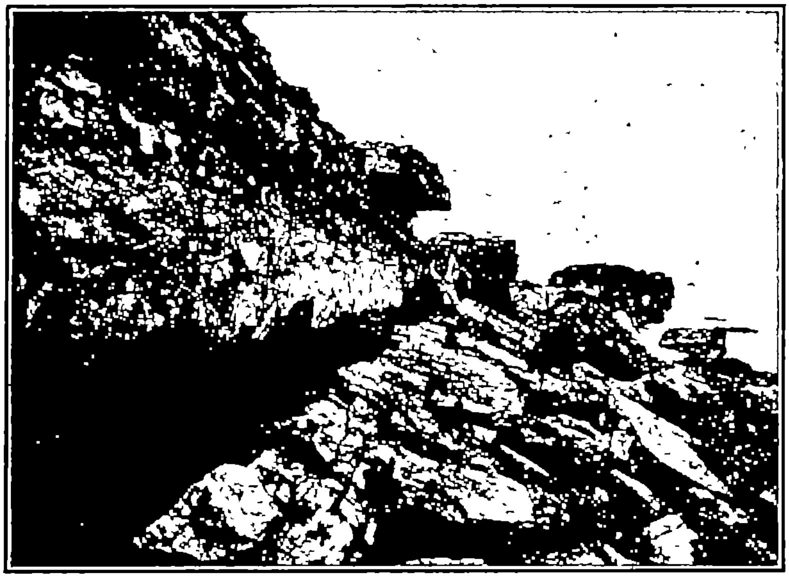
Some of the transported slabs we measured were 4 ft. in length by 3 ft. in width. This piling-up of blocks is a feature of the whole coast-line where low-dipping limestones run out to sea. It is particularly well seen on the western side of Coney Island, where there are rows of blocks, fringing the low coast-line, the source of which can be traced to two or three ledges below H.W.M. which have been stripped to provide the blocks piled up above H.W.M.



Photo] [R. J. Welch.

FIG. 2.—The so-called 'shelter' at Rosses Point. The black cross marks the 'floor' of limestone and the white crosses blocks of the same rock which have been thrown up by wave-action.

At the western end of the northern side of Coney Island, Mr. Burchell has described another rock-shelter or cave, out of which he supposes 'implements' to have been washed. This part of the coast again bears obvious traces of rapid erosion, due in that case partly to the exposed position, partly to the existence of well-bedded rocks with shaly limestone underlying more massive beds, and partly to the exceedingly well-marked joints, which run roughly parallel to that part of the coast. The cave which Mr. Burchell describes is interesting, because not long ago (? fifty years) a beacon was erected near the edge of the cliff (Fig. 3). The concrete base of the beacon has now been undermined by the collapse of the cliff over the cave, and the whole bed which formerly supported it has come away in one piece to a width of about 7 ft. and length of at least 30 ft. Since the beacon would certainly not be built on an unsupported overhanging concrete base, we may say that since it was erected the coast has receded not less than 7 ft. by erosion.



Photo] [R. J. Welch.

FIG. 3.—Coney Island, Sligo, showing supposed 'shelter,' collapsed limestone and, above the figure, the old masonry foundation of the beacon.

Such low sea-caves, about 3 to 4 ft. in height and due to the undercutting action of the sea, in no way resemble inland shelters and caves in limestone districts, which are usually solution-phenomena.

Finally, we may perhaps be permitted to say that we went to Sligo unprejudiced and prepared to find that there was a real case to be considered. We are convinced that there is absolutely no case whatever for supposing that the sites concerned are of any antiquity, with the exception of Ballyconnell, the 'implements' from which, as we have said, are not enthusiastically accepted. Not having seen any of the 'implements' which were exhibited in London, we offer no opinion on them.

Nova Pictoris.

THE article entitled "Nova Pictoris as a Double Star," in NATURE of April 7, attributes to me views which I do not hold. This is doubtless due to an incompletely cabled report of an interview which I gave to a reporter of the *Cape Times*, after the announcement from Johannesburg of the duplicity of the star, which was announced in the local press as a splitting of the star. In this interview I mentioned various theories which have been advanced as possible explanations of the outburst of a nova, including the theory of a grazing impact of two stars. I referred to the inherent improbability of the latter occurring, but added that as Nova Pictoris had behaved in such an exceptional manner from the time of its first discovery, it should not be left out of consideration in seeking an explanation of the star's behaviour, and that subsequent observation of the star would doubtless throw further light on the matter. I do not, however, adopt the view that the outburst was definitely due to such a collision.

There has also been some misunderstanding in regard to the separation of the stars. The figure of one-fifth of a second was merely a hypothetical figure which I adopted for the sake of argument to show that if the companion was in reality a background star, previously hidden by the nova but afterwards uncovered, the proper motion required to render it visible in a large telescope was not excessive. I adopted the figure of one-fifth of a second as the minimum separation at which the duplicity would be certainly detected with the 26½-in. refractor at Johannesburg, as at that time I was not aware of the separation observed at Johannesburg. It is unfortunate that it has been interpreted as a measure of the separation made at this observatory. With the 18-in. visual refractor here, the duplicity has not been conclusively seen, though suspected. The most prominent feature of the star is the very strong nebulous envelope.

The Johannesburg observers are satisfied that there are three components, and suspect a fourth, thus still further adding to the mystery of this extraordinary star. The star is surrounded by rings which are probably due to matter ejected with high velocity at the outburst. The diameter of these rings suggests that the star is relatively near, much nearer than indicated by the spectroscopic parallax derived by Mr. Davidovich, and that the parallax should be easily measurable by direct methods. The star has therefore been placed upon the parallax observing list of the Cape Observatory.

Mechanical Production of Short Flashes of Light.

In the study of phenomena which occur in a very short interval of time, it is usually necessary to have some kind of 'light shutter' that operates with extreme rapidity. An electro-optical shutter which lets through very short flashes of light has been previously described (Beams, *J.O.S.A. and R.S.I.*, 13, 597; 1926; Lawrence and Beams, *Proc. N.A.S.*, 13, 207; 1927), but in some experiments it is highly desirable that the shutter operate as many times per second as possible in order that enough intensity can be obtained to observe the phenomena accurately.

If one sends monochromatic light into an interferometer, say of the Michelson type, and projects approximately straight fringes upon a slit or slit system parallel to the fringes, and then changes the optical path in one arm of the interferometer with respect to the other, the fringes move perpendicular to their length. The slit then becomes a source of light flashes the duration of which depends upon the time required for a bright fringe to cross the slit. If, then, the optical path in one arm of the interferometer is changed rapidly enough with respect to the other, very short flashes of light can be produced. Thus, if light of 5000 A. is used, and the optical path changed at the rate of 1 cm./sec., then 2×10^4 flashes are produced per second, each flash lasting not longer than 5×10^{-5} sec.

There are, of course, several ways of changing the optical path with considerable rapidity, but the following device has been adopted because of its simplicity and the tremendous rate of change of optical path which it effects: two right angle prisms of identical material and dimensions are placed in one arm of the interferometer so that their hypotenuses are parallel, and so oriented that if the hypotenuses were in contact, the two prisms will form a rectangular block.

Light incident perpendicular to one of the sides is then undeviated as it passes through the prisms. If the two prisms are moved with respect to each other horizontally and parallel to the side upon which the light is incident, the optical path is changed and the fringes in the interferometer move. The rate of change in optical path depends upon the index of refraction of the glass, the angles of the prisms and the speed with which the prisms move, while the total difference in optical path at any time is limited only by the coherence length of the monochromatic light used.

In my preliminary experiments a single glass prism with a small vertical angle was mounted on a balanced steel arm, which was fastened to the shaft of an electric motor so that the prism moved approximately parallel to an identical fixed prism in the optical path. On the same shaft an opaque disc with a small slit in its edge revolved in front of a mercury arc source, so that light passed through the interferometer only while the optical path was being changed. A filter which permitted only the mercury green line to pass was used in front of the arc. The duration of each light flash was slightly less than 10^{-7} sec. These light flashes when sent back through the interferometer form two sets of fringe systems. These fringes are viewed by means of a mirror placed in front of the mercury arc in such a way as to avoid undesirable reflected light. One of these fringe systems is approximately stationary and serves to indicate when the apparatus is working properly. Although not used in this preliminary work, the instrument can be calibrated if desired in terms of the velocity of light by letting the light flashes pass over a measured distance before sending them back through the interferometer and observing the relative shift of this stationary fringe system. In fact, it is even possible to make this calibration with the slit removed.

One of the applications of this apparatus might be mentioned. If light flashes of the proper wave-length are focused on a bulb containing metallic vapour, and the resonance light from the bulb sent back through the interferometer, the resulting fringes will appear stationary, due to a sort of stroboscopic effect when the length of light flashes are constant, but will move or change their character when the flashes are shortened, depending upon the average time between excitation and emission for the vapour.

The present arrangement is not very satisfactory, because the two prisms twist slightly, and hence a very narrow slit in the opaque disc must be used, thereby sacrificing light intensity. However, a new apparatus is to be constructed in the near future that should eliminate these difficulties as well as give shorter light flashes. It should be easy to produce flashes of 10^{-8} sec. and possibly 10^{-9} sec. duration.

The writer desires to express his appreciation of the valuable suggestions made by Mr. Donald Cooksey with regard to the design of the mechanical parts of the apparatus.

The Band Spectrum of Mercury excited by a High Frequency Discharge.

A method of exciting spectra by a high frequency discharge has been described by Wood and Loomis (Nature, 120, 510; 1927), Clarke (Nature, 120, 727; 1927), and others. The method consists of sending a high frequency current through a wire coiled around the tube in which the discharge is excited. While experimenting with a low voltage Tesla coil in which the primary circuit power was supplied from a 110-volt buzzer, it was observed that when contact was made between one side of the secondary and a metal support on a diffusion pump, a brilliant green discharge was produced in the mercury circulating through the pump at a pressure of about 5 cm. The spectrum of this discharge showed a very intense emission of the green fluorescence band of mercury.

This observation suggested an experiment to study the conditions of excitation of the mercury bands. Accordingly, a quartz tube, 0·7 cm. in diameter and 15 cm. long, having a small bulb near each end, was evacuated and sealed off containing about 1 c.c. of mercury. A piece of wire was wrapped around one end to serve as a single external electrode, and the tube was supported by this wire in a vertical position. One side of the secondary of the Tesla coil was connected to this wire and the other earthed through the primary circuit.

When the mercury in the tube was heated to boiling by a Bunsen burner, the Tesla coil produced a bright discharge in the tube. The spectrum of this discharge showed the mercury arc lines and the mercury bands, the maxima of which come at λλ4850, 3300, 2540, and 2345. No trace of a band at 2650, observed by Houtermans (*Zeit. f. Phys.*, **41**, 140; 1927) and Rayleigh (*Proc. Roy. Soc. Lon.*, **114**, 620; 1927), was found. Light from the middle of the quartz tube was focused on the slit of the spectrograph. If the middle of the tube was heated by a blow torch, the spectrum showed that the 4850 band had disappeared, the 2345 band had been weakened, but the 3300 and 2540 bands were unchanged in intensity. As soon as the middle of the tube cooled to the same temperature as the upper part, the 4850 band appeared again, and the spectrum was the same as before heating. If the mercury is vigorously boiled, the 3300 band is weakened with respect to the 4850, 2540, and 2345 bands.

In order to find the effect of distillation of the mercury on these bands, the tube was suspended in a furnace so that stagnant vapour resulted, and the discharge studied at various pressures from that at room temperature to that at which the discharge ceased. The arc lines appeared at all pressures, and at the higher pressures there was a faint trace of the 2540 band, but there was no observable emission at any pressure of the other mercury bands.

This experiment shows that distilling vapour is necessary for the excitation of the mercury bands 4850, 3300, and 2345 in a high frequency discharge. It is well known that distilling is necessary in many cases for the excitation of the 4850 band in fluorescence. Wood (*Jour. Frank. Inst.*, **205**, 488; 1928) and Pringsheim and Terenin (*Zeit. f. Phys.*, **47**, 342; 1928) have explained this as due to the sweeping away of impurities by the vapour stream. The same explanation probably applies here. These impurities in stagnant vapour are supposed to destroy the excited molecules of mercury through collisions of the second kind before they have a chance to emit the mercury bands.

The destruction of *only* the 4850 band through local heating is hard to explain. The local heating prevented the formation of extra fresh vapour through condensation and evaporation at the point of observation, but there was still a stream of mercury vapour past this point. It may be that the excited molecules which emit the 4850 band have an energy which very nearly coincides with that which the impurities may absorb, and it is, therefore, more probable that collisions with impurities will be of the second kind. This may also account for the non-appearance of the 2650 band.

This experiment, and those of Houtermans and Rayleigh (*loc. cit.*), show that the 3300 and 4850 bands originate in different initial excited states. This experiment shows in addition that the initial excited state for the 4850 band is also different from that for the 2345 and 2540 bands. This disagrees with the association of the 2540 and 4850 bands made by Houtermans. The final states for the 2345 and 2540 bands must be the same, since both are obtained in absorption. The results of this experiment also indicate that the 3300, 2540, and 2345 bands are emitted from separate initial states.

Active Nitrogen.

I REGRET having to request valuable space in NATURE, but it seems necessary to answer a criticism by E. J. B. Willey in the issue of Mar. 10. Quoting a single sentence from one's publication is generally unsatisfactory unless the correct meaning is carried with it. To one who reads my article in the *Journal of the American Chemical Society* (**50**, 27; 1928), it is evident that the statement does not, as Dr. Willey suggests, stultify a good deal of the work under consideration. It is meant merely to indicate that, besides the reactions studied by Willey, there are actions initiated by active nitrogen which require more than two volts, of which he is aware. One need only direct attention to the vast amount of literature on the excitation of spectra requiring up to 10 volts.

Aside from strictly spectroscopic data, which are themselves sufficient evidence for my original statement, I may point out that iodine is ionised by active nitrogen (Constantinides, *Phys. Rev.*, **30**, 95; 1927); 9·4 volts are required for this reaction. $\mathrm{Cu\,Cl} \rightarrow \mathrm{Cu} + \mathrm{Cl}$ requires 3·3 volts. The Cu lines are also strongly excited (Mulliken, *Phys. Rev.*, **26**, 1-32; 1925), and should this occur simultaneously, the total energy requirement is more than 8 volts. Other energetic reactions occur in active nitrogen, but one hesitates to insist on the exact energy requirement since we are not sure of what is happening, that is, whether the nitrogen molecule or atom is effective. Admission of oxygen or water to active nitrogen gives nitric oxide spectra. Admission of carbon monoxide or carbon dioxide gives cyanogen and nitric oxide spectra. If a single atom does the work, as, for example, $\mathrm{CO} + \mathrm{N} = \mathrm{NO} + \mathrm{C}$, this requires about 8 volts. Although direct proof is lacking, it is not inconceivable that metastable nitrogen molecules in level *A* can actually dissociate oxygen (7·02 volts). The criterion for water formation by $\mathrm{H_2} + \mathrm{O} = \mathrm{H_2O}$ is considered ill-chosen, as it is problematical whether this reaction as given will take place (see "Photochemical Clustering," NATURE, May 19, p. 792). It is worthy of note that J. Kaplan has observed a green and red line in oxygen excited by active nitrogen (abstract in *Bull. Amer. Phys. Soc.*, April 7). In the case of hydrogen, it is well known that the molecule can possess electronic energy greatly in excess of that necessary for dissociation and can lose this energy in band spectrum emission. Dissociation also cannot be expected with carbon monoxide, as indeed Willey and others have found, since the energy required is larger than is available from the metastable nitrogen molecule in level *A*. (Heat of dissociation of carbon monoxide is 10·8 volts. Birge and Sponer, *Phys. Rev.*, **28**, 283; 1926.)

I regret the unfortunate wording which drew Dr. Willey's next criticism. I meant to convey that 2-volt nitrogen molecules do not issue only from the discharge, but that spectroscopic data make it appear very probable that they may also be created outside the discharge by collisions of the second kind. I am well aware of Willey's work with an uncondensed discharge, where certain chemical actions occur in the absence of the afterglow. In this connexion it would be especially interesting to see whether there is sufficient energy in active nitrogen from an uncondensed discharge to bring out the band spectrum in cuprous iodide and the arc spectrum of copper.

As to the experiments with active hydrogen and ordinary nitrogen, my results are not extraordinary or new. The experiments are simple and were perfectly and easily reproducible. My negative results are, moreover, supported by several other investigators, including Bonhoeffer, who employed the same method (for literature see *J. Amer. Chem. Soc.*, *loc. cit.*). It still remains, I believe, for Dr. Willey to explain the kind of active hydrogen with which he was dealing, for (1) at 10 mm. pressure and 150 cm. (corrected in private communication) from the discharge no atomic hydrogen can exist (Kaplan, *Phys. Rev.*, 30, 639; 1927); (2) electronically excited atoms or ionised species are out of the question; (3) there is no real evidence for the existence of H_3, in fact, there is much evidence against it (see Urey and Smallwood's exhaustive attempts to prepare it with negative results, *J. Amer. Chem. Soc.*, 50, 620; 1928; also Paneth and others, p. 29 of my paper).

The criticism is meaningless that since ammonia extinguishes the glow of active nitrogen (of which I am aware), that this constitutes a grave objection to my theory of ammonia formation—which by the way is not mine, since it has been expressed by Olsen (for reference see my paper, p. 33). My experimental procedure indicates that the pressures of nitrogen and hydrogen were low, down to 0·04 mm., and that a liquid air trap condensed out the ammonia immediately following the mixing chamber. It is certain that some of the ammonia formed, which would have otherwise reached the trap, was again decomposed. It is quite beyond the human eye to detect changes in the afterglow intensity at these low pressures, and it is rendered even more difficult due to stray light from the discharges. The results published in Table I. are only a few of the numerous runs made.

I feel that private communication in controversial matters, once experimental data have been presented, is a far more satisfactory means of discussion.

The Mechanism of Formation of the Latent Photographic Image.[1]

IN a communication to NATURE of Sept. 24, 1927 (vol. 120, p. 441), the preliminary results were described of experiments made in an attempt to correlate the mechanism of the latent image formation with that responsible for producing changes of conductivity on illumination. It was shown that the apparent absence of the photo-conductivity effect in the ultra-violet was due to two things: (1) the small penetration of that light, and (2) the use of thick layers of the silver halide. With thinner layers, of the order of 70μ, the ultra-violet (λ3650) effect in silver bromide was found to be about twice as great as that produced by the blue (λ4358), thus supporting the original prediction that in very thin layers of the order of 1·5μ the effect at λ3650 would rise to nearer ten times that at λ4358, which is the ratio of *photographic* effects in very thin layers of slow, pure silver bromide emulsions. It was further predicted that in very thin layers the 'hump' of maximum sensitivity at λ4600 in the photo-conductivity–wave-length curve would disappear. How completely these conclusions have now been verified can be seen from the accompanying graph (Fig. 1). The inference is that in very thin layers of silver bromide the three curves representing (1) the relative photo-conductivity effects, (2) the relative photographic effects, and (3) the relative light absorptions, each plotted against the wave-length for equal incident intensity, are closely the same, indicating that in all probability the primary stage of the photographic mechanism is intimately connected with that which produces conductivity changes on illumination.

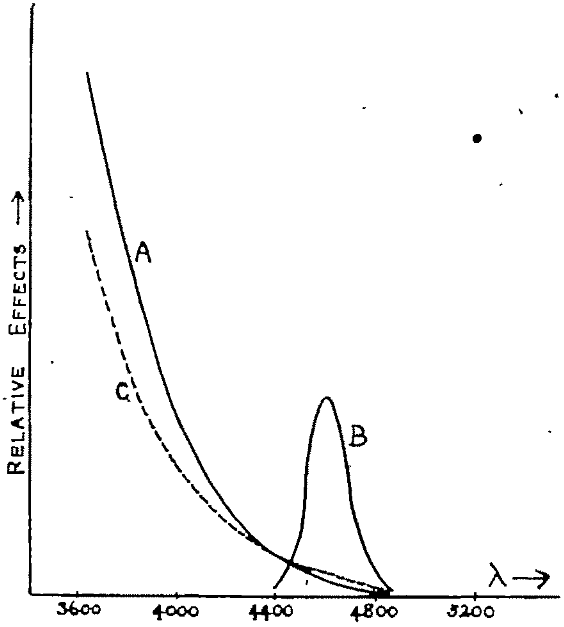

FIG. 1.—Curve *A* represents the relative photographic effects in 'single layer' emulsions of silver bromide. It also closely represents the absorption curve of this halide. The relative effects at λ3650 and λ4358 are as 10:1.
Curve *B* represents the relative photo-conductivity effects in layers of silver bromide of the order of 0·7 mm. and upwards. As the thickness is decreased, this curve gradually changes and approaches the form of Curve *A*. The closest approach yet obtained experimentally is given in Curve *C*, where the ratio of effects at λ3650 and λ4358 has risen to 7:1. The thickness of layer in this case was roughly of the order of 20μ.

It is hoped that these results will be presented in detail and discussed at the forthcoming International Congress of Photography to be held in London on July 9-14.

Forestry and Agriculture in Great Britain.

ALL forest economists will agree with the writer of the leading article in NATURE of May 5 that national poverty greatly increases the difficulties of a scheme of State afforestation, and that periods when money can be borrowed cheaply are most suitable for afforestation development. Only those, however, who take a superficial view of our national forest problem are likely to be greatly influenced by this consideration.

For many decades those who were alive to the facts of the case have advocated a policy of national afforestation, and various Commissions have recommended in favour of it. It took a great war and the imminent danger of an alarming timber shortage, when we were cut off from foreign supplies, to rouse the public to action. The Forestry Commission was constituted immediately after the War, and now, at the end of its first ten-year period, there is a danger that national lassitude will allow the Commission to languish from lack of adequate funds.

---

[1] Communication No. 67 from the British Photographic Research Association Laboratories.

Statistics of so many million trees planted on so many thousand acres are apt to be unconvincing, and we are liable to forget what lies behind these figures—an organised staff and a trained personnel which cannot be easily recruited and must not be lightly disbanded. Without continuity of administration, forests cannot be effectively managed and no efficient forest service can be built up, so that a gradual and systematic development is likely, in the long run, to be far more economic than sudden growths stimulated by war panic, unemployment, or cheap money, alternating with periods of decay due to apparent national security or financial stringency.

The benefits which may be derived from national afforestation are not confined to the timber, which, as the writer of the leading article says, can only be reaped after many years. Forestry helps to maintain the rural population, and when co-ordinated with the formation of small holdings, as in many of the Forestry Commission schemes, it stimulates agricultural and horticultural output. The agricultural depression is throwing a great deal of land out of cultivation, and it is very important that forestry should step in where possible and utilise the land and labour thus rendered unproductive. The present cheapness of land is also a direct incentive towards immediate afforestation.

W. E. Hiley.
(Editor, *Quarterly Journal of Forestry*.)

Imperial Forestry Institute,
University of Oxford,
May 9.

Mr. Hiley misses the point of the article on "Forestry and Agriculture in Great Britain." No suggestion was put forward that the afforestation work now being undertaken should be discontinued. The view was expressed, however, that the Government should perhaps consider whether some of the heavy overhead charges which have little bearing on the actual planting of trees, that is, the afforestation work proper, could not be curtailed. The plea that forestry should step in and plant up land, which, owing to agricultural depression is being thrown out of cultivation, is surely unsound. The first axiom of scientific forestry is that no land which can be made to produce food should come under the ægis of the forester. The money Mr. Hiley would devote to afforesting such land would be more justifiably employed in assisting the agriculturist to bring it once more under crops or stock.

The Writer of the Article.

Salt Crystals as Nuclei of Sea Fog Particles.

I have received from Dr. J. S. Owens a note of observations of a fog drifting from westward which he experienced recently on the Bay of Biscay. I cannot recall any observations exactly similar, so I append a copy of the note. It will interest readers of Nature, and at the same time revive an old question as to the real meaning of an observation of the wet bulb in a sea fog, of which there are many thousands on record.

Napier Shaw.

May 17.

"On Sunday, April 29, 1928 (R.M.S.P. *Demerara*), we were a little south of Ushant, about 49 degrees north and 6 degrees west, when after a bright sunny morning a fog came on about 12·30 p.m. and remained till about 7 p.m. The sea was very smooth, no white caps or spray. A light breeze from west. The fog could be seen blowing in wisps across the ship. My cabin being on the west, the breeze was blowing into the port, and I placed a well-polished tumbler in the port hole so that fog particles blown in might hit it and stick. After about an hour visible spots were on the tumbler, and at about 5·30 p.m. the side facing the west was well covered with minute drops obviously liquid, when magnified. I removed the tumbler and filled it with hot water, when all drops disappeared, and in their place were whitish spots, such as one would expect if the droplets contained a soluble salt. On emptying the glass and allowing it to cool again, after about 10 minutes the whitish spots became converted into drops of liquid, evidently the soluble salt deliquescing. It seems, therefore, evident that the fog particles were formed round salt crystals, and that for such a fog to form the relative humidity need not rise much above 75 per cent, assuming, as is fairly certain, the salt present was sea salt, which deliquesces at 74 per cent or 75 per cent relative humidity.

J. S. Owens."

Correlation.

For the determination of a linear function of X approximating to Y for a range of corresponding values (X, Y), a graphic method is desirable.

If the plotted values are divided into two classes by the median of X, in each class, the same number of points should lie on each side of the required line, which is thus found by inspection.

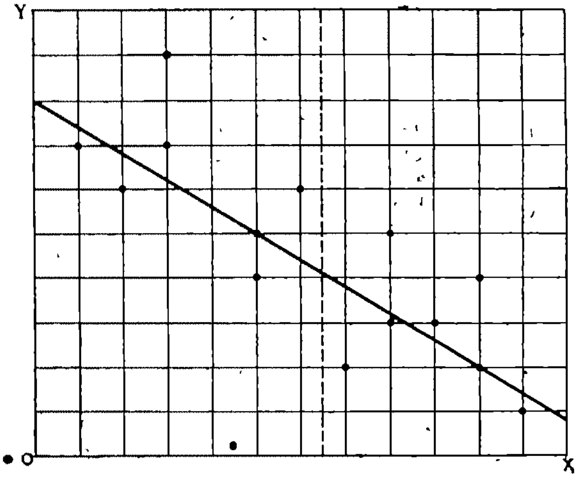

Fig. 1.

The method is much more expeditious than that of least squares. It appears, moreover, to be free from undue bias by outlying values.

For the values plotted in Fig. 1, the straight line is $Y = (40 - 3X)/5$, with a mean deviation of 1·00. The method of least squares gives $Y = (1940 - 137X)/236$, with a mean deviation of 1·05.

The Centenary of the Institution of Civil Engineers.

By Engr.-Capt. Edgar C. Smith, O.B.E., R.N.

FOUNDED through the action of six young engineers, the first formal meeting together of whom took place at the Kendal Coffee House in Fleet Street on Jan. 2, 1818, the Institution of Civil Engineers on June 3-7 is celebrating the centenary of its incorporation by Royal Charter. It was in January 1820 that Telford was asked to become the first president of the new society, and it was largely through him its charter was obtained eight years later. The celebrations are to commence with a memorial service in Westminster Abbey at 3 P.M. on Sunday, June 3; on Monday, June 4, the president, Mr. E. F. C. Trench, and the council will receive the delegates, and Sir Alfred Ewing will deliver the thirty-fourth James Forrest Lecture on "A Century of Inventions"; during the three succeeding days there will be a conversazione, a banquet, a conference at which some thirty different problems in engineering will be discussed, and a series of visits to important engineering works and undertakings.

In the petition of a hundred years ago to the Attorney-General for the grant of a charter, it was laid down that "Civil Engineering is the art of directing the great sources of power in Nature for the use and convenience of man," an all-embracing phrase which covers almost all the manifold activities of the engineer, and it is not without interest to find that practically all the subjects to be dealt with at the conference—docks, harbours, shipbuilding, railways, fuels, gas, boilers, domestic lighting and heating, road traffic, tidal power, mining, water supply, and sewage—were all matters of vital interest to the engineer a hundred years ago, while even at the time of the incorporation of the Institution, the internal combustion engine was a subject of practical debate, and in the laboratory of Faraday was being laid the foundation of our electric power and lighting.

The birth of the Institution and its incorporation by charter are but two of many landmarks in the material progress of Great Britain. It was not the first society of its kind, neither did it mark the beginning of any new branch of engineering. Docks, harbours, bridges, viaducts, and aqueducts had been constructed for centuries; France many years before had founded a School and Corps of Civil Engineers; while in Great Britain we see the rise of the Smeatonian Society and the short-lived Society for the Improvement of Naval Architecture. These, however, were but the forerunners of the great modern engineering institutions of Great Britain which really had their foundations in the vast extension of the work of the engineer due to the widespread application of mechanical invention to manufacture and to transport during the eighteenth and the early part of the nineteenth century.

When the Institution was incorporated, Brindley, Smeaton, Arkwright, and Watt had long since passed away, but the movements they inaugurated gained in volume day by day. No one had added more to the roads of McAdam and the canals of Brindley than Telford himself, while as a bridge-builder he will always be remembered for that most graceful bridge which spans the Menai Straits. In 1828 the steamboat was a recognised factor in overseas transport, though both Bell and Symington still survived in undeserved poverty. Through David Napier the mails were regularly carried by steam vessels: in 1825 the little *Enterprize* had made her historic voyage to India, and in 1827 the British-built Dutch vessel *Curocoa* crossed the Atlantic to the West Indies. In 1828, steam vessels were included in the Official List of the Royal Navy, but another ten years had to pass before Brunel's famous *Great Western* inaugurated regular trans-Atlantic passages. The same period also saw the beginning of the railway systems of England. Blenkinsop's locomotives had been at work since 1812, passengers were carried on the Stockton and Darlington Railway in 1825, and in 1828 George Stephenson was engaged in the construction of the Liverpool and Manchester Railway. with which the epoch-making *Rocket* is associated. On the roads, too, steam carriages such as Goldsworthy Gurney's were seen, and had a more enlightened policy prevailed, the steam motor-car might well have been common eighty years ago.

With the increasing demand for engines and machinery arose a new type of engineer, known as the 'mechanical engineer,' devoted to the founding and fashioning of iron. Not only was he called upon to make steam engines in great numbers for factories, ships, and railways, but it was he who built the iron bridges and the iron ships. Thanks to the work of Cort, the iron masters of Great Britain were able to meet all demands, and the country came to boast of some thousands of puddling furnaces. With these things came the rise of the machine tool makers. From the shops of Boulton and Watt at Soho, the Butterley Iron Works, and Maudslay's shops at Lambeth, came a long line of successful pioneers, such as Roberts, Muir, Whitworth, and Nasmyth, who gave us the planing machine, the true plane surface, the standard screw thread, and the steam hammer.

Among the first members of the Institution of Civil Engineers were to be found men engaged in all the various branches of engineering, and the *Proceedings* of the Institution contain a progressive review of the great achievements of the engineering profession. In the early days of the Institution, however, engineering work was carried out mainly by practical men trained in the hard school of experience. Of scientific education for the engineer, in England at least, there was none, and scientific research was in its infancy. If there is one thing more than another which separates the present from the past, it is the attitude towards scientific discovery, but for many years now in matters of education and investigation the Institution of Civil Engineers has taken a leading part. In connexion with this it is perhaps worth recalling that when William Anderson inaugurated the annual lectures which keep alive the memory of the most famous of the Secretaries of the Institution, James Forrest, he took for his subject "The Interdependence of Abstract Science and Engineering." That was in 1893. Since then many men famous both as engineers and as men of science have delivered the James Forrest Lecture, but the happy choice of the Council in selecting Sir Alfred Ewing to give the lecture which will mark the centenary of the incorporation of the Institution will not fail to gain general approval; his lecture on "A Century of Inventions" will be awaited with more than usual interest. In the voluminous publications of the Institution, which in themselves form a veritable engineering library, it may be there are few, if any, more valuable records than these James Forrest lectures, which have often rivalled in interest the famous presidential addresses of Sir John Rennie, Robert Stephenson, Sir William White, and others.

The Accuracy of Shortt Free Pendulum Clocks.

By Dr. J. Jackson and W. Bowyer.

The period of vibration of a simple pendulum, swinging in a vacuum through the small semi-arc a is given by $2\pi\sqrt{\frac{l}{g}}\left(1+\frac{1}{16}a^2\right)$.

Variations in the rate of a pendulum clock are produced by variation in (1) the length of the pendulum; (2) the arc of vibration; and variation in several factors which produce a departure from the above formula; namely: (3) air resistance; (4) elasticity of the spring; (5) interference with the free motion of the pendulum by the escapement and impulsing mechanism.

We will consider these in turn.

(1) The principal cause of variation in the length of the pendulum is change of temperature. This can be overcome by keeping the pendulum at constant temperature. Attempts have also been made with more or less success to compensate the effect by the use of metals of different coefficients of expansion so as to make the effective length of the pendulum practically independent of the temperature. But the parts of such compound pendulums may not take up changes of temperature at the same rate, and those of the grid-iron type are apt to roll. The discovery of invar has greatly simplified the temperature question. But invar is a rather unstable substance and its growth produces slow secular change in the clock rate.

(2) If the bob moves in a cycloid instead of a circle the period is independent of the amplitude. Clocks have been constructed with 'cycloidal cheeks' to guide the pendulum, but these have not proved of value. When the semi-arc of vibration is 1° a change of 1′ in the amplitude affects the daily rate of a simple pendulum by only 0·05*s*. The change of arc in precision clocks is not great, and, moreover, as a result of the action of the suspension spring, the effect of change of arc in such clocks may easily be less than the theoretical amount given, so that this source of irregularity is not very serious.

(3) A change of 1 per cent. in the air pressure under ordinary conditions changes the daily rate of a standard type of pendulum by about 0·1*s*. This can be fairly accurately compensated in various ways, but for the most accurate clocks it is best to keep the pressure constant. For Riefler clocks this is usually about 600 mm. of mercury, but for the Shortt clocks it is of the order of 30 mm.

(4) The effect of the suspension spring does not appear to be very great, although various methods of supporting the pendulum have been invented. Change of elasticity with temperature and fatigue of the material from continuous bending, may produce variations of arc and so affect the rate of the clock.

(5) The most difficult problem in clock making has been in the escapement. In the usual type of clock the escapement serves a double purpose. It enables the number of vibrations to be counted, and through it the impulse is given which maintains the vibrations of the pendulum. The pendulum is in more or less continuous contact with the escape wheel, and although this is generally situated fairly near the point of suspension, it is clear that frictional forces and continuous interference by the escape wheel may easily produce considerable irregularity in the clock rate.

At the end of 1924 the clock Shortt 3, made by the Synchronome Co., Ltd., was installed at the Royal Observatory, Greenwich, and it proved so reliable that it was introduced as standard on Jan. 1, 1925. It consists of a 'free pendulum' and a 'slave clock.' The free pendulum is made of invar swinging in an air-tight case at a pressure of about 1 inch of mercury. The free pendulum has no escapement. On a bar about one-fifth of the way from the top it carries a very light wheel about 6 mm. in diameter. At every fifteenth swing to the left (30 seconds) a gravity lever carrying a weight of ½ gm. and released by the slave clock, falls on the wheel, giving it an impulse. As this lever gets clear of the wheel a tail-piece releases mechanism which resets the impulse lever and also causes an electric contact to be made which synchronises the slave clock. An action of the synchroniser on the slave clock advances its phase by approximately 0·004*s*. The slave clock is rated to lose about 5*s*. a day, or 0·002*s*. per 30*s*. Under these conditions the synchronising action on the slave pendulum occurs at alternate half minutes with considerable regularity. The slave clock does all the work of counting the vibrations and releasing the impulse lever. Consequently, the only interference with the free pendulum is the impulsing during a fraction of a second every thirty seconds. The great advantage which the Shortt clock has shown over all other types of clock is undoubtedly due to the relative freedom of the pendulum from mechanical interference.

This clock was started at a practically zero rate at the beginning of 1925, but it acquired a losing rate at about 0·04*s*. per day per month. By the autumn of that year the rate of change of rate had fallen to about 0·012*s*. per day per month. It remained at approximately this value until June 1926, when the clock stopped as a result of the failure of the release of the lever which resets the impulse arm of the free pendulum. This failure was caused by two steel surfaces jamming, and to avoid a recurrence of the fault a jewel was introduced at the locking surface.

The clock was restarted in July 1926, since which time its performance has been remarkable. The rate showed the previous change of about 0·012*s*. per day per month, but apart from this the going appeared nearly uniform. During October and November 1926, when special time determinations were being made for longitude purposes, the temperature was subject to unusually large fluctuations, and it appeared that there might be a temperature term of the order of 0·003*s*. per day per 1° F. Consequently thermostatic control was introduced, and the clock rate became very steady. This continued until May 1927, when the clock error commenced to depart from the predicted value, but this was traced to an irregularity in sidereal time and not in the clock rate. For those not acquainted with the exact definition of sidereal time, we may state that sidereal time is defined by the hour angle of the first point of Aries measured westward from the meridian. The motion of the first point of Aries is for convenience divided into two parts, the uniform part called precession and the non-uniform part called nutation. The principal part of the latter is given by the formula

$$-1{\cdot}06s.\ \sin\Omega - 0{\cdot}08s.\ \sin 2L.$$

The period of the first of these terms is 18·6 years, and this term can with sufficient accuracy be expressed in the form $a+\beta t+\gamma t^2$ for an interval of a year or two. The second term, though of much smaller amplitude, runs through its period in six months, and this term cannot be expressed in quadratic form for more than four or five months. The clock error was therefore analysed in the form $a+\beta t+\gamma t^2$ + nutation, and this satisfactorily explained all the observations while the temperature was approximately constant. The temperature of the clock room had been maintained near 55° F., but in the summer of 1927 it rose to about 62° F., and by comparison of the observed clock error with the formula, it was found that there was a temperature term of very nearly 0·0030*s*. per day per 1° F. When this effect was allowed for, a formula was obtained which fitted all the observations from March 1927 to December within 0·1*s*. The formula was extrapolated backwards and found to leave residuals of about three-quarters of a second in the autumn of 1926 and to fit the observations again in July 1926. Extrapolation forwards fits the observations to 0·1*s*. at the end of March 1928.

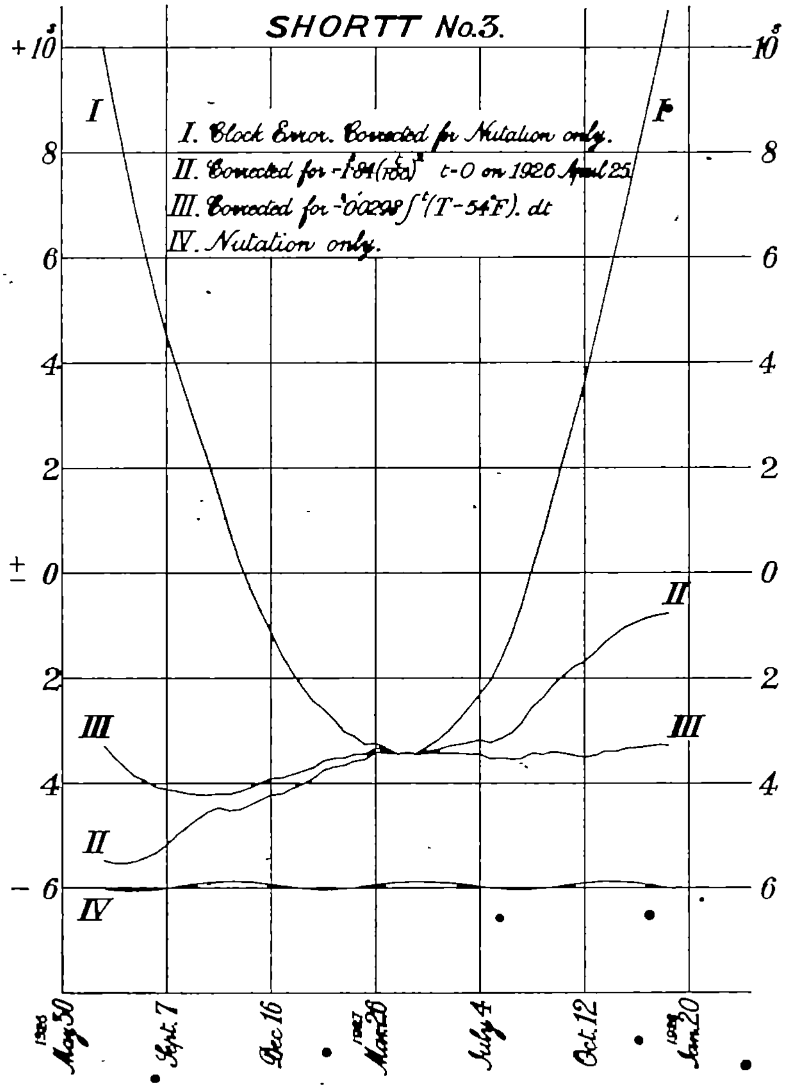

FIG. 1.

It should be stated that although the temperatures were not known with great accuracy in 1926, the residuals must be due to change in γ or some other irregularity.

The two diagrams (Figs. 1 and 2) show how closely the observed clock errors can be explained when the irregularities are allowed for. The points in the diagrams are based on curves drawn through all the errors determined with the transit circle. A more detailed comparison of the observed and computed clock errors is given in the *Monthly Notices of the Royal Astronomical Society* for March 1928.

The temperature term of 0·0030*s*. per day per 1° F., or 1·1*s*. per year per 1° F., is much smaller than that for most high-grade clocks, but it was not expected to exist. It is said by the makers to be larger than would arise from uncertainty in the coefficients of expansion of the materials used in the construction of the pendulum. The second Shortt clock which was erected in the same clock room in May 1926 shows a temperature coefficient of similar amount.

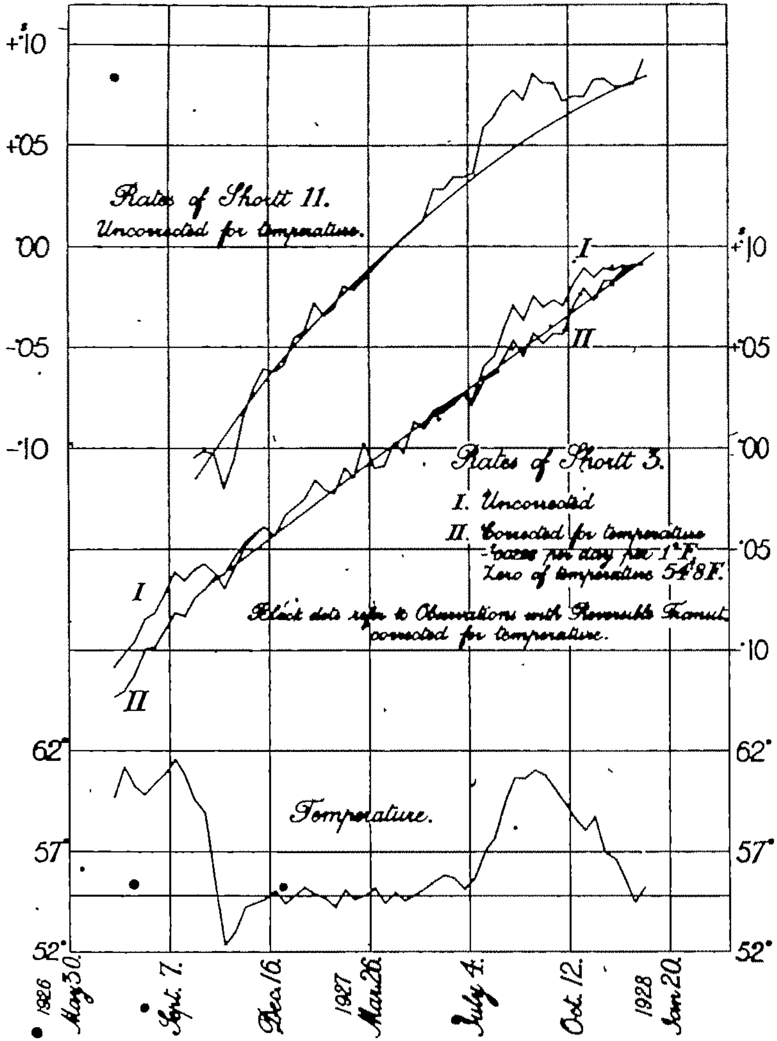

FIG. 2.

The temperature term in the clock error is, however, of comparatively small importance. The important term for long-distance forecasting of the clock error is γt^2, γ being 1·84*s*. when t is in units of 100 days. This term will amount to more than three minutes in 3 years. There can be little doubt that it is due to growth in the length of the pendulum. It is known that invar grows for years after its manufacture, and that the growth may be irregular. To explain the above coefficient the growth in the length of the pendulum (994 mm.) is 0·001 mm. in 118 days. Changes in the rate of growth of the pendulum do not affect the prediction of clock errors for a month or so, but may become serious when a formula fitting the observations for a year or more is considered.

Possible changes in the rate of rotation of the earth have recently attracted the attention of astronomers. Observations of the positions of the moon, supported fairly well by observations of more slowly moving bodies in the solar system, indicate that the rotation of the earth may be subject to variation amounting in extreme cases to about 1*s*. per year. One second a year is only 1 part in 30 millions, and if residuals of this order in the relative times shown by the earth and the free pendulum are demonstrated, the question will arise as to whether they are caused by:

(*a*) Residual secular change in the length of the pendulum.

(*b*) Variation of gravity.

(*c*) Variation in the actual rate of rotation of the earth.

(*d*) Seismic disturbances.

(*b*) and (*c*) may be inseparable, as changes in the earth's moment of inertia may be accompanied by changes in gravity as well as in the earth's angular velocity.

The real difficulty in the clocks is (*a*). It appears that the principle of their construction is such that they could be used to check the uniformity of the earth's rotation if only material stable for several years to 1 part in 100 millions could be obtained for the manufacture of the pendulums. At present the two sidereal Shortt clocks at Greenwich have been running continuously for 20 months, and a run of a few years would possibly suffice for errors of 1*s*. to accumulate in the earth's rotation, but a variation of 1 per cent. in the rate of growth of the pendulums would introduce greater irregularity in the clock error. It appears impossible to be certain that any piece of material has the required degree of stability, and until pendulums of different materials in different parts of the earth agree in supporting the motion of the moon and planets against the earth's rotation, clocks will not play an important part in checking the uniformity of the earth's rotation.

Cruise VII. of the *Carnegie*, 1928–1931.

By Dr. J. A. Fleming and Capt. J. P. Ault,
Department of Terrestrial Magnetism, Carnegie Institution of Washington.

After an interval of more than six years, the *Carnegie* began again on May 1, 1928, a world-wide cruise planned to continue to September 1931. This will be the seventh cruise of the vessel and, as indicated by the tentative route shown in Fig. 1, will add 110,000 statute miles to the total of nearly 290,000 miles traversed in all oceans during Cruises I. to VI. (1909–1921). Thus the plans for the magnetic and electric survey of the oceans envisioned in 1904, under the enthusiastic and energetic directorship of Dr. Louis A. Bauer, will be further realised and the results already obtained will be greatly enhanced.

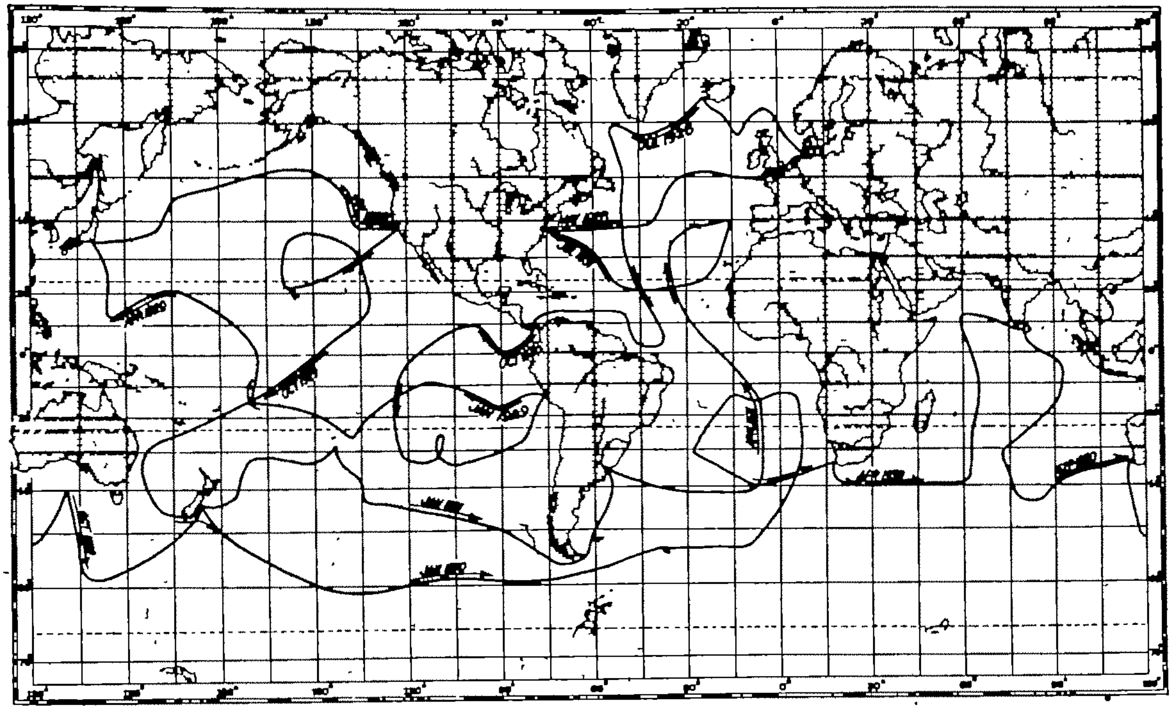

Fig. 1.—Tentative route for Cruise VII. of the *Carnegie*, 1928–1931.

The survey of the oceans of the world was begun during 1905–8 on the chartered brigantine *Galilee* in the then magnetically unexplored Pacific under the command, respectively, of J. P. Pratt for the first cruise, and W. J. Peters for the second and third cruises. Upon completion of the specially designed yacht *Carnegie* in 1909, the survey was continued with greater efficiency, because of non-magnetic construction of the vessel and the steady evolution of suitable instruments and observational methods, in all oceans during 1909–21 under the command, respectively, of W. J. Peters for Cruises I. and II., of Capt. J. P. Ault for Cruises III., IV., and VI., and of H. M. W. Edmonds for Cruise V.

The practical and theoretical value of the magnetic work already done on the *Carnegie* is attested by the principal hydrographic establishments of the world and by individual investigators. While magnetic data are needed for practical navigators, yet future magnetic work at sea is far more necessary for the advancement of theoretical studies. Accumulated data indicate that the accelerations in the secular variation changes may not be extrapolated safely over periods so long as five years. Observations will be repeated in localities previously surveyed by the *Galilee* and the *Carnegie*, and additional information will be obtained regarding the distribution of the magnetic elements in some large areas not already covered.

Experience during previous cruises has shown that results with certain magnetic methods and instruments are more trustworthy than with others, so that the duplication of instruments and methods need not be continued. Thus the magnetic declination will be determined by use of the marine collimating-compass, omitting the deflector; the horizontal intensity will be determined by the deflector, omitting the dip circle method; the magnetic inclination will be determined with the earth inductor, omitting the dip circle. Some improvements have been made in the magnetic instruments, chief among which is the addition of a constant speed apparatus and drive for rotating the coil of the earth inductor, with amplifier and microammeter to determine inclination electromagnetically. Electromagnetic methods are also to be attempted with the earth inductor for the measurement of the horizontal intensity, thus replacing the more laborious deflector method by a more rapid and accurate electric method.

For the further investigations on the origin and maintenance of the earth's electric charge and of their relation to the earth's magnetic condition, determinations of changes in the values of the atmospheric electric elements with geographic position are needed in addition to those already made. A photographic recorder will be used to record variations in atmospheric potential gradient continuously; it will be mounted near the top of the mainmast and will be controlled by the apparatus for eye-readings mounted on the quarter-deck railing as heretofore. A motor has replaced the spring and clock-work mechanism in the ionic-content apparatus for drawing the air through the instrument.

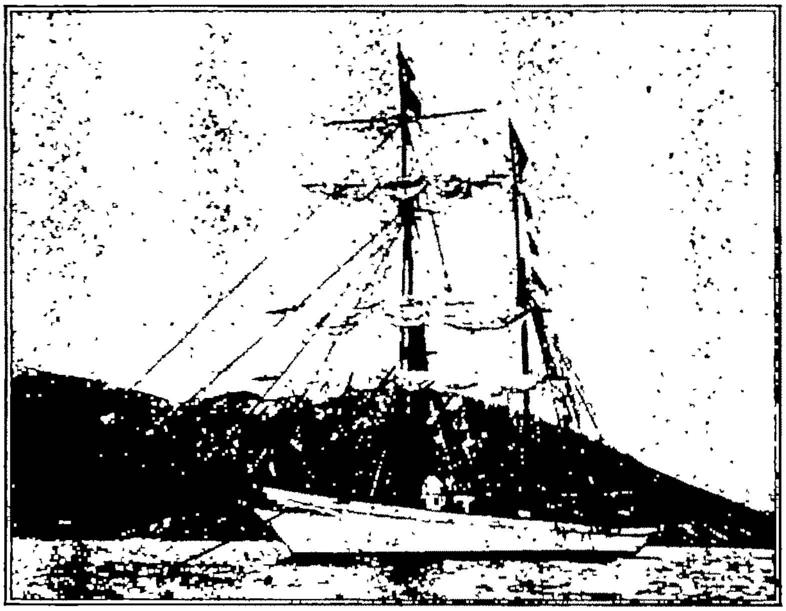

FIG. 2.—Non-magnetic yacht *Carnegie* off Port Lyttelton, New Zealand. During six cruises in all oceans (1909–21), the vessel has sailed about 290,000 miles.

Some improvements have been made in the instruments and methods used for measuring the penetrating radiation and the radioactive content, and more frequent series of observations extending over a period of twenty-four hours are planned. In addition to the programme previously followed for observations of the penetrating radiation, parallel observations will be made with a Kolhörster instrument which Dr. Kolhörster is testing thoroughly and comparing with his 'standard' instrument. It is planned to observe especially for variations with time, with geographical position, and with depth. Dust-count observations, using an Aitken dust-counter, will be made for correlative studies with atmospheric electricity. The measurement of marine electric currents will be attempted by trailing electrodes on cables from the stern of the vessel.

The important contributions to the study of various geophysical problems, which are being made by investigations of the Heaviside conducting layer and of radio transmission and variations with changing magnetic and electric conditions, greatly enhance the value of the atmospheric electric data already collected on the *Carnegie* over the ocean areas, and indicate co-operative investigations along similar lines for the coming cruise.

The omission of duplicate magnetic methods and instruments previously mentioned, and addition of two men to the scientific personnel, make possible a substantial programme in physical and biological oceanography. In physical oceanography it is planned to investigate the topography and configuration of the ocean depths by the sonic depth-finder; to study the causes of movements of vast bodies of water relatively to one another, the dynamics of the sea, by measuring differences in temperature and salinity over the surface and at various levels down to a maximum of 20,000 feet; to secure information regarding the nature and derivation of inorganic marine deposits by sampling the bottom muds and sediments; and to increase our knowledge of the physical interchange between the surface of the ocean and the air above it by measuring the temperature and humidity lapse-rates of the air in the first 100 feet above the surface, and by observing the variations in the amount of solar radiation received at the ocean surface.

Work in marine biology will be confined to microbiology, to determine the abundance and distribution of plankton and other small organisms. Most of the collecting will be done by tow-nets and dip-nets. A special boom-walk, similar to the one used by Beebe, has been installed on the starboard forward side of the vessel, where the collector may walk 30 feet out from the side of the ship on a plank suspended by a netting of rope from two boat-booms and about three feet below them. The booms are hinged at the rail and are suspended from the mast by a pendant with preventer stays both forward and aft. Shallow-water dredging will be undertaken to secure diatoms and foraminifera, and specimens of porpoises, dolphins, birds, and other creatures will be collected from special regions.

To carry out this programme of oceanographic investigations and to provide for new equipment required many changes in the *Carnegie*. The structural changes were made during the summer of 1927, when the vessel was completely overhauled and reconditioned at Hoboken, New Jersey. The two lifeboats were removed from the quarter-deck to overhead platforms amidships, thus leaving the quarter-deck free for the operation of the winch, sounding wire, water-bottles, deep-sea reversing thermometers, tow-nets, bottom-samplers, and earth-current cables. Two new laboratories were constructed on the main-deck, one designed for oceanographic investigations, and one for radio and sound work. In the oceanographic laboratory are mounted the Wenner electric salinity apparatus, the Negretti and Zambra distant-recording surface temperature thermograph operating on a 24-hour rate, and the various equipment and apparatus for the study of plankton and of the chemistry of the air and of sea water.

In the radio and sound laboratory is mounted the depth-finder loaned by the United States Navy Department for measuring rapidly and accurately the depths of the sea. The short-wave transmitting and receiving radio equipment made after the design of the United States Naval Research Laboratory, for the investigation of variations in transmitting and receiving conditions and on skip distances and signal intensity, is installed in this laboratory.

In a new galvanometer house on the port side of the quarter-deck aft of the radio laboratory, are mounted the Einthoven type string galvanometer for the earth inductor and for the earth-current apparatus, the control portion of the constant speed apparatus, amplifying unit, microammeter, special inductance coils, and appurtenances for the earth inductor work, the recording apparatus for six resistance thermometers located at various places from the masthead to near the ocean surface, and the roll-and-pitch recorder.

The oceanographic equipment includes a Wenner electrical salinity apparatus made in the Department's shop, Richter and Wiese thermometers and water-bottles, Nansen water-bottles, special non-magnetic winch with 6800-foot and 20,000-foot aluminum-bronze cables for depth-work, sonic depth-finder loaned by the United States Navy Department, chemical and biological apparatus, silk metre and half-metre plankton nets, various types of bottom-samplers, and necessary appurtenances.

The meteorological instruments are in general of the recording type, and a special programme of observation and control has been arranged. At Plymouth and at Hamburg, additional recording wet- and dry-bulb thermograph and wet- and dry-bulb resistance thermometer equipment with recording galvanometer for three stations at masthead, cross-tree, and meteorological screen are to be installed. It is hoped that, despite the difficulties of such work on a sailing vessel, data on the general upper-air circulation may be obtained by pilot-balloon flights, for which equipment is provided.

The members of the scientific personnel and their special fields of activity are: Capt. J. P. Ault, commander and chief of scientific staff; Wilfred C. Parkinson, senior scientific officer, atmospheric electricity and photography; Oscar W. Torreson, navigator and executive officer, magnetism, navigation, and meteorology; F. M. Soule, observer and electrical expert, magnetism and physical oceanography; H. R. Seiwell, chemist and biologist, oceanography; J. H. Paul, surgeon and observer, medical work, meteorology, and oceanography; W. E. Scott, observer, navigation and commissary; Lawrence A. Jones, radio operator and observer, radio investigation and communication. The sailing staff will consist of 17 men, making the total number of men on board 25; of the sailing staff, A. Erickson, first watch-officer, C. E. Leyer, engineer, and F. Lyngdorf, steward, occupied similar positions during the entire two years of the *Carnegie's* last cruise.

The first leg of the cruise will be to Plymouth, England, where the vessel was due to arrive at the end of May. After a call at Hamburg, the next ports of call will be at Iceland, at Barbados, and at the Panama Canal Zone (about the end of October 1928). The remainder of the cruise (see Fig. 1) will cover the North Pacific, South Pacific, South Atlantic, Indian, and North Atlantic oceans. Among the ports of call will be Easter Island, Callao, Papeete, Apia, Guam, Yokohama, San Francisco, Honolulu, Lyttelton, South Georgia, St. Helena, Cape Town, Colombo, St. Paul, Fremantle, Rapa Island, Buenos Aires, Ponta Delgada, and Madeira.

The preparations for this cruise have had generous co-operation and expert advice on all sides from interested governmental and private organisations and individuals both in America and Europe, who have also either loaned or presented much of the special oceanographic equipment and many books for the reference library on board. Among these the Carnegie Institution of Washington is indebted to the following: United States Navy Department, including particularly its Hydrographic Office, Naval Research Laboratory, Signal Corps and Air Corps of the War Department, Coast Guard, National Museum, Bureau of Fisheries, Weather Bureau, and Coast and Geodetic Survey; Scripps Institution of Oceanography of the University of California; Museum of Comparative Zoology of Harvard University; School of Geography of Clark University; American Radio Relay League; Geophysical Institute, Bergen, Norway; Marine Biological Association of the United Kingdom, Plymouth, England; German Atlantic Expedition of the *Meteor*; Institut für Meereskunde, Berlin, Germany; British Admiralty, London; Carlsberg Laboratorium, Bureau International pour l'Exploration de la Mer, and Laboratoire Hydrographique, Copenhagen, Denmark; and many others. Dr. H. U. Sverdrup, of the Geophysical Institute at Bergen, Norway, research associate of the Carnegie Institution of Washington, is consulting oceanographer and physicist.

Obituary.

Dr. H. F. Gadow, F.R.S.

Dr. Hans Friedrich Gadow died suddenly on May 16, aged seventy-three years. He was born in Pomerania, the eldest son of the Inspector of the Prussian Royal Forests. He was a Wend by birth, and he was deeply interested in the languages and aspirations of all the peoples of East Prussia. He was being trained for a commission during the Franco-German war. Afterwards he was educated at Frankfurt, Berlin, Jena, and Heidelberg, and he regarded himself as a pupil both of Haeckel and of Gegenbaur. For the former he edited "The Last Link," and he suggested his striking and picturesque comparison of past evolution with the spectrum. In his morphological work he always remained a pupil of Gegenbaur, who suggested his employment by the British Museum in 1880. Here he remained until 1882, when he was appointed Strickland curator of birds at Cambridge, in 1884 becoming lecturer on the advanced morphology of vertebrates as well; he also became naturalised. He remained in these same posts until 1920, when his lectureship was changed into a readership. During all these years he was responsible for the advanced teaching in the comparative anatomy of vertebrates at Cambridge, but on becoming reader he undertook at his own desire for some years the elementary teaching as well. He also lectured at times on the history of zoology and on geographical distribution. He was elected a fellow of the Royal Society in 1892.

Dr. Gadow's early researches were largely concerned with the musculature of reptiles and birds, in much of which he broke a new field. His volume in Bronn's "Klassen und Ordnungen des Thier-Reichs" on the anatomy of birds, more than 1000 pages and 59 plates, 1884–91, will always remain classical, and this was followed by a systematic volume in 1893. He was also responsible for all the anatomical parts in Newton's "Dictionary of Birds." His two papers (1895–6) on the vertebral column were a great attempt to bring into line the anatomy of different groups. He established the existence in each vertebra of four pieces, but the whole question is still very involved. He examined his material directly and by sections cut at all sorts of angles, and above all he made pilgrimages, wherein he saw practically all the fossil material of Europe. His lectures on the cloaca, on ear ossicles, and on other organs, were largely founded on his own researches, and in all his work on the hard parts he treated fossil with living forms in a single story.

With further discoveries in palæontology and embryology much of this work has been superseded, but Gadow's method undoubtedly exercised a stimulating influence on all zoology. In 1898 he published his "Classification of Vertebrata," which most of the critics of that time judged severely for its division of suctorial and jawed forms and for the placings of many fossil groups, most of which are now accepted. The volume on amphibia and reptiles (1901) in the "Cambridge Natural History," next occupied his attention. He personally examined practically every beast that he mentioned, and he made himself acquainted with very many by keeping them alive, by studying them in Nature or in zoological gardens. He started *de novo*, and the result is seen in unquestionably one of the greatest works in zoological science.

Dr. Gadow's explorations led him to caves and mountains in northern Spain and in Mexico among other places. He visited the latter on several occasions, being always warmly welcomed by President Diaz. He camped when and where he liked and at all elevations in complete safety in that land of brigands, for he had the gift of friendship with such wild peoples. His results are seen in two travel books and many papers, of which perhaps the most remarkable were on the colorations of lizards, snakes, and birds. His presidential address to Section D of the British Association (1913) was on the necessity for the study of structure and function taken together.

In many respects the late Dr. Gadow was a man of strong personality. He was always ready to fight any- and everyone over any zoological research or teaching matter. He seemed to us to enjoy it, and for the time being it entirely dominated his life, his opponent for the moment in all his works and characteristics being a villain. Yet this never lasted long, and he made no enemies and many friends, for his very faults were all lovable. His ideas of research were Teutonic—a professor and an obedient school, a system unsuited to England—and consequently he had few direct pupils, though all zoologists appreciate his potent and excellent influence on the development of their science in the last fifty years. All Cambridge men in particular will deeply regret his death, but he has left a good name and a fine record.

J. S. G.

Prof. J. V. Daneš.

The Charles' University of Prague has lost one of its leading professors, Prof. Jiří Václav Daneš, who died on April 13 in Los Angeles in his forty-eighth year, having been run over by a motor-car. This disaster happened when he was on a scientific tour through the United States, where he had been invited by several universities to lecture on geographical problems.

Daneš was our professor of general geography at Prague, and his aim was to make his subject a truly scientific one. He studied under Palacký in Prague and under Penck in Berlin. In the year 1919 he was nominated ordinary professor of the Charles' University, but soon afterwards accepted the post of a general consul in Sydney. Daneš worked especially in the domain of geomorphology and anthropogeography in the Czechoslovak Republic, in Yugoslavia, together with its famous geographer, Cvijić, in the United States, Mexico, Jamaica, Java, Australia, and Oceania, where he spent some time in travelling with his colleague, Prof. Karel Domin, professor of botany, and after his return to Australia he worked there and on some of the islands for the Australian Government. The results of these scientific travels were published, jointly with Domin, in a volume, "Through the Double Paradise," and his further work was "Three Years in the Pacific."

Daneš published a series of papers in the *Proceedings of the Bohemian Academy of Prague* (with summaries in English), and the following further papers: "Physiography of some Limestone Areas in Queensland" (*Proc. Roy. Soc. Queensl.*, 1910); "On the Physiography of North-eastern Australia (*Roy. Soc. Prague*, 1911); "Absence des traces glaciaires dans la Californie méridionale" (*La Géographie*); "La région des rivières Barrow et Russell (Queensland)" (*Annales de Géographie*, 1912); "Further Kars-Studies in Jamaica" (1914); "Glacial Studies in territory of Ljuma" (*Bull. Soc. Serbe de Géographie*, 1914); and many others. Daneš was in 1925–26 dean of the Faculty of Natural Sciences in the Charles' University; he was honorary, ordinary or corresponding member of many scientific societies, among them being—the Royal Society of Science and the Bohemian Academy of Science in Prague, the Royal Society of Queensland and the Royal Geographical Society of Australasia (Queensland branch, Brisbane), the Serbian Geographical Society in Beograd, the Royal Academy in Beograd, the Polish Geographical Society in Warszawa, and the Commission Internationale de l'Atlas photographique des Formes du Relief Terrestre. BOHUSLAV BRAUNER.

PROF. EDGAR F. SMITH.

By the death of Prof. Edgar Fahs Smith on May 3, the United States loses a distinguished and versatile chemist who had many friends in England. Prof. Smith was born at York, Pennsylvania, on May 23, 1856. He graduated at Pennsylvania College in 1874 and proceeded to Germany, where he obtained his Ph.D. (Göttingen) in 1876. He was awarded the D.Sc. of Pennsylvania in 1899, and was afterwards honoured by many American universities and societies both in the United States and outside. He took up his duties as professor at Philadelphia in 1888 and continued there until his death.

Prof. Smith contributed to the advance of chemical knowledge in many fields, having carried out investigations in organic, inorganic, and physical chemistry. His earliest publications described the preparation and properties of the derivatives of certain aromatic acids and bases, and in this branch he claimed attention by translating Richter's "Chemistry of the Carbon Compounds," the first English edition appearing in 1886. Before this Smith had already turned his attention to the advantages to be gained by the application of electrical methods in analytical chemistry, and he worked out a number of procedures for separating and estimating metals by electro-deposition methods. So early as 1878 he published a book on "Electrochemical Analysis," which was favourably received and reached its sixth edition in 1917.

Most of Prof. Smith's researches, however, were concerned with tungsten and the tungstates, and although he carried out much painstaking work, this does not seem to have attracted the attention it merited. Indeed, Prof. Smith is best known as a biographer of American and other chemists and as a writer upon the history of science. His essays on the early American chemists, such as Martin Hans Boyé (1610–1686), Jacob Green (1790–1841), Robert Hare, J. Cutbush, Charles Baskerville (whose obituary he wrote for the *Journal of the Chemical Society*), and others, have done much to stimulate an interest in the achievements of these pioneers. In 1918 he published a "Life of James Woodhouse" (1770–1809), and last year there appeared his "Old Chemistries," in which he presented to "interested readers a hint of the vast stores of early literature relating to chemistry."

J. G. F. D.

The issue of the *Physikalische Zeitschrift* for April 1 contains an obituary notice of Prof. Eilhard Weidemann from the pen of his former colleague and assistant, Dr. G. C. Smith. The son of the physicist Gustav Weidemann, he was born in Berlin on Aug. 1, 1852. He was educated at the high schools of various university towns, and at eighteen years of age entered the University of Heidelberg to study under Helmholtz, Bunsen, and Kirchhoff. He got his doctor's degree under his father at Leipzig in 1876 for a research on the elliptic polarisation of light. Two years later he received the title of extra-professor, and in 1886 was appointed professor of physics at Darmstadt, and a few months later at Erlangen. Here he spent the rest of his days and did his best work. In conjunction with his father he founded the *Beiblätter* to the *Annalen der Physik* and edited it for twenty-four years. He could speak with fluency several languages, and his studies in the history of science in Arabia are well known. He resigned his professorship in 1926 and died on Jan. 7 last. His principal researches dealt with specific heats and vacuum tube discharges He was a fluent and clear lecturer.

We regret to announce the following deaths:

Dr. Edward S. Burgess, for thirty years professor and head of the department of biological sciences at Hunter College, New York City, an authority on the asters of North America, on Feb. 23, aged seventy-three years.

Dr. Thomas Bruce Freas, professor of chemistry at Columbia University, to which he had been attached since 1911, who was known for his work on thermodynamics in chemistry, on Mar. 15, aged fifty-nine years.

Dr. F. M. Perkin, C.B.E., past-president of the Paint and Varnish Society and of the Oil and Colour Chemists' Association and one of the founders of the Faraday Society, on May 24.

Dr. C. G. J. Petersen, Director of the Danish Biological Station, Copenhagen, distinguished for his work on animal associations on the sea-bed.

Mr. W. E. Plummer, Director of the Liverpool Observatory at Bidston, Birkenhead, on May 22, aged seventy-nine years.

News and Views.

The airship *Italia*, under the direction of General Nobile, has made two long flights from its base in King's Bay, Spitsbergen. The first was eastward past Franz Josef Land to Northern (Nicholas) Land. Details are awaited, but apparently no new land was discovered. The second flight was to the Pole, which was reached about midnight on May 23. Wireless messages report that it was impossible, as had been hoped, to lower anyone on to the pack-ice. Before returning, an attempt to reach the site of Peary's Crocker Land seems to have been made. A course was then set for Spitsbergen, against strong winds which reduced the speed of the *Italia* to 25 miles an hour. Fog was encountered, which led to ice accumulating on the envelope and added greatly to the weight. The airship was said to have ninety hours' fuel on board, and in case of forced descent a month's provisions. On Friday, May 25, the *Italia* was north-east of Spitsbergen, and apparently at no great distance from land. A north-westerly wind was blowing. On May 28 no further news had been received. Great anxiety as to the safety of the *Italia* and her crew was felt in Spitsbergen, and search parties had been sent out.

The Friday evening discourse delivered by Mr. A. C. Egerton at the Royal Institution on May 25 dealt with engine knock and related problems. 'Knocking' is a sound which comes from the cylinder of an internal combustion engine during the abnormal explosion of the charge. It limits the compression of the charge and therefore the efficiency of the engine. The efficiency can be improved by suitable engine design, by the admixture with the petrol fuel of large percentages of non-knocking fuel, such as benzene, or by the addition to the petrol of small quantities of 'antiknocks,' such as lead tetra-ethyl or iron carbonyl. Thus the function of an antiknock is to make possible the use of higher compressions in the engine, thereby increasing the efficiency and preventing the unnecessary wastage of large quantities of petrol fuel. It was Sir Humphry Davy who, at the Royal Institution, first directed attention to the influence of small quantities of combustible substances on the combustion of other mixtures. The remarkable features of antiknocks, such as lead tetra-ethyl or iron carbonyl, are the small quantities needed to be effective—one part in 200,000 of the fuel and air mixture—and, secondly, the fact that although they deaden down explosion they themselves in the pure state are highly inflammable and explosive substances.

Mr. Egerton stated that antiknocks do not impede the progress of a detonating gaseous explosion, which makes their action in preventing 'knocking' still more obscure. They inhibit the processes of oxidation which occur prior to ignition of the gaseous mixtures. Metallic vapours—for example, of thallium, lead, and potassium—were found to be effective in delaying the ignition of petrol. A general theory of the combustion of hydrocarbons was set out, depending on the formation of chains of reacting molecules; centres of high energy are formed wherein ignition can be set up. Antiknocks act by interfering with these chains and delaying the setting up of ignition. 'Knocking' is accounted for by enhanced vibratory combustion in the neighbourhood of the walls towards the end of the travel of the explosion in the cylinder, favoured by regions of high energy; compression waves may thereby be set up which give rise to the 'knocking' sound.

The Committee on Immigration and Naturalisation of the United States House of Representatives has published a statement, submitted by Dr. Harry H. Laughlin, dealing with the eugenical aspects of deportation, which embodies the results of a detailed investigation of the statistics and other data bearing upon the evidence of defects among immigrants and native-born Americans. One point upon which stress is laid is that of differential fecundity. While the upper levels tend to maintain themselves when there is racial contact owing to the purity of their women, there is a tendency for the lower race to breed up by the 'pure sire' method, the men of higher level mating, legitimately or illegitimately, with the women of the lower. On the other hand, the upper classes tend to have smaller families. While, therefore, controlled immigration could be used in promoting race conservation, a family standard, that is, an examination of the stock from which an individual sprang, might be made the basis of admission. In a large number of institutions from which particulars were obtained, the overwhelming proportion of defectives were native born, and very few were legally deportable. In dealing with distribution, defectives are low in number in agricultural areas, as they tend to gravitate to the commercial and industrial districts or to the poorer land of the hills. The so-called Ishmaels or American gypsies, of Indiana, who migrate north in summer and south in winter, are traceable historically through Kentucky back to Virginia. It is thought, though not proved, that they may be descended from exiles dumped from Great Britain in Virginia in the early days, as undesirables were dumped in Botany Bay. In these degenerate families increase is very rapid.

Following the work of Whipple and his collaborators on the favourable influence of feeding with liver on blood regeneration in dogs made anæmic by repeated hæmorrhages, Minot and Murphy showed that the administration of at least half a pound daily to patients suffering from pernicious anæmia resulted in a marked amelioration of the symptoms, with permanent benefit in most cases provided that the diet was continued. This advance in the treatment of a disease of obscure etiology has been confirmed by other workers, and the dietetic treatment appears to have obtained a permanent place in therapeutics. The only drawback to it is the difficulty some patients have in consuming the necessary amount of liver daily; numerous recipes have been published with the aim of tempting the most fastidious palate. A further step forward has, however, recently been made by Cohn, Minot, and Murphy and their co-workers, when they found that an extract of liver has the same effect as the liver itself. This work leads in the direction of the discovery of the actual substance which produces the beneficial effect and at the same time improves the treatment of the disease, since the extract is much less bulky and more palatable than the original liver. We have received from Messrs. The British Drug Houses, Ltd., a sample of their liver extract, B.D.H., which has been made by a process adapted from that described by Cohn. The results of clinical trials, already published, show that the extract exerts a marked effect in pernicious anæmia; a month's treatment may restore the number of red blood cells to normal. The extract is a dry powder, and is administered in the same manner as meat extract. It is put up in glass tubes, each containing one daily dose, the equivalent of half a pound of fresh raw liver.

IN *L'Europe Nouvelle* for Mar. 17, M. Genissieu, the transport engineer to the French Government, discusses the novel problems which will arise when electrical energy on a large scale is imported and exported between European countries. In 1923 the League of Nations suggested that transmission of electrical energy should take place freely between States, and in 1927 it recommended that all frontier dues in this connexion should be abolished. In Italy a law forbids the import and export of energy except when specially authorised. It also taxes this electrical energy at a rate which averages about ¼*d.* per unit. Switzerland sells to other countries about a fifth of its power production, but permission for export must be obtained from the Federal Council. The difference between the transport of energy and the transport of goods is whether the former could have been produced in the country being traversed. When Westphalian coal wagons cross Switzerland, the Federal Railways find it profitable and do not grudge this foreign product passing. They would not regard with equanimity, however, a high voltage line crossing Switzerland and delivering energy produced in the Ruhr to Milan. The electric energy, whether flowing north or south, could have been produced from its own water power, and custom payments would not compensate for the loss. M. Genissieu thinks that with the possible exception of Denmark, every European country would oppose the transmission of electric power over it. He thinks that the evolution of technique will gradually solve the problems. Perhaps energy will be transmitted across seas and frontiers by Hertzian waves. Power lines of greater and greater length will continually be made. The prodigious power of the Congo cataracts may be transmitted to Europe, and then solutions to these international problems will have to be found.

EVERY teacher of electricity, when lecturing, attributes to Oersted the discovery that when a wire carrying an electric current produced by a battery is brought near to a poised electric needle, the needle is deflected. It generally happens that a few members of his class wonder who Oersted was, and some possibly think that no great credit is due to the discoverer of such an obvious phenomenon. Mr. Rollo Appleyard, in *Electrical Communication* for April, has done well to write a careful biography of this great physicist and show why great credit is rightly his due. H. C. Oersted was born in 1777 and was educated at the University of Copenhagen. His bent at first was towards literature and philosophy, and in his early writings it is easy to trace the influence of the great German metaphysicians. In 1800 he gained a money prize which enabled him to travel for a few years. He found that Germany was a realm of theory, but that Paris was the home of experimental philosophy. His great discovery was made in 1820, after he had been appointed a professor at Copenhagen. For some years he had a suspicion that just as an electric current can produce heat and light, so it might be able to exert magnetic influence. He was convinced by his experiments that every voltaic circuit had a magnetic field, and that the direction of the movement of the needle was determined by that field. He sent an account of his investigations to societies in all the capitals of Europe, and honours were bestowed on him by practically all of them. The Royal Society sent him a Copley medal and the Institut de France gave him a prize of 3000 francs. Faraday describes the discovery well. Oersted discovered "a fact of which not a single person beside himself had the slightest suspicion, but which, when once known, instantly drew the attention of all who were able to appreciate its importance and value." Mr. Appleyard gives many novel and interesting biographical details.

WE have received the fifth Annual Report of the Benzole Research Committee, issued by the National Benzole Association. Much useful and fundamental work has been done during the past year, particularly on the cause and prevention of resin formation in motor spirit of the benzole type derived from coal. The use of ultra-violet light in indicating tendency to resin formation was studied in the previous year and this work has been continued. The conclusion is drawn that the test, although useful, is not altogether satisfactory, since resin formation may occur in the test but not in actual storage. Another test, depending on an examination of oxidation whilst the benzole is refluxed under exposure to oxidising conditions, has been examined. The use of inhibitors, particularly aniline and tricresol, has been investigated. There is also an account of the comparative efficiency of wash oils for benzole recovery, one of the materials examined being tetralin. It will be seen that the report contains much valuable and interesting information, and is of importance at the moment, when the possibility of increasing the yields of motor fuel from coal is prominent in the minds of all users of internal combustion engines.

THE annual publication of the Edinburgh University Forestry Society, *Sylva*, is now in its eighth year. This Society comprises the students following the forestry courses within the University and their predecessors, now serving in every part of the Empire where forest conservation is in progress. The major part of the articles in the magazine come from the pens of present students and their predecessors, now in the services. A yearly record is published of the names, appointments held, and addresses of all forestry graduates. In the present number this information has been summarised in an article, "The E. U. Forestry Department and the Empire," where it is shown that between 1919 and 1927 one hundred and seventy-seven men qualified and are now serving in almost every corner of the British Empire overseas, as well as in Great Britain and Ireland. Lord Clinton, chairman of the Forestry Commission, was the honorary president of the Society during the year 1926–27. In his presidential address he traced the history of British forestry from early times, and then dealt with the present position of afforestation work in the country and the various aspects of research work being undertaken under the auspices of the Commission. In the latter connexion an interesting paper deals with 'Powder Post Beetles,' based on investigation work initiated by an Edinburgh graduate at the Forests Products laboratory. The work carried out shows that serious damage is committed in timber yards by this type of beetle, and these species of *Lyctus* have been, and still are being, brought into the country in American oak and ash lumber of low grade. A far too brief paper of considerable interest deals with the low-level conifers of Sarawak, in which it is shown that two species, *Dacrydium elatum* and *Agathis alba*, which are found in Sarawak and elsewhere in the Malaya region on the higher hills, occur in the former country in utilisable stands practically at sea-level. *Dacrydium* occurs with a slight admixture of *Casuarina sumatrana* on low swampy lands in the north. The *Agathis* is found on light soils in mixture with various broad-leaved species. The timber of both has a commercial value.

THE publication by the Cambridge University Press of the second volume of abstracts of theses for the Ph.D., M.Sc., and M.Litt. degrees at Cambridge contains an interesting statement in the preface suggesting the establishment in the near future of a complete university research intelligence service. One gain that such a service might bring to workers in a subject would be the rendering accessible of degree theses which do not reappear in the pages of some generally accessible scientific (or literary) journal. As it is, something might perhaps be done if these summaries, and similar summaries from other universities, reappeared in such a publication as *Science Abstracts* or in specialised bibliographies, in cases where the main work of the paper is not published elsewhere.

As these special research degrees are still quite a modern feature in Cambridge, it is not without interest to examine some of the statistics of the present volume. Out of the 55 research degrees granted in the year 1926–27, no fewer than 41 were for scientific investigations. The large excess of scientific degrees may represent the fact that more emoluments are available for scientific than for literary research by young graduates, and that more encouragement is given by the teaching staff of scientific departments at Cambridge and elsewhere to young graduates to continue with research work after taking their degrees. It is perhaps significant that 12 of the 14 literary graduates came from other universities to do post-graduate work at Cambridge; while of the 41 science graduates, 26 came from outside and 15 were purely Cambridge students. The unequal distribution in subjects is reflected in an unequal distribution among the colleges. Trinity with 10, Caius and Emmanuel with 9 each, and St. John's with 7 account for two-thirds of the students, while six colleges are unrepresented in the list. Physics heads the list of subjects with 10 names, followed by mathematics, 6; biochemistry, 5; physiology and botany, 4 each. It may be mentioned that 6 of the 55 graduates are now fellows of colleges.

THE Report of the National Physical Laboratory for 1927 is a quarto volume of 264 pages, 200 of which are devoted to detailed accounts of the work done in the various departments of the Laboratory. These are well illustrated, and enable the reader to follow the advances which are being made towards the solution of the problems which at present confront science and industry. The staff consists of about 560, 72 of whom are engaged in administrative and clerical work. About 43,000 tests have been carried out during the year as against about 46,000 in the previous year, the decrease being mainly in the Metrology Department. A considerable amount of work is done for Government departments and for the numerous industrial research associations which have been formed under the auspices of the Department of Scientific and Industrial Research. The equipment of the high voltage research building is proceeding, but nothing has been done towards the new physics building which has been urgently needed for more than six years and for which funds were provided by Parliament in 1925 and then withdrawn. To meet the requirements of aeronautics a compressed air wind tunnel is under consideration. There have been few changes in the senior staff, but the Superintendent of the Engineering Department has been knighted for his long and distinguished services to the country.

THE Mining Institute of Scotland has issued a tastefully got up pamphlet to commemorate the jubilee of its foundation. This dates from Jan. 24, 1878, when a number of gentlemen interested in mining met in Hamilton and decided to form an Association called the West of Scotland Mining Institute. The direct cause of the formation of this Association may be said to have been a disastrous explosion which took place at Blantyre Colliery in 1877. Not long after its formation the title was changed to that which it holds at present, namely, the Mining Institute of Scotland; and not many years afterwards its headquarters were transferred from Hamilton to Glasgow. The pamphlet gives a full and interesting account of the work of the Institute, including a long list of special committees, amongst the objects of which the problems of increased safety in coal-mining operations take a prominent place. A list of the principal presidents of the Institute, together with their photographs, form an interesting feature of the pamphlet.

The following prize awards have recently been announced by the Belgian Royal Academy of Sciences: Maurice Nuyens (1500 francs), for his memoir on the resolution of problems with axial symmetry in general relativity; A. Monoyer (1500 francs), for anatomical and ethological researches on one or more plant species interesting through their mode of life; Théophile Gluge Prize (1300 francs), to L. Dautrebande for his work on the study of gaseous metabolism in man in health and disease; P. J. and Ed. van Bereden Prize (3400 francs), to Hans de Winiwarter for his work published during 1924–26; Adjutant H. Lefévre Prize (1500 francs), to Hélène Massart for her researches on the phenomena of secretion in plants; Ad. Wetrems Prize (7500 francs), to Louis Verlaine for his studies on instinct and intelligence in Hymenoptera Agathon de Potter Foundation. The following grants have been made: W. Conrad (2000 francs), for the continuation of his researches on the lower organisms, particularly on the Belgian fresh-water flagellates; J. Pasteels (500 francs), to continue at Wimereux his researches on the cyto-physiological action of the dilution of sea water on the eggs of lamellibranchs; the Jean Massart experimental garden (5000 francs), to continue a series of experiments on plant physiology commenced by the late Jean Massart; E. Zunz (6000 francs), for the purchase of instruments necessary to the continuation of his researches on glycæmia; Th. De Donder (7500 francs), for the publication of his "Théorie des invariants intégraux"; Gilta (1000 francs), for the publication of plates of chemical crystallography; E. De Wildemann (3000 francs), for assisting the publication of parts of vol. 4 of "Plantæ Bequærtianæ"; Comité national de Géodésie (5000 francs), to enable it to print the reports of 1920–25 and 1926, on the geodesic work done by the Institute cartographique militaire since the War; Beeli (500 francs), for the execution of plates relating to the mycological flora of the Congo. Jean Servais Stas Prizes to Lucie De Brouckère, Léon Navez, Louis Henry; the Decennial Prize of the mineralogical sciences to Armand Renier.

Two exhibitions of special interest to students of South African archæology and ethnology will be held at the rooms of the Royal Anthropological Institute early in the month of June. A collection of copies of Bushman drawings will be on view on June 4–12. The collection is of exceptional interest, as some of the drawings are said to be of a type not hitherto recorded. Col. S. P. Impey, the author of a recently published work on the origin of the Bushman drawings and paintings, by whom this collection is exhibited, will give a demonstration of the drawings on Tuesday, June 5, at 4 P.M. Tickets of admission to the demonstration may be obtained from the Secretary of the Institute, 52 Upper Bedford Place; admission to the exhibition only on presentation of a visiting card. On June 11-19 a collection of stone implements from South Africa, belonging to Col. W. E. Hardy, will be on view at the Institute preparatory to the reading of communications on the South African Stone Age by the Rev. Neville Jones and Col. Hardy, on Tuesday, June 19, at 8.30 P.M., when specimens of South African stone implements of special interest and exceptional type, collected by the Rev. Neville Jones, will also be exhibited. The collection to be shown by Col. Hardy is noteworthy for the examples showing affinities with Sahara types which it includes. Admission to the exhibition and evening lecture may be obtained on presentation of a visiting card.

The Huxley Memorial Lecture next year will be delivered by Prof. F. O. Bower in the Royal College of Science, London, on Friday May 3, at 5.30 P.M.

The President of the French Republic has conferred the Cross of Officier de la Légion d'Honneur on Dr. George H. F. Nuttall, Quick professor of biology in the University of Cambridge.

Prof. D'Arcy W. Thompson, professor of natural history, University of St. Andrews, has been elected a foreign honorary member of the American Academy of Arts and Sciences, Boston, Massachusetts. The list of honorary foreign members of the Academy is limited to seventy-five, and among the distinguished zoologists in the section of zoology and physiology are Sir E. Ray Lankester and Prof. G. H. F. Nuttall.

One of the houses occupied by Newton when living in London stood on the corner site between St. Martin's Street and Orange Street, where the Westminster City Council is now erecting a new public library. The Council has decided to commemorate Newton's connexion with the site by cutting an inscription on the stone face of the building to read as follows: "Sir Isaac Newton lived in a house on this site, 1710–1727."

The May meeting of the Royal Society of Canada was held at Winnipeg on May 21–24, under the presidency of Prof. A. H. Reginald Buller, professor of botany in the University of Manitoba, who delivered an address on "The Plants of Canada, Past and Present." A popular lecture on "The Air we breathe" was delivered by Prof. J. J. R. Macleod. The programme of the meeting includes abstracts of a very large number of papers contributed to the sections. Most of the meetings were thrown open to the public.

At the anniversary meeting of the Linnean Society of London, held on Thursday, May 24, the following were elected officers for the year 1928–29: *President*, Sir Sidney F. Harmer; *Vice-Presidents*, Dr. W. T. Calman, Mr. H. N. Dixon, Mr. Horace W. Monckton, Dr. E. J. Salisbury; *Treasurer*, Mr. Horace W. Monckton; *Secretaries*, Dr. G. P. Bidder (Zoology) and Mr. John Ramsbottom (Botany).

The following have been elected officers of the British Institute of Radiology for the session 1928–29:

President, Dr. G. W. C. Kaye; *Vice-Presidents*, Sir William Bragg, Dr. Robert Knox, Mr. L. A. Rowden; *Honorary Treasurer*, Mr. Geoffrey Pearce; *Honorary Secretaries*, Dr. Stanley Melville and Dr. G. Shearer; *Honorary Editors*, Dr. Robert Knox and Dr. G. W. C. Kaye.

THE annual general meeting of the Faraday Society was held on Wednesday, May 16, when the report of the Council was presented and the members of the Council for the session 1928-9 elected. The new president is Prof. T. M. Lowry. The retiring president, Prof. C. H. Desch, delivered an address entitled "Diffusion in Solids." During the past session the Faraday Society has held seven meetings, eighty-two papers being presented. Three of the meetings were general discussions on the following subjects: Atmospheric corrosion; the theory of strong electrolytes; and cohesion and related problems. In future, the *Transactions* of the Society will be published in monthly, instead of bi-monthly, parts.

"NATIONAL Baby Week" is again being celebrated in Great Britain this year during the first week of July (July 1-7). Full particulars and suggestions for the celebration may be obtained from the secretary, National Baby Week Council, 117 Piccadilly, London, W.1. While all aspects of the maternity and child welfare problems are regarded as suitable subjects for propaganda, it is especially desired this year to focus attention on three subjects: (1) immunisation as a means of protecting young children against disease, (2) prevention of maternal mortality, and (3) new developments in child welfare work. A conference on infant welfare will also take place on July 4, 5, and 6, followed by an International Child Welfare Conference in Paris, July 8-12.

A RECENT *Daily Science News Bulletin*, issued by Science Service of Washington, D.C., reports the discovery by Mr. J. H. Sinclair, of the American Geographical Society's expedition, of a new volcano in eastern Ecuador in lat. 0° 8′ S., long. 77° 32′ W. It lies in a heavily forested uninhabited region and rises from a base elevation of about 4000 ft. to nearly 7000 ft. The crater appears to be very large. Activity of the volcano is reported to have begun in 1925 with a violent explosion that carried away the entire top of the mountain. Ash is said to have fallen in appreciable quantities as far away as a hundred miles. The expedition was surveying in that little-known region and made other important discoveries before its recent return to the United States.

THE Second International Conference on Light and Heat in Medicine, Surgery, and Public Health, organised by the *British Journal of Actinotherapy* (17 Featherstone Buildings, London, W.C.1), will be held on Oct. 29–Nov. 1, at the University of London, South Kensington, S.W.7. There will be discussions on both therapeutic and scientific aspects, and it is hoped to arrange visits to representative clinics, where the most modern methods of utilising light and heat for therapeutic purposes will be seen. Simultaneously with the Conference, an exhibition of apparatus for ultra-violet, radiant heat, and allied forms of therapy, will be held in the Great Hall of the University, adjoining the conference hall. Reduced railway fares will be obtainable in England and Scotland for those attending the Conference.

AT the anniversary meeting of the Royal Society of South Africa, held on Mar. 21, Dr. W. A. Jolly, professor of physiology in the University of Cape Town, was elected president for the year 1928. Dr. A. Ogg, professor of physics in the University of Cape Town and retiring president of the Society, was elected honorary general secretary, and Dr. L. Crawford, professor of pure mathematics in the University of Cape Town, honorary treasurer. Dr. Ogg delivered his presidential address on "Some Aspects of Modern Physics," in which he discussed the origin of relativity and the quantum theory, passing on to Bohr's work on spectrum analysis and its modifications by Sommerfeld and others, and to Schrödinger's wave mechanics, and dealing in conclusion with Sir Ernest Rutherford's picture of the nuclear structure of radioactive elements.

THE Council of the Institute of Metals has issued a preliminary programme of the four-day annual autumn meeting of the Institute, which is to be held this year in Liverpool. This is the first time that the Institute has visited Liverpool. The proceedings will begin on Sept. 4 with a lecture on "Non-Ferrous Metals in the Shipping Industry," by Mr. F. G. Martin. The mornings of Sept. 5 and 6 will be devoted to the reading and discussion of papers, and the afternoons to visiting works of interest in the neighbourhood, the Gladstone Dock, and a large liner. In the evening of Sept. 6 there will be a reception at the Town Hall by the Lord Mayor (Miss Margaret Beavan). The meeting will conclude on Sept. 7 with an all-day motor trip to North Wales, during the course of which it is expected that an electric power station and aluminium works will be visited. Full particulars of the meeting can be obtained from the honorary local secretary, Mr. H. F. Richards, 42 Bedford Street, Liverpool, or from the secretary of the Institute of Metals, Mr. G. Shaw Scott, 36 Victoria Street, London, S.W.1.

UNDER the auspices of the National Association of Olive Growers of Spain (Alcalá 87, mod°. Madrid), a competition is being promoted with the object of simplifying and standardising the analytical and physico-chemical examination of olive oils and of mixtures in which they occur. It is hoped also to advance the olive-oil industry by gaining new information upon such fundamental problems as the mode of elaboration of the oil in the plant and the variations in its composition during the period of ripening. Moreover, an examination is required of the associated essential oils, colouring matters, and ferments, and of the products of enzymatic hydrolysis; while "as to the vitamins in olive oils, a brief study should be made to ascertain the quantities present, their class and their beneficial influence upon the human organism." In addition, competitors are asked to report upon the practicability of applying 'cracking' processes to olive oils, with the aim of producing petrol and related materials from it. The details of the competition, which closes on July 30, are laid down in a circular issued by the Association through the Spanish Ambassador in London, and prizes of 20,000 pesetas (about £700) and 5000 pesetas are offered.

MESSRS. Dulau and Co., Ltd., 32 Old Bond Street, W.1, have just issued a useful catalogue (No. 159) of a thousand works on geology, ornithology, and general natural history, including conchology, entomology, fishes, mammalia, etc. Many long runs of serials are included. The catalogue can be had free upon application.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—Teachers of electrical engineering and of engineering drawing at the East Ham Technical College evening classes—The Secretary, Education Office, Town Hall, East Ham, E.6 (June 7). An assistant curator in the Royal Botanic Gardens, Kew, in charge of the Herbaceous and Alpine Department—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (June 9). A head of the mechanical and civil engineering department of the Sunderland Technical College—The Chief Education Officer, Education Offices, Sunderland (June 12). A full-time teacher of mining subjects in Rotherham and South Yorkshire—The Secretary for Education, Education Offices, Rotherham (June 15). A teacher in mechanical engineering at the Birmingham Central Technical College—The Principal, Central Technical College, Suffolk Street, Birmingham (June 16). A full-time itinerant poultry instructor for the County of Essex—The Clerk of the Essex County Council, Shire Hall, Chelmsford (June 18). A demonstrator of chemistry at St. Bartholomew's Medical College—The Dean, St. Bartholomew's Hospital Medical College, E.C.1 (June 19). An assistant lecturer in agricultural economics in the department of agriculture, The University, Leeds—The Registrar, The University, Leeds (June 21). A leather research chemist for the New Zealand Tanners' Research Association—The High Commissioner for New Zealand, 415 Strand, W.C.2 (June 30). A full-time engineering workshop instructor at the Borough Polytechnic Institute—The Principal, Borough Polytechnic Institute, Borough Road, S.E.1. Instructor lieutenants in the Royal Navy with a university training and an honours degree in mathematics, science, or engineering—The Advisor on Education, Admiralty, S.W.1. A lecture assistant and laboratory steward for the chemistry department of the Royal Technical College, Salford—The Secretary for Education, Education Office, Salford. A head teacher in the electrical engineering and physics department of the Rochdale Technical School—J. E. Holden, Education Office, Rochdale. Two assistants in the department of geography of University College, London—The Secretary, University College, Gower Street, W.C.1. A lecturer in dairy accountancy and economics at University College, Cork—The Secretary, University College, Cork.

Our Astronomical Column.

A PROBABLE METEORIC DISPLAY.—Mr. Issei Yamamoto, of the Tokyo Observatory, has pointed out in the *Mon. Not. R.A.S.* that the orbit of Skjellerup's bright comet, seen last December, lies near the earth's orbit on about June 7 next, and that as the distance separating the orbits is only three millions of miles, there may probably ensue a meteoric shower. The radiant point has been computed as at 42°·3 + 41°·4. Dr. Crommelin has also calculated the place of radiation and gives the point a few degrees west of that given by Yamamoto.

It will be desirable to watch the heavens on June 7 in order to witness the shower should it occur. The distance of three millions of miles between the orbits need not negative the prospective display, for Halley's comet is responsible for a shower early in May though its orbital distance from us is greater than that separating us from Skjellerup's comet. There are a few other instances where meteors are seen from comets the orbital distance of which exceeds three millions of miles. At 10 P.M., the computed radiant will be unfavourably placed a few degrees above the northern horizon. The gibbous moon will rise on June 7 a few minutes before midnight.

THE SYSTEM OF PROCYON.—This is a difficult system to study owing to the extreme faintness of the companion, which was discovered by Schaeberle in 1896, but has not been satisfactorily observed since 1913. It is of interest owing to the fact that its mass seems to be too low for its bolometric magnitude according to the Eddington curve. Dr. Spencer Jones makes a very exhaustive study of the system in *Mon. Not. R.A.S.* for March, using meridian observations of the bright star from 1755 onwards, also micrometric observations of the companion, and spectroscopic determinations of the radial motion of the bright star made at the Cape between 1909 and 1924. The adopted orbit for the bright star about the centre of gravity is Periastron 1886·50, period 40·23 years, inclination 30°·6, omega 65°·7, node 307°·8, e 0·310, a 1″·020. For the faint star about the bright one a is 4″·26, node 127°·8, the other elements being the same as above. The bright star is taken as 3·18 times the mass of the faint one, the masses in terms of the sun being 1·24 and 0·39. The mass of the bright star according to Eddington's curve would be 1·46. This could be obtained by changing the adopted parallax from 0″·308 to 0″·292, but that is considered an improbably large reduction. In any case this research has made the discordance less than it was before.

COMETS.—*Lick Observ. Bull.*, No. 398, contains an investigation by N. T. Bobrovnikoff on the outward motion of matter in the tail of Morehouse's comet 1908 III. This comet was well situated for such examination, owing to its high north declination and the activity manifest in the tail. The repulsive force from the sun for three different condensations was found to be 154, 148 and 88 respectively in terms of gravitation at the same distance; the probable error of each is about 8 units. The projected condensations travelled in hyperbolæ that were nearly parabolic, the average eccentricity being 1·01. The sun of course was outside the branch described. The acceleration was observed to diminish at a distance from the comet's head; this is accounted for by dissipation of the cloudlike masses, and increase of resistance from slower-moving matter in the tail; others have suggested the gradual leakage of electrical charges.

Research Items.

Mummies from Colombia.—In *Man* for May, Mr. Warren R. Dawson publishes the results of a recent examination of two mummies now in the British Museum. Of these the first is that of an adult female in the sitting position, which is labelled as having been given by W. Turner, Esq., and found in a cave near Leiva, northern Grenada. The arms of the mummy are placed across the chest, the forearms nearly parallel. The head is slightly bent forward and inclined to the left. The knees are vertical, and the left foot over the right. All the nails of the toes are missing, and apparently those of the fingers as well, though this cannot be ascertained with certainty owing to the position of the hands. Part of the scalp is missing, and the condition of the sutures suggests middle age. Impressions of woven cloth show the body was wrapped up. Round the neck is a necklace of thirteen objects, and there are traces of red pigment on thighs, cheeks, knees, and elsewhere, which may be derived from the wrapping. The mouth is packed with wool which has distended the cheeks. The nose is broken away but the septum is intact, and there is no trace of a forced passage into the cranial cavity through the nose. The perineum is incised and the anus and vulva united into a single widely distended opening, probably due to the evisceration. The mummy was probably smoke dried. The second mummy is an adult male in poor condition from Gachansipa, northern Grenada. It is in the contracted posture with the head inclined forward. Wherever the integuments remain they are of a dark red colour, almost black in parts, suggesting the application of a resinous stain. The anterior part of the abdominal wall is broken away, exposing an empty cavity. There are no traces of the thoracic viscera, so the body was almost certainly eviscerated through an incision which appears in the left flank. The condition of this mummy suggests that it also has been smoke dried.

The Extinction of the Passenger Pigeon.—A letter written in March 1838 from Camp Gaugh, New Jersey, by J. T. Waterhouse to his parents in London, emphasises once again the former abundance of the passenger pigeon, and the great slaughter which took place during the migration (*Condor*, vol. 29, p. 273; 1927): "For the last fortnight the air has been almost black with wild pigeons emigrating from the Carolina swamps to more northerly latitudes, making their summer quarters in the lake countries. Within ten miles square during the last fortnight I suppose they have shot or netted twenty thousand. They fix up a kind of hut in a field made of the limbs of trees and buckwheat stubble. They have one or two fliers which they throw out every time a flock passes; the fliers are of the wild pigeon breed usually wintered over, or sometimes they take them direct from the flocks, tie their legs to a small piece of twine and throw them up." The writer then describes the operation of the fall net, and says that sometimes at one haul as many as three or four hundred pigeons were taken. "Whilst I am writing they are in the adjoining room picking seven pigeons for our breakfast. They were shot this morning at one fire of the gun."

Unusual Gestation of Roe Deer.—The breeding of the roe deer is anomalous in respect of the period which elapses between the pairing season and the birth of the calf. Mating takes place during July and August and the young appear in the following May or June. This, however, does not represent the true gestation period, since there is evidence that germinal development does not actually begin until December, the probability being that fertilisation of the egg may then take place by sperms which have lain quiescent since the mating season six months earlier. The true gestation period—December to May or June—is therefore about six months. Dr. James Ritchie records and comments upon an interesting departure from this sequence (*Scottish Naturalist*, 1928, p. 49). In December 1927 an early roe calf was found with its mother on the hills near Kingussie. The calf apparently was born about six months after the pairing season, and the suggestion is made that the six-months dormant period was omitted from this life-cycle, and that fertilisation and development of the egg took place immediately upon pairing, "an abnormal reversion to a normal occurrence." The fact that the new-born calf had to face the rigours of winter and spring, suggests how valuable the normal staving off of the gestation period must have been for the survival of roe deer.

Insect Types.—In his Report for 1926–27 on the Hunterian Collections, University of Glasgow, Prof. Graham Kerr refers to the completion by Mr. P. A. Staig of Part 1 of a monograph of the Fabrician types of insects contained in that museum. Dr. William Hunter afforded Fabricius ready facilities for studying the insects in his extensive collections and, as a result, Fabricius described many new species which he recorded in his classific works on systematic entomology. These 'antique' types constitute the standard by which it is possible to determine finally to what particular species a particular scientific name properly belongs. Fortunately, the Fabrician types contained in the Hunterian Collections are in a wonderful state of preservation, which has enabled Mr. Staig to prepare detailed descriptions, which should serve to assure entomologists as to which of the now well-known insects are rightfully assigned to the various Fabrician species. Part 1 of this monograph is now ready for publication, and deals with 55 out of a total of 250 of these early types.

Russian Fisheries Research in the Pacific Ocean.—The Pacific Ocean Scientific Fishery Research Station, recently established near Vladivostok (see Nature, Aug. 6, 1927, p. 198), has issued the first volume of its *Bulletins*, of 328 pages, well produced with numerous illustrations. Apart from two papers by the Director of the Station, Prof. K. M. Derjugin, on the organisation and activities of the Station, the volume contains a number of papers based on original observations of its members. Of special interest is a description of the West Kamtchatkan fishing industry by J. T. Pravdin, containing detailed data on the economically most important species of fish, their bionomics, methods of rising, statistics of catches, labour problems in the industry, etc. Several papers deal with the chemical analyses of local fishes (*Oncorhynchus keta*, *O. gorbusha*, *Clupea melanosticta*), and of the sea-cabbage (*Laminaria*) and other sea-weeds of industrial value, of oysters (*Ostrea laperousi* Schrenk), mussels (*Mytilus dunkeri*), and of edible medusa (*Rhizostoma* sp.). G. U. Lindberg gives a description of the Kamtchatka grayling (*Thimallus arcticus pallasi* Val.), which was hitherto very imperfectly known. A detailed biometric study of Pacific herrings is presented by A. I. Rabinerson.

Fruit-rot of Cultivated Cucurbitaceæ.—For the past few years in Pusa, India, during the monsoon season, a fruit-rot disease of various members of the Cucurbitaceæ has been doing considerable damage to the fruit, both in the field and in storage. The etiology of the disease has been determined by Mitra and Subramaniam (*Mem. Dept. of Agri. of India, Bot. Series*, vol. 15, No. 3). The causal organism is ***Pythium aphanidermatum*** (Eds.) Fitz., which has also been reported recently by Drechshler as doing considerable damage to cucumber and egg-plant fruits in the United States of America. This fungus forms a woolly mycelial weft over the surface of the affected fruits, and penetrating inside causes the interior to become soft and watery; decay rapidly follows. It is very common in the field during and after the rains, and most of the fruits lying on the soil or hanging near the ground are attacked. Microscopic examination reveals unseptate mycelium, both in the interior and on the surfaces of the fruits, with large numbers of oogonia, antheridia, and oospores. All the strains grow very well in cultures of different kinds, especially in oatmeal agar, in which sexual reproduction takes place freely. Sporangia and zoospores are not formed in any medium, but can be obtained within six hours, if a little of a culture is placed in a vessel containing water to which has been added some ants killed by boiling water.

DRYING SULTANA GRAPES.—The standard methods for drying sultana grapes are described by A. V. Lyon (Australian Council for Scientific and Industrial Research, Pamphlet No. 6). The fruit is treated by one of three processes prior to the drying, the method chosen depending chiefly on the class of fruit, local climatic conditions, and the capacity of the drying plant. In general, the cold dip and modified temperature caustic dip give the best results in early and mid-harvest periods with good quality fruit. The berries are picked directly on to perforated tins, which are immersed in the desired solution. Since the concentration of the liquid and the duration of the treatment are important factors, preliminary trials are made with the dip to ensure the correct conditions. Details for the adjustment of the concentration according to the condition of the fruit are given. The *boiling dip* consists of a caustic soda solution (approximately 3 lb. in 100 gallons) in which the berries are immersed for 1½ seconds, the bloom being thereby removed and the rate of drying increased. Only slight cracking of the berries results if the conditions are well managed. The *modified temperature caustic dip* closely resembles the boiling dip, except that it is used at 190°-196° F., and at a slightly higher concentration. It is imperative that the proper temperature should be maintained if the browning action of the soda is to be avoided. The *cold dip* consists of a solution of potassium carbonate (approximately 1 lb. in 2 gallons) to which an olive oil emulsion (1½ pints in 50 gallons) is added. The fruit must be immersed for 4 minutes in this case. After dipping, the fruit is drained and immediately spread thinly on drying racks; spraying with the cold dip solution, though not always essential, is recommended, as it hastens the drying and thereby increases the quality of the final product. Cold dipped fruit, in contrast to that treated with the caustic dips, retains its natural colour, and exposure to the sun after treatment is necessary to destroy the pigments. When bleached, a wash is given before the final drying. Care must be taken to avoid bundling partially dried fruit or thick spreading during drying, as uniformity in the sample is essential for good value.

BIOLOGICAL FUNCTIONS OF THE PROTEINS.—In a recent paper Dr. Dorothy Jordan Lloyd defines two biological functions of the proteins (*Biological Reviews*, vol. 3, No. 2). In the first place the amphoteric and colloidal properties of the proteins make them highly sensitive to changes in composition or condition of the cell fluids, thus establishing a relation between the proteins of different cells, and between those cells and the external environment. The inertia of the colloidal particles also gives stability to the system and protects its general equilibrium. Proteins play no part in the metabolic cycle of the living cell, but exist associated with chemically active groupings which play a direct part in the cycle of chemical change, whilst the physical condition of the proteins affects the chemical activity of the complex. A second function attributed to the proteins is that they form the chemical basis of differentiation of species. The various ratios in which the large numbers of amino-acid molecules condense to form protein molecules make possible a multiplicity of detailed structure combined with uniformity of fundamental structure. Dakin and Dale showed that albumins from the blood of hens and ducks, although closely similar in chemical composition, are actually different proteins in the two species. Working along similar lines, Dudley and Woodman pointed out that the casein from sheep's milk is not the same substance as the casein from cow's milk. This biologically specific character of the different proteins is sharply contrasted with the wide distribution of certain chemically active cell constituents such as glutathione, insulin, and cytochrome. Even in the cell nuclei the active chemical groupings seem to be non-specific in character. It is not suggested, however, that the same chemical cycles of metabolism are found universally in the animal and plant kingdoms, for there is plenty of evidence to show that different chemical cycles serving the same end have been produced in the course of evolution. In the animal world various respiratory pigments have been evolved independently and at different times. Proteins in the plant world are found only as intra-cellular substances or as food reserves in the seeds, the protective and supporting tissues being built up from carbohydrates. In animals, on the other hand, protein materials are also used for extra-cellular structures such as the keratins of the epidermis or the supporting fibres of connecting tissue.

THE PROBLEM OF CROCKER LAND.—The publication of the full report of the Crocker Land expedition, led by Dr. D. B. Macmillan in 1913–17 (*Bulletin of the American Museum of Natural History*, 56, 6; 1928), throws interesting light on the possibility of non-existent lands being reported. In 1906, R. E. Peary reported Crocker Land to lie about a hundred and twenty miles north-west of his position on Cape Thomas Hubbard (Heiberg Island). As he sledged towards that site in 1914, Dr. Macmillan on two consecutive days saw 'land' to the west, a hilly, ice-capped land extending through 150°. Its appearance changed very slowly, and it gradually faded in the evening. On the site of Crocker Land in 82° 30′ N., 108° 22′ W., there was no sign of land within the range of view in any direction. But on his return, Dr. Macmillan, from Peary's view-point on Cape Thomas Hubbard, again saw extensive 'land' from south-west to north-north-east. These were obviously mirages, but their persistence in that area may indicate land farther west, though this is improbable. Yet the pack ice on the site showed a much broken appearance, indicating the existence of cross-currents which occur only in the vicinity of land. Recent transpolar flights have given no indication of land in that area. Low and snow-covered land might, however, be indistinguishable from pack ice.

MARSHALL ISLANDERS' CHARTS.—In a lecture before the Royal Geographical Society on May 14, Sir Henry Lyons directed attention to five examples of sailing charts made by the Marshall Islanders, lent to the Science Museum by the Royal Colonial Institute. Only a few of these charts are known, and the present collection supplements the accounts of similar charts published in 1898 by Capt. Winkler and in 1902 by A. Schück. Narrow strips of the mid rib of a palm leaf are tied in certain positions by lengths of palm fibre. The relation of the strips to one another gives the information which the chart is designed to provide. The strips represent the wave front of the swell caused by prevalent winds. Curved rods indicate that the swell movement is checked in the neighbourhood of an island; where two swell fronts meet, rough water may be expected. Currents near islands are sometimes shown by short straight strips. Islands are marked, but only approximately, by small shells tied to the frame-work. Some of the simpler charts were made only for instructional purposes. The more complicated ones are not drawn to scale and are difficult to decipher with any degree of accuracy, but they are so frail that they can scarcely have been used on canoe voyages. The construction of these charts was kept a secret by the chiefs, and consequently it is difficult to be certain as to their full meaning and use.

Electrical Conductivity.—The principles of the wave mechanics appear very clearly in an application of it by W. V. Houston to the problem of electrical conductivity. His work, which appears in the *Zeitschrift für Physik* of May 7, is an extension of Prof. Sommerfeld's revived electron theory of metals, already widely applied since its announcement last October. Each electron is treated as a system of waves occupying the whole of the metal, and its motion is supposed to be determined by the diffraction of the waves in the crystal lattice of the positive ions, conduction being thus referred to an interference phenomenon. The effect of increase in temperature is to make the thermal vibration of the positive ions more violent, and so permit of greater diffraction in the distorted lattice, most of the electrons being unaffected at low temperatures, because their wavelength exceeds the grating constant. Impurities in the metal are equivalent to a more or less periodic fault in the normal lattice, and the effect of this upon the motion of the electrons is the analogue of the production of 'ghosts' by errors in a ruled grating. The mathematical development of these ideas leads without further assumptions to a very satisfactory account of the temperature coefficient of resistance, except in the region of super-conductivity. The weak point of the theory appears to be that in other applications a definite form has to be assumed for the electric field of an ion, but even then the agreement with experiment is remarkably good.

Platinum Alloys in Thermionic Valves.—The American Telegraph and Telephone Company, which manages the long-distance communication arrangements of the United States, is very busy this year. It has to erect nearly a million poles, and the lengths of the underground and aerial systems to be installed amount to about three and a half million miles. It will soon complete a second cable route between New York and Chicago. For much of the success the company has achieved it is indebted to the thermionic valve repeater. In the *Bell Laboratories Record* for April, J. E. Harris describes the manufacture of the platinum alloys used in manufacturing the valves. It appears that a platinum alloy is used because there is no chemical action between it and the barium and strontium oxides with which it has to be coated. It is found that chemical reaction weakens the thermionic activity of the coating when metals such as tungsten are used. The platinum used in the alloy has a purity of not less than 99·98 per cent. The purity can be determined at once by the thermal electromotive force developed between the sample and a standard piece of metal. Frequent use is also made of the spectroscope to detect minute impurities. The platinum and alloying metals are melted in a high frequency induction furnace, the temperature attained being about 1750° C. The final diameter of the wires from which the wire ribbon required for the repeater is rolled vary from one to thirteen thousandths of an inch. Although platinum is twenty times heavier than water, an ounce of the metal can be drawn into a mile and three-quarters of the finest wire used in this work. Within recent years, improvements in the core and the coating and pumping processes have increased many fold the life of the thermionic repeaters. This enables the service to be improved and has effected considerable economies.

The Equilibrium between Alcohols and Salts.—The *Journal of the Chemical Society* for March contains an account of an investigation by E. Lloyd, C. Brown, D. Bonnell, and W. J. Jones of the equilibrium between alcohols and salts. They have determined the solubilities of a large number of salts in methyl and ethyl alcohols, and of a few salts in higher alcohols. A number of alcoholates have been isolated and their dissociation pressures at various temperatures measured. This paper includes a discussion of the variation of alcohol vapour–air mixtures from the ideal gas equation, and the Van der Waals' equation. The authors also point out that in many cases of alcohols and salts, solvation, ionisation, and alcoholysis are not the only reactions which take place. Thus, above 50° C., ferric chloride solutions in methyl or ethyl alcohol evolve chloroform and deposit a red precipitate.

The Synthesis of Ammonia by Alpha Rays.—The *Journal of the American Chemical Society* for March contains an account by S. C. Lind and D. C. Bardwell of the effect of the α-radiation of radon on a mixture of nitrogen and hydrogen in the proportion of 1 to 3 by volume. The gas flowed through a glass bulb at the centre of which was mounted a thin α-ray bulb and the ammonia formed was absorbed by water. The rate of synthesis of ammonia was determined by titration with acid and the yield was found to be 0·2 to 0·3 molecule of ammonia for every pair of ions produced in the gas. In comparison with other gas reactions taking place under α-radiation, the ionic efficiency is low and it is difficult to derive the mechanism of the reaction. The possibility that *ions* of both gases are involved is interesting, in view of the fact that B. Lewis has recently found that for the synthesis of ammonia both the nitrogen and the hydrogen require activation.

A New Device for Reading Burettes.—We have received from Messrs. Andrew H. Baird, of Edinburgh, a simple device, named Hyman's burette-reader, which will be very serviceable to those who are constantly using burettes. A strip of transparent celluloid is firmly fixed by two pins upon a larger strip of opaque celluloid, which is divided into an upper white and a lower black portion by a sharp straight edge. The upper edge of the transparent slip is made to coincide exactly with this division, and the burette is pushed between the strips. The device, which costs ninepence, greatly facilitates the reading of the meniscus and, with the aid of a lens, the estimation of fractions of the intervals engraved on the burette. Since the edge of the transparent cover is viewed against the sharp dividing line there is no danger of any parallax error.

The Elements of Wave Mechanics.[1]

THE path of a material particle of mass m moving in a conservative field of force in which the potential energy V is a function of position (x, y, z) only is determined by Hamilton's Principle. If E is the constant total energy and A and B the points of departure and arrival, this may be expressed in the form

$$\delta\int_A^B \sqrt{2m(E-V)}\,ds = 0. \qquad . \quad . \quad (1)$$

Consider a group of light waves emitted at A in a suitably dispersive medium. The path of the light which reaches B is determined by Fermat's Principle

$$\delta\int_A^B \frac{1}{u}\,ds = 0,$$

where u is the wave velocity. If in this relation we put $u = \dfrac{E}{\sqrt{2m(E-V)}}$, thereby determining the character of the medium, Fermat's Principle gives for the path of the light the condition

$$\delta\int_A^B \frac{\sqrt{2m(E-V)}}{E}\,ds = 0, \qquad . \quad . \quad (2)$$

which is exactly equivalent to (1), and hence the path of the light given by (2) is in this case the same as the path of the particle given by (1). If we now determine the frequency ν of the light waves by the relation

$$\nu = \frac{E}{h}, \qquad . \quad . \quad . \quad . \quad (3)$$

where h is Planck's constant, the *group* velocity g of the waves is given by

$$\frac{1}{g} = \frac{d}{d\nu}\left(\frac{\nu}{u}\right) = \frac{d}{dE}\left(\frac{E}{u}\right) = \frac{m}{\sqrt{2m(E-V)}},$$

so that g is equal to the velocity of the particle. It follows that under the above conditions the motion of a group of light waves not only follows the same path as the particle, but also that the group velocity is the same as that of the particle at each point of the path. It would therefore be possible to predict the velocity and position of the particle by considering the velocity and position of the corresponding group of light waves. This principle may be regarded as a method of inferring from a problem in geometrical optics the solution of a problem in dynamics.

Now the methods of geometrical optics suffice only when the wave-length is small compared with the obstacles encountered. If this condition is not fulfilled, the wave theory of light must be used. The question then naturally arises as to whether the solution of a small scale optical problem by means of the wave theory can be made to yield the solution of a corresponding small scale mechanical problem. In other words, does there exist a theory of 'wave mechanics' which should be applied to small mechanical systems in a way similar to the application of 'wave optics' to small optical systems? Schrödinger answers this question in the affirmative.

The equation of wave propagation is

$$\nabla^2\phi = \frac{1}{u^2}\frac{\partial^2\phi}{\partial t^2}.$$

To search for periodic solutions of frequency ν put $\phi = \psi(x, y, z)e^{2\pi i\nu t}$ and use the value of u given above,

$$u = \frac{E}{\sqrt{2m(E-V)}} = \frac{h\nu}{\sqrt{2m(E-V)}}.$$

The equation for ψ then becomes

$$\nabla^2\psi + \frac{8\pi^2 m}{h^2}(E-V)\psi = 0. \qquad . \quad . \quad (4)$$

This is Schrödinger's Amplitude Equation, ψ being the amplitude of the periodic function $\psi e^{2\pi i\nu t}$. Solutions of this equation are sought which shall be (i) finite, (ii) single-valued. In the case of the hydrogen atom, the potential energy is $V_0 - \dfrac{e^2}{r}$, where V_0 is a constant chosen to make V positive and e is the charge on the electron. It may be shown[2] that solutions satisfying conditions (i) and (ii) only exist in two sets of cases:

(a) $E = E_n = V_0 - \dfrac{2\pi^2 me^4}{h^2n^2}$, $n = 1, 2, 3 \ldots$

(b) $E > V_0$.

(a) corresponds to Bohr's elliptic orbits, each of which has its appropriate energy E_n. Transference from one orbit to another implies a definite quantum emitted or absorbed. The values E_n are called *eigen* values.

(b) corresponds to the hyperbolic orbits which are not quantised. The frequency in the nth elliptic orbit is given by $\nu_n = E_n/h$. If in the fundamental equation (4) we put $E = E_n$, we get n^2 independent values of ψ called *eigen* functions. The n^2 *eigen* functions appropriate to E_n correspond to the multiplicity of orbits in Bohr's model, the phenomenon known as degeneracy. If, however, as in the Stark effect, an electric field is applied, E_n is split up into n^2 slightly different *eigen* values to each of which corresponds a (now) definite *eigen* function. The combinations of the transitions between the $n_1{}^2$ energy levels corresponding to E_{n_1} and the $n_2{}^2$ energy levels corresponding to E_{n_2} give lines which are theoretically possible. Not all these lines are observed, but the theory accounts for this by yielding zero intensity for the absent lines. A magnetic field has an analogous effect and in this way the results of Stark and Zeeman are accounted for. Thus by the application of an electric or magnetic field the system is rendered non-degenerate and experimental control can be applied to numerical calculations.

If we suppose the system rendered non-degenerate in this way, to E_k there corresponds an *eigen* frequency $\nu_k = E_k/h$ and an *eigen* function ψ_k. It is possible to choose the ψ_k in such a way that they form a complete orthogonal system; *i.e.* so that

$$\iiint \psi_k\psi_l\,dx\,dy\,dz = \delta_{kl},$$

where $\quad \delta_{kl} = 1$ if $k = l$, $\quad \delta_{kl} = 0$ if $k \neq l$.

Schrodinger considers the function

$$\psi = \sum_k c_k\psi_k e^{2\pi i(\nu_k t + \theta_k)}, \qquad . \quad . \quad . \quad (5)$$

where $\Sigma c_k{}^2 = 1$ and interprets $|\psi|^2$ as the electric density ρ. With this assumption an atom in which the only vibrations excited correspond to elliptic orbits will emit like an infinitesimal dipole of moment (M_x, M_y, M_z), where

$$M_z = \iiint \rho z\,dx\,dy\,dz = -\sum_k c_k{}^2 a_{kk} - 2\sum_k\sum_l c_k c_l a_{kl}\cos(\nu_{kl}t + \theta_k - \theta_l),$$

$$a_{kl} = \iiint ez\psi_k\psi_l\,dx\,dy\,dz, \quad \nu_{kl} = \nu_k - \nu_l.$$

It follows that a_{kl} depends only on the nature of the system and not on its state.

---

[1] Based on lectures delivered by Prof. Erwin Schrödinger at the Royal Institution of Great Britain on Mar. 5, 7, 12, and 14.

[2] Cf. A. S. Eddington, NATURE, July 23, 1927, p. 117.

Moreover, $\nu_{kl}=\nu_k-\nu_l$, so that the frequencies of the emitted radiation are the differences of the frequencies of the various orbits. This leads to Bohr's Selection Rule, for the lines not emitted are found by calculation to be just those for which $a_{kl}=b_{kl}=c_{kl}=0$. For linear polarisation parallel to z, say, $a_{kl}\neq 0$, $b_{kl}=c_{kl}=0$. For circular polarisation $a_{kl}=0$, $b_{kl}=c_{kl}$, and the phases differ by $\pi/2$. These results are obtainable by actual numerical computation.

Returning to the amplitude equation (4), we see that the value of ψ given by (5) is not a solution of the amplitude equation, but that it is the sum of solutions of the various amplitude equations obtained by giving E the values E_1, E_2, E_3 . . .

Since

$$\frac{\partial}{\partial t}\left(\psi_k e^{\frac{2\pi i E_k t}{h}}\right)=\frac{2\pi i E_k}{h}\left(\psi_k e^{\frac{2\pi i E_k t}{h}}\right)$$

we can eliminate E_k between this and the equation of type (4) in which $E=E_k$. The resulting equation,

$$\nabla^2\psi-\frac{4\pi m i}{h}\frac{\partial\psi}{\partial t}-\frac{8\pi^2 m}{h^2}V\psi=0, \quad . \quad . \quad (6)$$

where ψ is now written for $\psi_k e^{\frac{2\pi i E_k t}{h}}$, is Schrödinger's Wave Equation and is satisfied by all the $\psi_k e^{\frac{2\pi i E_k t}{h}}$ and therefore by the function ψ of (5). Hitherto V has been considered as a function of x, y, z only. The further assumption is now made that V may also be a function of the time. This enables us to discuss the effect of an alternating field on the atom and leads to Schrödinger's theory of dispersion, that is, the alteration in a primary wave incident on a body of atoms, caused by the disturbance due to the secondary wavelets emitted by the atom under the excitation of the incident primary radiation.

Suppose then that an alternating field $F=A\cos 2\pi\nu t$ is applied in the z direction. We put

$$V=V_1+Aez\cos 2\pi\nu t,$$

where V_1 is the potential energy when $A=0$, the case which has just been discussed, the solution being given by (5). We take A to be small and suppose the c_k of (5) to be now slowly varying functions of the time. If we substitute from (5) in (6), multiply by ψ_l, and integrate throughout space we get, on account of the orthogonal property of the ψ_k,

$$\frac{dc_l}{dt}=\frac{\pi i A}{h}\sum_k a_{kl}c_k\left[e^{2\pi i(\nu_k-\nu_l+\nu)t}+e^{2\pi i(\nu_k-\nu_l-\nu)t}\right], \quad (7)$$

an infinite set of linear equations of the first order.

If $\nu_k-\nu_l\pm\nu$ is large compared with Aa_{kl}/h, resonance is excluded, the frequencies are large and we can suppose the c_k to remain approximately constant. If only the k level is excited, $c_k=1$, and all the others are zero. The z component of the electric moment is found to be

$$M_z=\iiint ez\rho\,dx\,dy\,dz=-a_{kk}+\frac{2}{h}A\cos 2\pi\nu t\sum_l\frac{(\nu_l-\nu_k)a^2_{kl}}{(\nu_l-\nu_k)^2-\nu^2}.$$

The first term is a spontaneous emission coefficient, the second shows that whether the vibrations are in or out of phase depends not only on the sign of $(\nu_l-\nu_k)^2-\nu^2$ but also[3] on that of $\nu_k-\nu_l$. It is also seen that the secondary waves have the same frequency as the incident waves. If two levels, say c_k and c_l, are excited, it is found that the secondary waves are not all of frequency ν, but that some of the secondary radiation is of frequency $\nu\pm(\nu_k-\nu_l)$.

The case of resonance is fundamental. If $\nu_k-\nu_l+\nu=\epsilon/2\pi$, where ϵ is infinitesimal, and if we retain only those terms which contain ϵ in the exponent, the system (7) reduces to

$$\dot{c}_l=i\sigma c_k e^{i\epsilon t}, \quad \dot{c}_k=i\sigma c_l e^{-i\epsilon t}, \quad \sigma=\pi A a_{kl}/h.$$

To solve these put

$$c_l=xe^{i\epsilon t/2}, \quad c_k=ye^{-i\epsilon t/2},$$

so that $$\dot{x}=i\sigma y-\frac{i\epsilon}{2}\cdot x, \quad \dot{y}=\frac{i\epsilon}{2}\cdot y+i\sigma x.$$

If the l level is initially unexcited, $x=0$ when $t=0$, and we obtain, denoting $\sigma^2+\epsilon^2/4$ by p^2,

$$|x|^2=4B^2\sin^2 pt, \quad |y|^2=4B^2\cos^2 pt+B^2\epsilon^2/\sigma^2.$$

Thus the total intensity is

$$|x|^2+|y|^2=4B^2+B^2\epsilon^2/\sigma^2,$$

and the total oscillating intensity is

$$4B^2\sin^2 pt+4B^2\cos^2 pt=4B^2.$$

Hence $$\frac{\text{Oscillating intensity}}{\text{Total intensity}}=\frac{\sigma^2}{\sigma^2+\epsilon^2/4}.$$

If then $\epsilon=0$, the resonance is complete and the total intensity oscillates continually between the k level and the l level. Thus Bohr's orbital jumps may be interpreted as a resonance phenomenon between the exciting frequency and the natural frequencies.

In generalised co-ordinates, the motion of a mass point can be represented by a trajectory AB in space of n dimensions, the co-ordinates of a point on AB being the n quantities required to specify the position and motion. By using a generalised Laplacian ∇^2 appropriate to these co-ordinates the amplitude equation (4) retains the same form. In this way the motion of the nucleus may be taken into account. In the case of the single electron problem, let m_1 be the mass of the electron (co-ordinates x_1, y_1, z_1) and m_2 be the mass of the nucleus (co-ordinates x_2, y_2, z_2). The generalised equation (4) is then

$$\frac{1}{m_1}\nabla_1^2\psi+\frac{1}{m_2}\nabla_2^2\psi$$
$$+\frac{8\pi^2}{h^2}\left(E+\frac{e^2}{\sqrt{(x_1-x_2)^2+(y_1-y_2)^2+(z_1-z_2)^2}}-V_0\right)\psi=0.$$

Now in the Keplerian problem of two bodies, we may regard m_2, say, as fixed and m_1 moving about it, provided that we replace m_1 by the 'combined mass' μ given by $\frac{1}{\mu}=\frac{1}{m_1}+\frac{1}{m_2}$. In the previous discussion m_2 has been regarded as infinite. It has been found that certain hydrogen lines would coincide with certain He$^+$ lines if the Rydberg constant $R=2\pi^2 m_1 e^4/ch^3$ were replaced by $4R$ on the assumption that m_2 is infinite. Sommerfeld has shown, however, that a modified Rydberg constant must be used to obtain exact agreement, got by replacing m_1 by μ. To explain this put

$\psi=\phi$ (co-ordinates of G)

$\times\chi$ (relative co-ordinates with respect to G),

G being the mass centre of the system. The generalised amplitude equation above is now equivalent to the two equations

$$\frac{1}{m_1+m_2}\nabla^2\phi+\frac{8\pi^2}{h^2}E_T\cdot\phi=0 \quad \text{(co-ordinates of } G\text{)}, \quad (8)$$

$$\frac{1}{\mu}\nabla^2\chi+\frac{8\pi^2}{h^2}(E-E_T-V)\chi=0 \quad \text{(relative co-ordinates)}, \quad (9)$$

E_T being the constant energy of translation of G.

(8) refers to the motion of G, while (9) shows that only the energy relative to G is quantised. Schrödinger's method gives *eigen* values for the relative energy $E-E_T$ in terms of the combined mass μ. Thus Sommerfeld's results are retained in the new theory.

L. M. MILNE-THOMSON.

Fisheries of Madras.

Recent work done by the Madras Fisheries Department is detailed in the administration report for the year 1925–26 by the Director, Dr. B. Sundara Raj (*Madras Fisheries Bulletin*, vol. 21, pp. 1-94. Madras. 2 rupees, 4 annas. 1927). This report deals mainly with the commercial development of the department as applied to fish, pearl, and chank (a gastropod, *Turbinella pyrum*) fisheries. The fish cannery at Chaliyam was not a success, but it is hoped that with the help of Sir F. A. Nicholson in the management of its experimental and manufacturing operations, the cannery will improve. At Tanur, researches were continued in the methods of curing fish for sale in the interior markets, of avoiding saline excrescences in semi-dried prawns, of manufacturing paint oil, and of refining sardine oil to take the place of cod-liver oil. Attempts in preparing fish-meal from sardines with a low fat content had to be abandoned for want of material. Investigations for improving the resources of edible fish in inland waters have been continued. It has been observed that the fish gourami (*Osphromenus sp.*) feeds voraciously on certain common garden shrubs, and that the tench and the English carp can be acclimatised.

In 1926, after a lapse of more than a quarter of a century, a pearl fishery was commenced on Feb. 17 at Tuticorin. The time-honoured method of fishing and of disposing of the oysters was in vogue, except for the fact that the lots for sale were not counted, but weighed out according to the average weight of 1000 oysters worked out every morning. Considerable success attended the fishery, yet the fishing operations had to be closed on Mar. 27 on account of an outbreak of cholera in the camp. In spite of the short period of fishing, the Government made a net profit of Rs. 136,417. The chank fishery was an improvement on the previous year, though the best chank diving season coincided with the pearl fishery.

The marine aquarium continued to be popular. It is proposed that if the suggested biological station at Krusadai Island is established, other aquaria at Rameswaram and at Vizagapatam should be established with facilities for conducting scientific research and for popularising natural history among the Indians. It is very gratifying to note that the Fisheries Department is endeavouring to introduce elementary education to the children of the fishing population, to organise and to spread the co-operative movement, and to promote temperance and the social and economic advancement of the country.

University and Educational Intelligence.

Cambridge.—Sir Archibald Denny, Bart., has offered to endow an annual prize of £15 for the student who does best in the theory of structures in the Mechanical Sciences Tripos.

Leeds.—By the will of the late Mr. F. C. Clayton, a sum of £2000 has been provided to establish a scholarship of £100 a year, to be called the "Richard Reynolds Scholarship," tenable in the University by a student qualified to benefit by the same in the study of chemistry or pharmacy. Miss Florence Watts and her sister have presented a collection of photographs, scientific apparatus and specimens, in memory of their uncle, the late Sir Edward Thorpe.

With the object of assisting the further development of the research work of the Textile Industries Department, the Clothworkers' Company is making an additional grant to the University at the rate of £3000 a year for the next four years. Since the foundation of the Yorkshire College, donations and annual grants of more than a quarter of a million pounds have been received from the Company. The new building will be officially opened in October. It will allow of extension of the Textile Museum, improved laboratories for the Silk Research Association, and the extension of the mechanical and scientific equipment of the Textile Industries Department. The new grant of £3000 a year will allow of additions to the research staff, and of the award of a number of post-graduate fellowships or scholarships for research in both the Textile Industries and the Dyeing Departments.

The following lectures in metallurgy have been arranged for by the Armourers and Brasiers' Company: At the Royal School of Mines, at 5.15, on June 4, 11, and 18, by Mr. G. Mortimer, "The Founding of Aluminium and its Light Alloys." At the Battersea Polytechnic, at 7, on June 5, 12, and 19, by Dr. J. M. Robertson, "The Heat Treatment of Steel." Admission will be free, and no tickets will be required.

Applications are invited for the Dickinson Research Travelling Scholarship in Medicine, value £300, and tenable for one year. Candidates must be university graduates who have taken the full course of clinical instruction required by their examining bodies in the Manchester Royal Infirmary and the University of Manchester, and have earned distinction in so doing. Applications (in each case six in number) should be sent not later than June 14 to Mr. F. G. Hazell, Secretary to the Trustees, Manchester Royal Infirmary.

A course of three advanced lectures in anthropology will be given at the London School of Economics on June 4, 5, and 6, at 5 p.m., when Dr. Marcel Mauss, Director of the École des Hautes Études (Sorbonne) and professor at the Institut d'Ethnologie of the University of Paris, will lecture on "The Theory of the Elementary Forms of Prayer (Australia)." The course will cover the definition of prayer, the general characteristics of prayer formulæ, the formulæ of religion, totemic and initiation cults, and dramatic, magic and negative ritual. The chair will be taken at the first lecture by Dr. E. Westermarck, Martin White professor of sociology in the University of London. Admission is free without ticket.

University College, London, announces in its recently issued annual report that the total number of its students in 1926–27 was 3218, showing a decrease of ten. Excluding evening (456) and vacation-course students (290) the figures show an increase of 46. Students from parts of the Empire outside the British Isles numbered 287; those from other countries in Europe, 417 (including 212, chiefly vacation-course students, from Germany); and those from foreign countries outside Europe, 152, of whom 60 were from the United States of America. There were 1376 students in different stages of the degree course, and 534 post-graduate and research students. The College has for many years taken an active part in promoting adult education by providing public lectures open without fee. More than 8000 persons attended these lectures during 1926–27, the approximate aggregate number of attendances being 18,678. The report contains a record of the centenary celebrations, including the most important speeches and addresses. The centenary fund amounted, at the time the report was printed, to £178,445, and has since risen to above £200,000. The appeal was for £500,000.

Calendar of Customs and Festivals.

(Addendum to May) May 17.

In Morocco, the first day of summer, known as *Mût l-arḍ*, "the death of the ground." No one may sleep on this day under penalty of losing his courage, while a wife is in danger of losing her husband's affections. Among the Tsûl, to avert evil influences everyone rises at daybreak and has a bath; this is said to strengthen the body, as the water this morning, coming from the well Zemzem, has special virtue. The magic of the death of the earth is used in various ways, especially in connexion with preparations of barley, for charms and magical purposes. But it is also the commencement of a new season. Therefore the women of the Aiṭ Ṣáddĕn fill their handmills with wheat and cover them up; the men of the Aṭ Ubáḥṭi buy new clothes for themselves and their women.

June 3.

TRINITY SUNDAY.—That Trinity Sunday, said to have been instituted by Beckett, was also a popular festival of older standing is suggested by the number of fairs held about this date, and also by the processions with garlands of flowers and ribbons which took place in many localities on this day. Aubrey, in his "Miscellanies," describes a garland ceremony at Newnton when, after prayers had been read, an exchange of a garland and a money gift took place between a maid and a bachelor of another parish.

In Carnarvonshire an offering was made of calves and lambs bearing the mark of St. Beuno, a natural mark on the ear, in the church of Clynnok Vaur. The beasts were sold and the proceeds used for the benefit of the poor or for repairs. At Paignton Fair, held at Exeter, as described in an account of 1809, an immense plum pudding decorated with ribbons and evergreens was drawn through the town by eight oxen, and then distributed among the people.

June 4.

TRINITY MONDAY.—An annual fair, lasting until Wednesday, was held at Southampton. This was declared open by the Mayor, who erected a pole on which was a glove. A bailiff held the jurisdiction of the fair, and no one might be arrested within its precincts. At the close of the fair the glove was shot down by the young men. A fair was also held at Deptford on this day, when the Master and Brethren paid their annual visit to Trinity House.

June 6.

EVE OF CORPUS CHRISTI.—In Wales this was specially regarded as a health-restoring time, when it was customary for those suffering from any ailment to kneel before the altar and pray for recovery. In North Wales, at Llanasaph, green herbs and flowers, and St. Caerwis ferns, were strewn before the doors of the houses.

June 7.

CORPUS CHRISTI.—Instituted by Pope Urban in 1264 to celebrate the doctrine of Transubstantiation. In England it became in a special sense a community festival, in which the civic authorities took part, and the guilds were required to provide a pageant. Although the religious element declined in importance at the Reformation, the civil celebration continued for some time. Thus it is recorded that down to Queen Mary's day, the Skinners' Company went in procession on this day, with two hundred clerks, the officers of the Company, the Mayor and Aldermen in scarlet, and then the Skinners in their livery. At Norwich the crafts or companies, each with its banner, marched from the Common Hall around the market and back.

It is, however, on account of the performance of religious or 'mystery' plays, that the celebration of Corpus Christi is best known. A record at Newcastle-on-Tyne, dated 1426, mentions the Merchant Adventurers as concerned in the production of five plays, and no doubt other companies, drapers, mercers, etc., each one responsible for at least one. One of the most celebrated of the Corpus Christi performances was at York, but the Chester and Coventry plays were almost, if not quite, as important. Every trade in the city was obliged to furnish a pageant at its own expense—each individual had to personify some particular passage in the Old or New Testament. The part played by the miracle as well as the mystery in the development of the drama is too well known to call for comment; but here again it must be noted that the Church had adapted a popular custom to its own uses, as it had adopted the pagan dance, and had brought its performance, at least in the case of the miracle play, within the church walls.

The mystery play at Corpus Christi and the miracle play at Christmas, like the great classical drama of Greece, which itself was attached to a religious festival, grew out of, or was an adaptation of, a rustic performance which survived in Greece in the satyric drama, and in England in the folk-drama. This, as played by itinerant mummers, lasted in the north of England to within living memory, and has now been revived in a number of localities. That this popular English folk-drama was originally of a ritual character is shown by its uniformity in structure and motive—a combat in which one of the characters is slain and brought to life again by the 'doctor'; in other words, a dramatic representation of a ritual death and resuscitation.

June 8.

On the first Friday after Trinity, Coventry Fair opened, lasting for a week. It was one of the most famous of the English fairs, in which was represented the ride of Lady Godiva through the city, by which it was freed from the exactions of her husband Leofric.

June 9.

ST. COLUMBKILLE or COLUMBA, Abbot of Iona and Apostle of Caledonia, A.D. 597, next to St. Patrick the most famous of Irish saints. He was of royal family, belonging to the Dal Ariadha, said to be of Pictish extraction. His birth was foretold long before Christian times in a vision to his royal ancestor, Fedhlimidh Reachtmhar, and also by the renowned Finn Mac Cumhaill.

St. Columbkille is associated both with holy wells and with holy stones. The stone on which he was born of his mother Ethnea from that time seemed marked with a cross, and to another reddish-coloured stone, called Cloch Ruadh, long preserved in a gold and silver case at Rathen, great efficacy was attributed when it was borne to houses in which were infirm persons in danger of death, and also in cases of difficult parturition. A flat slab is still said to be the bed of his birth, four indentations in the surface having been made at the time by his mother. It was once the object of the peasants' pilgrimage, and stations are still made there on the saint's festival.

At the parish of Clonmany, Co. Donegal, of which St. Columbkill is titular saint, it was the custom on his festival day to drive cattle down to the beach and swim them where the water of St. Columb's well runs into the sea.

Societies and Academies.

LONDON.

Geological Society, May 9.—**W. B. R. King**: The geology of the district around Meifod (Montgomeryshire). The general succession is summarised as Salopian, Valentian, (unconformity), Ashgillian, Caradocian. The Caradocian can be divided into six subdivisions, each characterised by a special fauna, probably controlled by the type of sedimentation and food-supply rather than by time. The evidence of marked unconformity at the base of the Silurian is striking at certain localities, and in conjunction with the ground on the east shows that the base of the Lower Valentian gradually transgresses the Ashgillian until some 1200 feet of strata are cut out. The fact that the whole of the Gala, from the zone of *Monograptus turriculatus* to that of *M. crenulatus* inclusive, is represented by some 300 feet of fine grey and maroon shales, is in striking contrast with the developments in Shropshire and central Wales.

EDINBURGH.

Royal Society, May 7.—**G. S. Carter**: A zoological expedition to Brazil and Paraguay in 1926–27 (Address). A year was spent on zoological investigations by the author and Mr. L. C. Beadle. On the way to the Paraguayan Chaco, where most of the work was done, six weeks were devoted to collecting zoological material along the line of the new railway from São Paulo to Porto Esperanza on the Paraguay. The aim of the expedition was (1) to collect and bring home young larvæ of Lepidosiren with the intention of breeding them to maturity at Glasgow; this was accomplished without difficulty; (2) to study the conditions of life in the swamps of the Chaco. As a result of investigations of several physical and chemical characteristics of the water of these swamps, it was found that, of the characteristics studied, the oxygen-content of the water was the condition of greatest bionomic importance. It was very low, and the fauna, especially the fishes and the oligochætes, showed adaptations to the satisfying of this need. The shortage of oxygen in these waters is due to several conditions which must occur in many other tropical waters, but not in those outside the tropics.—**D. A. Allan**: The geology of the Highland border from Tayside to Noranside. The rocks of the serpentine belt are of pre-Old Red Sandstone age, and are bounded to the south by the Highland Boundary Fault, the course of which has now been determined, and further evidence of its reversed nature found. A new exposure of Highland Boundary rocks has been found in the valley of the Prosen. A sequence of Lower Old Red Sandstone lava flows and sediments, the latter mainly conglomerates, has been proved throughout the area, an important new datum line being the Lintrathen porphyry, hitherto regarded as intrusive, but now demonstrated to be a dacite lava flow of wide extent and constant stratigraphical horizon. Contemporaneous erosion of considerable importance occurred during Lower Old Red Sandstone times. An interesting series of normal faults was mapped in the vicinity of the Highland Boundary reversed fault, and it is suggested that they correspond to the phase of relief of pressure immediately following upon the compression, fracture, and over-riding of the Lower Old Red Sandstone strata.—**F. Walker** and **J. Irving**: Igneous intrusions between St. Andrews and Loch Leven. The intrusions between St. Andrews and Loch Leven are mainly sills, and include olivine-dolerites, teschenites, nepheline-basanites, monchiquites, and quartz-dolerites, the first four types being probably consanguineous. The quartz-dolerites, which are very abundant, occasionally contain analcite. At several localities the published maps have been modified, the most important alteration being the inclusion of the twin Lomond peaks amongst the volcanic necks of the district. All the igneous rocks under consideration are probably of Carboniferous age.

PARIS.

Academy of Sciences, April 30.—The president announced the death of Félix Lagrange, *correspondant* for the Section of Medicine and Surgery. **Charles Moureu, Charles Dufraisse**, and **Louis Girard**: Researches on rubrene (7). The dissociation pressure of rubrene peroxide at the ordinary temperature. The peroxidation of rubrene in solution by free oxygen under the influence of light is a reversible phenomenon and the dissociation pressure of the peroxide is appreciable at the ordinary temperature (of the order of 5 mm. of mercury). Attention is directed to the analogy between the peroxidation of rubrene and of hæmoglobin.—**Pierre Termier** and **Eugène Maury**: New geological observations in eastern Corsica: the upper Jurassic: the primary strata prior to the granite.—**Gabriel Bertrand** and **Georges Nitzberg**: The ketonic function of α-glucoheptulose. From the colour reactions with orcinol and phloroglucinol in dilute hydrochloric acid, stability towards bromine water, and the reduction products with sodium amalgam, the new reducing sugar obtained by the action of the sorbose bacterium on α-glucoheptite was shown to be ketonic.—**H. Vincent**: Some non-colloidal substances with cryptotoxic properties. It has been proved in earlier publications that various colloidal substances, many of them soaps, possess the property of neutralising microbial toxins, such as the toxin of tetanus. It has now been found that other substances, not colloidal, possess a similar property, although generally to a less extent. Sodium salicylate has proved to possess the most marked activity in this respect. After the addition of 5 per cent or less of a saturated solution of sodium salicylate to a solution of tetanotoxin, a quantity representing from 200 to 400 fatal doses can be injected into a guinea-pig without inconvenience, and with further doses the animal can be immunised. Experiments with rabbits gave similar results.—**Léon Guillet**: The applications of the addition of nitrogen to certain special steels: The extreme hardness obtained by nitriding certain steels suggests interesting applications in motor-car construction.—**J. Favard**: Algebraic numbers.—**P. Vincensini**: Congruences of normals in their relations with certain rectilinear congruences.—**Bertrand Gambier**: Geodesic lines, lines of zero length, lines of constant total curvature.—**W. Břečka** and **J. Geronimus**: The monotone polynomials deviating least from zero.—**Georges Valiron**: Circles of *remplissage* of meromorph functions.—**Arnaud Denjoy**: Series of rational fractions.—**J. Haag**: The calculation of certain elastic deformations, with application to the plane spiral.—**E. Carafoli**: The general movement round a contour.—**F. Wolfers**: Remarks on the theory of light. Energy, coherence, and supplementary fringes.—**J. Cabannes**: A new optical phenomenon. The beats which are produced when anisotropic molecules in rotation and vibration diffuse visible or ultra-violet light.—**F. Holweck**: The production and absorption of the *K*-rays of aluminium.—**Maurice François**: The preparation of mercurammonium iodide, $Hg_{\text{[illegible]}}N_{\text{[illegible]}}I_{\text{[illegible]}}$, in the crystallised state.—**Édouard Urbain** and **Victor Henri**: The formation of ammonia in the preparation of phosphorus. Charcoal impregnated with phosphoric acid is heated to 900° C. in a quartz tube in a current of nitrogen. Under these conditions the nitrogen is converted into ammonia.—**Charles Prévost**: Erythrene and its dibromides.—**Bourguel**: The phenylpropines.—**André Meyer**: The products of condensation of homophthalimide with aromatic aldehydes.—**J. Bougault** and **L. Daniel**: The sulphoxytriazines.—**Maurice Nicloux**: The oxidation of glucose in alkaline solution by oxygen or by atmospheric air. The formation of carbon monoxide. The oxidation of glucose in alkaline solution by gaseous oxygen gives carbon monoxide, carbon dioxide, and other oxidation products. The optimum conditions as regards alkalinity and temperature for the maximum production of carbon monoxide have been worked out. —**J. F. Durand**: A synthesis of quinone (rectification). Correction of a note in the *Comptes rendus*, 192, 1927. The experiment described in the previous note cannot be repeated, and the author concludes that a mixture of acetylene and carbon monoxide acting on solutions of cuprous chloride in pyridine does not give quinone.—**Louis Barrabé**: The Callovian at Madagascar between Cape Saint-André and Betsiboka.—**J. Jung** and **P. Geoffroy**: The efficacity of the method of magnetic prospecting for the detection of faults in the Oligocene of Alsace. The instrument generally used for the determination in absolute measure of the horizontal component was used for this survey and was found to be very useful in detecting the directions of certain faults affecting the Oligocene. It may prove to be of use in prospecting for petroleum in Alsace.—**Léon Bertrand**: The general metamorphism of the secondary strata in certain parts of the Pyrenees.—**H. Besairie**: The existence of *Syringopora* limestones in the south-west of Madagascar.—**H. Buisson**: Measurements of the ozone in the upper atmosphere during the year 1927. The method used was based on the use of a spectrograph with quartz prisms and measurement of the ozone bands. There is a large annual variation with a maximum of about 400 in the spring and a minimum of 200 in the autumn. The results are in general agreement with those of Dobson and Harrison and of Gotz.—**L. Lutz**: The influence exerted by the support on the morphological characters of the birch *Polyporus*. Contribution to the study of the antioxygen rôle of tannin. Oak wood is normally invulnerable to this fungus, but the removal of the tannins by systematic washing with water renders it liable to attack.—**G. Ollivier**: The *bromuques* of certain Ceramiaceæ. *Bromuque* is the name given by C. Sauvageau to certain plant cells, which redden under the influence of fluorescin, a reaction attributed to free bromine. The application of Sauvageau's reaction to fresh specimens of *Ceramium* has proved the presence of these cells in seven species, *C. byssoideum* showing them in the greatest abundance.—**B. Ganossis**: The deflocculation and plasmolysis of soil coatings.—**E. Roubaud**: The maternal influence in the determinism of acyclic asthenobiosis.—**L. Léger** and **C. Motas**: Parasitism and the phenomenon of transport of a Hydracarian in *Cricotopus biformis*. —**Maurice Piettre** and **André Chrétien**: Application of the acetone method to the study of the distribution of the antibodies in agglutinating sera in the course of immunisation.—**Y. Manouélian** and **J. Viala**: Lesions of the walls of the mouth and tongue in mad dogs.

CAPE TOWN.

Royal Society of South Africa, Mar. 21.—**A. Ogg**: Some aspects of modern physics (Presidential address). —**J. L. B. Smith** and **K. A. C. Elliott**: The essential oil of *Agathosma Microphylla*. *Agathosma Microphylla* or 'Stembok Buchu' is a short stunted shrub which grows in patches on the seaward side of the coastal hills, being found fairly extensively about Knysna and in neighbouring districts. It gives off a strong aniseed-like odour which is very noticeable in the still valleys where it flourishes. The oil content of the dried leaves appears to vary with the season, from 2 to 3 per cent of volatile oil when collected in summer, and as much as 5 per cent when collected in winter. Air-dried leaves yielded by distillation in steam a clear yellow oil of powerful odour, the chief constituent of which is methyl chavicol.—**Sir Thomas Muir**: Note on $(n-1)$-by-n arrays whose primary minors have a common factor.—**Theodora B. Auret**: Observations on the reproduction and fungal endophytism of *Lunularia Cruciata* (L) Dumortier. Female plants of this species are found in South Africa on slightly alkaline soil. Male plants and the sporophyte generation are not known. The gametophyte harbours a fungus which is confined to a definite zone below the assimilating tissue. The fungus has been identified as a species of Phoma. The association between the liverwort and the fungus is not a case of true symbiosis, but rather one of harmless parasitism.—**F. E. Fritsch** and **Florence Rich**: Contributions to our knowledge of the freshwater algæ of Africa. (7) Freshwater algæ (exclusive of diatoms) from Griqualand West. 183 species are recorded, 33 of which are new or represented by new varieties, and the total number of genera represented is 69, of which one is new (*Raphidiopsis*, a member of the Rivulariaceæ). Particular interest attaches to the discovery of two new species of *Sphæroplea*. There is another species of the hitherto monotypic genus *Centritractus*, and a highly peculiar new *Phacus*, *P. anomala*.

WASHINGTON, D.C.

National Academy of Sciences (*Proc.*, Vol. 14, No. 3, March).—**W. L. Ayres**: On the separation of points of a continuous curve by arcs and simple closed curves. —**H. Hopf**: On some properties of one-valued transformations of manifolds.—**G. A. Miller**: Harmony as a principle of mathematical development. Throughout mathematics, progress has implied greater intellectual harmony and is seen, for example, in the way in which the equation has steadily displaced the proportion. Increase in accuracy of knowledge generally discloses new elements of discord; hence the principle of harmony is a source of inspiration and also a guide to the novelty of the results obtained.—**Einar Hille**: Note on the behaviour of certain power series on the circle of convergence with application to a problem of Carleman.—**H. S. Reed**: Intra-seasonal cycles of growth. Lemon shoots generally show three distinct cycles of growth during a single season. The growth curves suggest a series of autocatalytic actions due to the periodic activity of a growth-promoting substance.—**Sophia Satina** and **A. F. Blakeslee**: Studies on the biochemical differences between sexes in Mucors. (4) Enzymes which act upon carbohydrates and their derivatives. It has been suggested that sucrase is present in one sex and not in the other. Mucors of varying habit were grown in different nutrient media, each containing a carbohydrate attacked by a specific enzyme. No enzyme tested for was found to be limited to one sex. Trehalose, maltose, and salicin were found to be the best carbohydrates for growth.—**Dontcho Kostoff**: Induced immunity in plants.—**Selig Hecht**: On the binocular fusion of colours and its relation to theories of colour vision. With a red filter before one eye and a green filter transmitting light of about the same brightness before the other (for example, Wratten 29 and 58), a brightly illuminated white surface on a black background appears yellow; similarly, yellow and blue filters make a binocular white. Thus the red (or yellow) sensation in one retina and the green (or blue) sensation on the corresponding retinal area of the other eye results in a yellow (or white) sensation, which arises in the brain. No special receptors in the retina for yellow or white are therefore necessary and the uniqueness of yellow and white as sensations is not opposed to Young's three-receptor mechanism of colour vision.—**Willem J. Luyten**: On the motion of the Magellanic Clouds. Only a very speculative computation is possible, and this indicates that the path of the clouds with respect to the Galactic System may deviate appreciably from a straight line and that they are permanent members of our galaxy.—**Albert Titlebaum**: Artificial production of Janus embryos of *Chætopterus*. Double embryos were obtained by compressing the eggs between slide and coverslip; pressure applied shortly after the extrusion of the second polar body gives the best results. It appears to be correlated with the equal distribution of the 'polar lobe' substance between the two blastomeres in the first cleavage.—**Carl Barus**: Anode and cathode sparks differentiated by the mucronate electrode.—**R. C. Gibbs** and **C. V. Shapiro**: A spectroscopic criterion for the benzenoid structure in some types of triphenylmethane derivatives. The absorption spectra of compounds of benzenoid or lactoid structure in neutral alcoholic solution include a pair of bands with average separation of about 100 mm.$^{-1}$ in the region 3500–3700 mm.$^{-1}$; both are relatively weak but of the same intensity, and the average molecular absorption coefficient is always of the same order of magnitude.—**Boris Podolsky**: The dispersion by hydrogen-like atoms in undulatory mechanics. Terms of the order of relativistic correction are neglected.—**Joseph Kaplan**: The production of active nitrogen. The discharge tube contained air at 5 mm. pressure; the discharge was condensed and a spark gap connected in series with tube and condenser. The glow was blue, changing to yellow-green with continuous spectrum when the spark gap was excluded. Second and fourth positive bands of nitrogen were identified.—**J. R. Oppenheimer**: On the quantum theory of the Ramsauer effect.—**Norbert Wiener** and **D. J. Struik**: The fifth dimension in relativistic quantum theory. The fifth dimension is introduced to account for the phenomena of incoherency and the atomicity of electricity.—**Richard C. Tolman**: On the extension of thermodynamics to general relativity. Two principles expressed in equations true for all sets of co-ordinates, which are the analogues of the first and second laws of thermodynamics, are discussed.—**William Rule**: On the variation of the electromotive force in a photoactive cell, containing a fluorescent electrolyte, with the intensity of illumination. Two quartz 'boxes' containing fluorescein solution, connected by a quartz capillary and with central platinum wire electrodes, are used, enclosed in an air-tight case, and one cell is illuminated. This method is considered to eliminate diffusion effects. The electromotive force generated increases with increase of intensity of illumination for a given time, tending to a maximum, and its variation with intensity is roughly paralleled by the variation with exposure. The results support the view that photochemical changes take place in the fluorescent electrolyte.—**A. W. Simon**: A note on corona at high humidity. Parallel copper wires were hung parallel to and equidistant from two parallel steel plates near an open window. Ordinarily, on applying a high voltage (plates positive), heavy visual corona appeared and persisted until an arc struck. On very wet days no corona was visible, the current to the plates was much reduced, and intermittent sparking occurred, possibly due to reduced mobility of the negative ions.—**H. N. Russell**, **K. T. Compton**, and **J. C. Boyce**: The spark spectrum of neon (v. Nature, Mar. 10, p. 357).—**Edwin B. Wilson**: On hierarchical correlation systems.

Official Publications Received.

British.

The Journal of the Imperial College Chemical Society. Vol. 7, containing Papers read during the Session 1927–1928. Pp. 68. (London.)

Report of the Kodaikanal Observatory for the Year 1927. Pp. 6. (Calcutta: Government of India Central Publication Branch.) 6 annas.

Commonwealth of Australia: Council for Scientific and Industrial Research. Bulletin No. 34: The Biological Control of Prickly Pear in Australia. By A. P. Dodd. Pp. 44+9 plates. Pamphlet No. 7: The Export of Oranges. By W. Ranger and Prof. W. J. Young. Pp. 12+8 plates. (Melbourne: H. J. Green.)

Transactions of the Royal Society of Edinburgh. Vol. 55, Part 3, No. 30: Pollination and Seed Production in the Rye-Grasses (*Lolium perenne* and *Lolium italicum*). By Dr. J. W. Gregor. Pp. 773–794. 2s. 9d. Vol. 55, Part 3, No. 31: Sporangial Variation in the Osmundaceae. By Dr. S. Williams. Pp. 795–805. 1s. 6d. (Edinburgh: Robert Grant and Son; London: Williams and Norgate, Ltd.)

Diary of Societies.

SATURDAY, June 2.

Royal Society of Medicine (Laryngology and Otology Sections).—Prof. G. Portmann: Vasomotor Affections of the Internal Ear.—W. S. Sharpe: The Influenzal Ear.

MONDAY, June 4.

Royal Society of Edinburgh, at 4.30.—G. L. Purser: *Calamoichthys calabaricus* (J. A. Smith). Part 1. The Alimentary and Respiratory Systems.—P. R. C. Macfarlane: Salmon (*Salmo salar*) of the River Moisie (Eastern Canada), 1926–1927.—Prof. R. A. Sampson: The Present-Day Performance of Clocks.

Victoria Institute (at Central Buildings, Westminster), at 4.30.—Dr. J. A. Fleming: Relativity and Reality (Presidential Address).

Royal Institution of Great Britain, at 5.—General Meeting.

Institute of Actuaries, at 5.—Annual General Meeting.

Royal Geographical Society (at Æolian Hall), at 8.30.—Capt. W. R. Hay: Pre-Ghal in Wazaristan.

Royal Society of Medicine (Social Evening), at 9.15.—C. L. Woolley: Recent Excavations at Ur of the Chaldees.

TUESDAY, June 5.

Royal College of Physicians of London, at 5.—Dr. C. Bolton: The Interpretation of Gastric Symptoms (I.).

Zoological Society of London, at 5.30.—Prof. E. B. Poulton: Note on the Feeding-habits of Insectivorous Bats.—Prof. J. P. Hill, F. R. Ince, and A. Subba Rau: The Development of the Fœtal Membranes in *Loris*, with Special Reference to the Mode of Vascularisation of the Chorion in the Lemuroidea and its Phylogenetic Significance.—Frances

M. Ballantyne. Note on the Male Genito-urinary Organs of *Ceratodus forsteri*.—Dr. C. Crossland: Notes on the Ecology of the Reef-builders of Tahiti.—Cambridge Suez Canal Expedition Reports.—L. M. I. Dean: Report on the Alcyonaria.—Dr. C. H. O'Donoghue: Report on the Opisthobranchiata.

London Natural History Society (at Winchester House, E.C.), at 6.30.—E. H. Ellis: Photomicrography.

WEDNESDAY, June 6.

Royal Microscopical Society, at 7.30.—From 7.30 to 10.—Annual Pond Life and General Microscopical Exhibition.

Eugenics Society (at Linnean Society), at 8.—Prof. Malinowski and Dr. Gray: Marriage and Eugenics.

Royal Society of Medicine (Surgery Section) (Annual General Meeting), at 8.30.—Dr. V. Veau, C. H. Fagge, and others: Discussion on Hare-lip.

THURSDAY, June 7.

Royal Society, at 4.30.

Royal College of Physicians of London, at 5.—Dr. C. Bolton: The Interpretation of Gastric Symptoms (II.).

Chemical Society, at 8.30.—F. L. Gilbert and Prof. T. M. Lowry: Studies of Valency. Part X. Electrometric Titration of Vernon's α and β-dimethyl-telluronium Bases.—F. L. Gilbert and Prof. T. M. Lowry.—Studies of Valency. Part XI. Molecular Conductivities and Extinction-coefficients of Derivatives of *cyclo*-telluropentane.—A. Key and P. K. Dutt: The Action of Diazo-salts on Aromatic Sulphonamides. Part II. The Mechanism of the Reaction and Constitution of the Diazo-sulphonamides.

FRIDAY, June 8.

Royal Astronomical Society, at 5.—W. H. Wright: Photography of the Planets in Light of Different Wave-lengths (George Darwin Lecture).—S. R. Pike: Note on the Separation of Gases in Prominences.—N. Goryatscheff: The Definitive Elements of the Orbit of Comet 1925 c (Orkisz).

Royal Society of Medicine (Ophthalmology Section), at 5.—At 6.15 (Annual General Meeting).—M. Hine: Report on a Case of Neurofibromatosis of the Eyelid, and of a Case in which a Glass Ball burst in the Socket.—F. Ridley: Lysozyme-antibacterial Body present in Great Concentration in Tears, and Especially its Relation to the Human Eye.

Physical Society (at Imperial College of Science), at 5.

Malacological Society (at Linnean Society), at 6.

Geologists' Association (at University College), at 7.30.—T. Robertson and T. N. George.—The Carboniferous Limestone of the Northern Outcrop of the South Wales Coalfield.

Geologists' Association (in Architectural Theatre, University College), at 7.30.—Dr. T. Robertson and T. N. George: The Carboniferous Limestone of the North Crop of the South Wales Coalfield.—Dr. R. L. Sherlock: The Alleged Pliocene of Buckinghamshire and Hertfordshire.

Royal Institution of Great Britain, at 9.—Prof. G. P. Thomson: The Waves of an Electron.

PUBLIC LECTURES.

MONDAY, June 4.

London School of Economics, at 5.—Prof. M. Mauss: The Theory of the Elementary Forms of Prayer (Australia) (I.) (Succeeding Lectures on June 5 and 6.)

Royal School of Mines, at 5.15.—G. Mortimer: The Founding of Aluminium and its Light Alloys. (Succeeding Lectures on June 11 and 18.)

TUESDAY, June 5.

Battersea Polytechnic, at 7.—Dr. J. M. Robertson: The Heat Treatment of Steel. (Succeeding Lectures on June 12 and 19.)

THURSDAY, June 7.

Chelsea Physic Garden (Swan Walk, Chelsea Embankment), at 5.—Prof. W. E. Dixon: Narcotic Plants (Chadwick Lecture).

Institute of Pathology and Research (St. Mary's Hospital), at 5.—Sir Oliver Lodge: The Uses we make of the Ether of Space.

FRIDAY, June 8.

King's College, at 5.30.—Dr. J. Krzyzanowski: Polish Culture in the Middle Ages: Education and the University of Cracow.

CONGRESSES.

June 3 to 7.

Institution of Civil Engineers (Celebration of Centenary of Incorporation. Also Engineering Conference).

Sunday, June 3, at 3 P.M.—Divine Service in Westminster Abbey.

Monday, June 4, at 11 A.M.—Address by President, etc.

At 4.30.—Sir James Alfred Ewing: A Century of Inventions (James Forrest Lecture).

Tuesday, June 5, 8 to 11.30 P.M.—Conversazione.

10.30 to 11.45.—Recent Developments in Concrete and Cement for Engineering Structures. Introduced by F. E. Wentworth-Sheilds.—Steel for Shipbuilding. Introduced by Sir William J. Berry.—Utilisation of Solid and Liquid Fuels. Introduced by Dr. C. H. Lander.—Coke-Oven, Town, and Producer Gas. Introduced by R. Ray.—(At Institution of Mechanical Engineers.) The Properties of Materials for Use at High Temperatures, with special reference to Boilers for Superheated Steam. Introduced by R. G. C. Batson.—(At Surveyors' Institution.) Electric Transmission of Power as applied to Large Areas. Introduced by A. Page.

11.45 to 1.—Developments in the Use of Materials in Railway Engineering. Introduced by C. J. Brown.—Railway Design and Maintenance as affected by the Application of Electricity. Introduced by A. R. Cooper and G. Ellson.—The Generation and Utilisation of High-Pressure Superheated Steam for Marine Propulsion. Introduced by Lord Weir and H. E. Yarrow.—Progress in the Adoption of the Internal-Combustion Engine for Marine Purposes. Introduced by Prof. C. J. Hawkes.—Waterless Gasholders. Introduced by F. Prentice.—(At Institution of Mechanical Engineers.) The Present Trend in Boiler Practice. Introduced by W. H. Patchell. (At Surveyors' Institution.) Domestic Lighting and Heating and its Influence on Load-Factor of Supply. Introduced by A. F. Berry.

Thursday, June 7.

10 to 11.30.—The Dimensions of Harbour and Dock Approaches. Introduced by Sir Cyril R. S. Kirkpatrick.—Harbour Breakwaters. Introduced by H. H. G. Mitchell.—Latest Types of Steam and Internal-Combustion Locomotives. Introduced by Sir Henry Fowler and H. N. Gresley.—The General Trend of Modern Development in Steam-Turbine Practice. Introduced by H. L. Guy.—(At Institution of Mechanical Engineers.) Tidal Power, and Turbines suitable for its Utilisation. Introduced by Prof. A. H. Gibson.—Progress in Hydro-Electric Installations, including Intakes, Leats, Tunnels, Dams, Headraces, Pipe-Lines and Tailraces. Introduced by J. McLellan.—(At Surveyors' Institution.) The Filtration and Treatment of Water for Domestic Purposes. Introduced by Sir Alexander Houston and H. E. Stilgoe.—Floods, with special reference to Waste-Weir Capacity. Introduced by W. J. E. Binnie and Dr. H. Lapworth.

11.30 to 12.15.—(At Institution of Mechanical Engineers.) Problems involved in Mining at Great Depths. Introduced by J. Whitehouse.

11.30 to 1.—Modern Road and Bridge Construction. Introduced by F. C. Cook.—The Problem of Road Traffic from the Engineering Point of View. Introduced by H. R. Hepworth.—Light High-Speed Internal-Combustion Engines. Introduced by H. R. Ricardo.—Heavy Internal-Combustion Engines. Introduced by G. Porter.—Prospective Development in the Generation of Electricity and its Influence on the Design of Station-Plant. Introduced by Dr. S. L. Pearce.—(At Surveyors' Institution.) The Advantages of Different Types of Sewage-Tanks. Introduced by W. Clifford.—Sewerage, with special relation to Run-off. Introduced by J. B. L. Meek.

12.15 to 1.—(At Institution of Mechanical Engineers.) The Metallurgy of Complex Lead-Zinc-Copper Ores. Introduced by S. Field.

June 4 to 9.

Institute of Quarrying (at Blackpool).—Prof. P. G. H. Boswell: Silica—its Commercial Properties and Markets.—W. J. Rees: Commercial Sands.—M. I. Williams-Ellis: Electric Traction as Applied to Quarries and Slate Mines.—T. R. Druitt: Cutting Costs in Slate Quarries.—H. S. Seaborne: Research.

June 6 to 9.

South-Eastern Union of Scientific Societies (at Rochester).

Wednesday, June 6, at 8 P.M.—Sir Martin Conway: Mountain Exploration (Presidential Address).

Thursday, June 7.

Archæological Section.

At 11 A.M.—

Dr. W. Martin: Presidential Address.

At 12 NOON—

A. E. Hurse: Archæology of the Medway Valley.

Botanical Section.

At 11 A.M.—

C. E. Salmon: Fruits and Seeds as a Means of distinguishing Allied Plants (Presidential Address).

At 12 NOON—

Rev. L. D. Sayers: Gall Formation in Plants.

At 12.30—

G. E. Hutchings: Vegetation of Rochester District.

Friday, June 8.

Geological Section.

At 10.30 A.M.—

H. H. Milner: Geology from the Air (Presidential Address).

At 11.30 A.M.—

Dr. S. W. Wooldridge: The Geomorphology of the North Downs.

At 12.30—

H. G. Dines: The Bapchild Palæolithic Site.

Zoological Section.

At 11 A.M.—

Prof. E. W. MacBride: The Conditions for Progressive Evolution (Presidential Address).

At 12 NOON—

H. H. S. Bovingdon: The Reflections of a Biologist on Food and Efficiency.

Saturday, June 9.

Regional Survey Section.

At 11 A.M.—

C. C. Fagg: The History of the Regional Survey Movement (Presidential Address).

At 12 NOON—

G. E. Hutchings: A Regional Survey of the Lower Medway Valley.

SATURDAY, JUNE 9, 1928.

Social Ethics, or Present-Day Conflicts.

THE conflict between religion and science, which a few years ago seemed nearly extinct, has recently revived in another form, this time not so much on the theological as on the ethical side. Doubtless there is a kind of ignorant bibliolatry still surviving, which may be said to have a Theological bearing; but apart from that there is a sort of conflict between the ideals of science and the ideals of religion—a conflict rather mingled with the emancipation of youth during the present century, and of some practical importance. The study of anthropology and of folk-lore has been pressed into the service; there is a tendency in some quarters to regard social conventions and other traditions as akin to savage taboos, and to expect sensible people to ignore them. Psychology, too, has developed a scheme called behaviourism, which seems to urge a freer rein to natural instincts, and has become an element in the emancipation of youth.

The revolution in physics, that has led to the examination and rejection of many ancient ideas, is by no means confined to that science. Something of the same sort has been going on contemporaneously in ordinary life. Old customs are being examined to see if they have a rational basis, and when they run counter to instinctive desires are apt to be discarded and rebelled against on hasty and irrational grounds. Youth is complimented on its courage, its willingness to run risks and try anything regardless of consequences. Its courage is undeniable, but its wisdom may be questioned. Even the physical risks which youth is willing to run, in such directions as swimming and flying and breaking of records, may involve the enticing of others to destruction. In other ambitious enterprises, the apparently growing idea that a social taboo has no rational basis and can be ignored with impunity, is becoming a danger.

Even among serious thinkers there is a difference of opinion on these matters. Some hold that we are entering on an age of reason, which submits everything to reconsideration and must involve changes in practice; while others have taught that an age of reason would mean the extinction of the human race, that animal instincts are necessary for its continuance, and that the struggle for existence and fierce competition are essential to its well-being and energetic development. It is argued that this competitive struggle has been all along essential to evolution, that the survival of the fittest can only thus be accomplished, and that rivalry and strife must and ought to continue, even though humanity has now reached a superior stage. It is urged, on the other hand, that with the attainment of consciousness mankind might aim at gradually superseding competition by co-operation and mutual aid, that is to say, by instigating a course of conduct, on a large and even an international scale, such as has hitherto been confined mainly to family life. It has long been known that a family prospers not by competition and strife among its members, but by individual sacrifice and mutual aid; and one ideal is to extend this atmosphere of family life to neighbours and ultimately to all humanity, whereas the opposing ideal is that competition and rivalry must continue, lest mankind sinks into a contented apathy and loses the motive for individual exertion.

The doctrine of evolution has no clear say in this matter. There are those who hold that the same conflict which has brought us to what we are must continue unchecked or even intensified, now that we have become conscious of its benefits and have the power of directing its course. There are others who hold that though this method has been of great service in the past, it should now be taken in hand and controlled by conscious intelligence; that in fact it is one of those good things which has had its day and should now gradually cease to be.

Thus on the ethical side of effective religion, which might be defined as the practical outcome of beliefs, there is a conflict between the ideals of competitive struggle on one hand, and the ideals of the Sermon on the Mount on the other. These two ideals have long been in the field against each other, and it would be a great mistake to suppose that our present condition is the result of one or other alone. Both have, as a matter of fact, contributed to the result. Opinions may differ as to the proportion of success attributable to either, but it is surely certain that our hospitals and other numerous philanthropic efforts—the servers of the infirm and helpers of the weak—have been a conspicuous and effective element in the advance of the social organism. Civilised instincts have never been limited to the graspings of benefits and the accumulation of property. It has long been found that happiness does not lie that way. There is a deep-planted instinct to help those in distress, to run even irrational risks for the help of our fellows, and to enter on forlorn hopes without counting the cost. Evolution surely teaches that many lines of conduct, of which it may be difficult to give a rational account, have grown up as the result of experience, and have been formulated in a system of convention, and what may thoughtlessly be called 'taboo,' as the outcome of experiments which have been made by our ancestors,—never perhaps rationally formulated, and yet handed down from one generation to another as an inherited result of experience. We find some of these conventions unconsciously implanted in animal and even in plant life. Methods of propagation deleterious to the race are guarded against in the very structure of organisms, so that they are inhibited not by reason but by physical difficulty. It may be that some of those conventions which are now being uprooted and rebelled against may have a similar evolutionary significance, and be more beneficial than we find it easy to explain.

Whatever view we take, if our conduct is to be regulated by intelligence in accordance with scientific ideals, it is surely necessary that the whole of the facts should be considered, and that we should not proceed to reason on data which are imperfect and incomplete, so as to determine our behaviour in the light of half knowledge. When youth proceeds to flaunt experience, to overthrow conventions, and to demonstrate its courage by all manner of experiments, it is bound to be proceeding without full knowledge of the facts. It cannot but be in a state of considerable ignorance; and in its exuberance it may be throwing away many of the safeguards which the experience of the race has wisely, though often unconsciously, set up.

It is proverbially rash to draw up an indictment against a nation or a class, and the tendency of the age can scarcely be generalised. There is undoubtedly a claim for greater freedom, less supervision, less restrictions; and this when granted may be selfishly abused by individuals, not necessarily young, for mere personal gratification. The mere desire to have a good time is not a lofty ambition. On the other hand, a reconsideration of old customs might result in a genuine effort towards improved social conditions, which admittedly are as yet far from perfect. In spite of perturbing incidents, the spirit which helped us through the War, and through the minor episode of the strike, is still alive, and only latent until a call comes. A few feel the call insistent and ever present; many a youth is asking him or her self *quo vadis*, and is endeavouring to exert a wholesome guiding influence. Youth should not be either praised or rebuked indiscriminately. Incitements to adventure are popular, but they are dangerous and unnecessary. Temptations are strong enough without pandering to them.

Meanwhile, those experimenters who ignore the ideals of religion, and claim to be following the ideals of science, must be warned that science at present speaks with a divided voice. Religion has always had some bearing upon conduct—sometimes good, sometimes bad; it is of long standing, in one form or other as old as the race; and in civilised countries it can scarcely be doubted that the influence of religion on the whole has been good. Science, on the other hand, is of recent growth, and until lately has not had much influence on conduct. If its ideals are to be followed they should clearly be based on complete knowledge, otherwise they may mislead. No one will claim that our scientific knowledge is complete. It would be rather rash to assume that our knowledge is anything like sufficiently complete to be a safe guide to conduct, or such as to justify the discarding of evolutionary experience and replacing it by a system based on half knowledge.

To make this point of view more definite: it is undeniable that a certain group of scientific men have claimed that the religious belief in a spiritual world is a dream, and the survival of the individual apart from his bodily organism an illusion. If this is true, then such beliefs cannot but have an influence upon conduct; and youth, already urged to such conduct by its instincts, will take advantage of those beliefs to justify its own tendencies and to rush unthinking to its fate.

On the other hand, there is a small though perhaps growing group of scientific men who hold that human life on this planet is but a small part of existence; that the organism is only a manifestation of something which has its roots in another order of being; that we are associated with matter only for a time; that we have to contend against the results of our animal ancestry while on this planet; and further, that individual personality and character, though grown and developed here, survive the change which we call death; that the consequences of our actions are perennial; that the spiritual world to which we really belong is a reality; and that these things are now becoming capable of demonstration. If this belief turns out to be true, then that also must have an influence on conduct; and even the possibility that it is true should not be ignored by those who are helping to determine the conduct of themselves and future generations. Any scientific system which ignores this aspect of things is based on one-sided knowledge, and as such is a dangerous guide. Religion has always taken these things into account, and it is excessively dangerous to ignore its sanctions and evolutionary traditions, the result of long experience on the part of those who must be considered the highest of the race.

The present-day conflict is no small matter. The two views are in the field against each other, and the outcome is in doubt. Knowledge comes but wisdom lingers; and during the conflict of opinion humanity does not stand still. Emancipated youth is claiming its privileges, and prides itself on living dangerously.

The literature of the present day is full of the signs of this conflict. It is exhibited in biological and psychological writings, and it is illustrated in its practical working by many novels. Perhaps the novels are the most important part of the literature, for they are widely disseminated and read, though doubtless many of the other books are read too. The art of the novelist is to make a study of contemporary life, to throw it into dramatic form, and to work out the actual consequences of the beliefs of the time.

There is one such novel, called "The Age of Reason,"[1] to which I wish to direct the attention of scientific men; partly because it is very readable, but chiefly because the author seems to have a genius for absorbing information from many different types and for elaborating it in a popularly intelligible form, with only the exaggeration which is characteristic and inevitable in any dramatic representation. The author is Sir Philip Gibbs, of whom I have no personal knowledge, who made a great reputation as a war correspondent. He has been able to weld his study of the types into a tale, and without ostensibly acting as advocate or drawing any moral, has depicted with considerable skill the interactions of certain types, and the possible tragical outcome of the conflict. To enter into detail would probably be unsuited to these columns. Suffice it to say that among those types are a well-to-do West End parson with broad views, and an absurd wife; a biologist of assumed eminence fully satisfied with the materialistic outlook; two young women of different characters and training, each well meaning up to her own lights; and some young men who are earnest and well intentioned, though weak and rather at the mercy of their surroundings. There is also another clergyman, of the highest ideals, though with insufficient knowledge to be able to exert much influence, who nevertheless sacrifices himself heroically in the effort, but ultimately retreats to the safety of a religious order. All these and other incidental persons pursue their various ideals of life in the light of their knowledge and beliefs—such as they are—as so many in actual life are now doing. The working out of the theme by a man of genius can scarcely fail to be instructive, in spite of a few ugly episodes; and however much opinions may differ as to details, a serious attempt has evidently been made to grasp the situation and to depict the conflict now going on. No apology is needed, therefore, for bringing the book before the notice of the readers of NATURE.

---

OLIVER LODGE.

A Critical Period in the Development of the Plant World.

Palæontologia Sinica. Ser. A, vol. 2, fasc. 1: *Palæozoic Plants from Central Shansi.* By T. G. Halle. Pp. 317 + 64 plates. (Peking: Geological Survey of China, 1927.)

FROM a comparative study of floras of the past, the palæobotanist, especially if he is assisted by the enthusiasm of youth, expects to make some contribution towards a better understanding of the process of plant evolution. The fewer facts we possess, the easier it seems to fit them into a prearranged scheme; the larger the mass of material, the more difficult it becomes to interpret the conflicting testimony of many witnesses. Palæobotanical research has thrown much light on the relative antiquity of certain genera and families; but it may also be said that the longer one studies the records of the rocks the problem of evolution assumes a more baffling complexity. In order to visualise the march of plant-life over the unstable surface of the earth, it is necessary to work out, so far as possible, the distribution of plants both in space and in time. The recent publication of a volume by Prof. Halle of Stockholm on a collection of fossil plants from northern China affords an exceptionally good illustration of the bearing of palæobotanical research on problems of general biological interest. The memoir on the Palæozoic plants from Central Shansi, published as a volume of the "Palæontologia Sinica," is appropriately dedicated to the memory of Alfred Gabriel Nathorst, whose post at Stockholm—the Mecca of palæobotanists and one of the very few places where the science has been deemed worthy of the status of a separate department—is now very ably filled by the author.

Prof. Halle went to China in the autumn of 1916 to study, as palæontologists should, the plant-bearing strata in the field: after collecting material from many localities he was compelled, by a serious illness under very trying conditions, to abandon further work. An even more disastrous misfortune overtook him: the ship which was carrying the fossils to Sweden went down with all hands in a typhoon in September 1919. New collections of Palæozoic and Mesozoic plants made by Dr. Norin and by members of the Geological Survey of China were afterwards forwarded to Stockholm. The recently issued volume is devoted to the collections made by Dr. Norin in Central Shansi. The labour involved in their investigation must have been prodigious; there were 184 packing-cases, and, moreover, many of the plants were strange types. It is hoped to publish in a later volume an account of the material obtained by Mr. C. C. Wang in north-western Shansi. Prof. Halle has earned the gratitude of all students of extinct plants; and he may rest assured that all his fellow-workers rejoice that he has been entrusted with the exploration of one of the most promising fields of palæobotanical research—an undertaking demanding not only a wide knowledge of ancient floras, but also the ability to correlate taxonomic data with problems of primary importance to geologists and botanists.

The later Palæozoic vegetation of North America and Europe differed in many respects from the contemporary floras in the southern hemisphere and in India. In the latter part of the Carboniferous period and in the early stages of the Permian period, there were two fairly well-defined botanical provinces: a northern province reaching into the Arctic regions and extending as far south as the shores of the Tethys sea; a southern province represented by Gondwanaland. It has long been known that some members of the southern flora had wandered into the northern territory before the Triassic period was well advanced. The discovery of *Glossopteris* in Upper Permian beds in northern Russia in 1901, and later discoveries of Gondwanaland plants in Siberia, raised the question of possible routes of migration across the world-encircling Tethys sea. The inter-relation of the two provinces in the Permo-Carboniferous period is still vaguely defined, and the comparative lack of information on the late Palæozoic floras of China has been a serious gap in our knowledge.

The plant-bearing strata with which the memoir under consideration is concerned are classified by Dr. Norin as follows: At the base is the Yuehmenkou series consisting of sedimentary beds and seams of coal. The lower members of the series were assigned on the evidence of the fauna to the uppermost part of the Lower Carboniferous system, and the upper portion was believed to be Permo-Carboniferous. Prof. Halle, on the evidence of the plants, regards the whole as Permo-Carboniferous in age. Then follows the Shihhotse series, a succession of delta deposits rich in plants: Dr. Norin assigns the series to the Permian period, and with this opinion Halle is in general agreement. Resting on the Shihhotse series is the Shihchienfeng series, a set of beds, without plant remains, but with layers of gypsum, deposited under more or less arid conditions.

After the formation of the Yuehmenkou and Shihhotse strata the physical environment changed; a well-drained region was converted into the marginal zone of a desert country. This change recalls a precisely similar shifting of the scenes in the northern hemisphere at the close of the Carboniferous period, when the humid forest belt across America and Europe was transformed into a semi-arid land inhabited by some of the hardier plants which remained as meagre representatives of the luxuriant vegetation of the Coal age. A comparison of the Permo-Carboniferous and early Triassic floras of the northern continents reveals a marked contrast in the nature and luxuriance of the vegetation. The floras which flourished during the closing stages of the Palæozoic era may be said to represent the last phase of a plant dynasty, which had gradually developed in vigour and in variety during the Devonian and Carboniferous periods and continued as a moribund vegetation into the Permian period.

The desert conditions which prevailed over a large continental area at the beginning of the Triassic period are reflected in the meagre vegetation which, in the later part of the period, was succeeded by a widely distributed and much richer flora. There are comparatively few clearly established connecting links between Triassic and Permo-Carboniferous floras: some types persisted, but the Triassic floras differ in many striking respects from those which preceded them; genera which may be described as modern suddenly become abundant and take the place of the familiar types of the Palæozoic era. We know very little about the world's vegetation at the period inaugurated by the Hercynian revolution, one of the revolutions which set a limit to the spread of the forests of the Coal age. In view of this apparent break in the orderly sequence of floras, it is of the greatest importance to seize opportunities of following the course of development of the plant world in an area such as that of northern China, where there is a conformable succession of fossiliferous strata at the upper limit of the Palæozoic system.

Another interesting question on which light may be expected from a fuller knowledge of the Far Eastern floras is the relation of them to contemporary floras in the northern and southern botanical provinces. Prof. Halle found that out of the 103 species described by him from northern Shansi, 70 are new and known only from China: the facies of the vegetation is similar to that of the northern Permo-Carboniferous province, and in the absence of *Glossopteris* and other genera it differs fundamentally from that of the Gondwanaland flora. The conclusions based on palæobotanical evidence may be briefly stated: many of the plants from the lower Yuehmenkou series are specifically identical with Stephanian (uppermost Carboniferous) forms from Europe, and may be regarded as Permo-Carboniferous in age. The upper portion of the series, which corresponds in age with the period of maximum coal production in northern China, is relatively poor in plants; the few species so far discovered range from Westphalian to Lower Permian. It would seem, therefore, that there is no palæobotanical reason for drawing a distinction in age between the lower and upper part of the Yuehmenkou series. Of the 58 species described from the lower Shihhotse series, only 15 occur in other countries, and these are Stephanian or Lower Permian types. Some suggest a Carboniferous age, while others agree more closely with Permian species. The boundary between late Carboniferous and early Permian forms is nowhere sharply marked.

Among the new species recorded from the Shihhotse series is *Gigantopteris Whitei*, one of several representatives of this remarkable fern, or possibly pteridosperm, which had previously been found in Lower Permian beds in Texas and in eastern Asia. Prof. Halle has added considerably to our knowledge of this genus, which had fronds reaching a breadth of 30 cm.: some of his species afford striking examples of the close correspondence between the flora of northern China and that of North America.

In some features the lower Shihhotse flora differs from European Stephanian floras: the widely distributed European genera *Callipteris* and *Walchia* are absent, and, on the other hand, the Shansi-flora includes certain forms such as a species of *Cladophlebis*, some species of *Tæniopteris*, and a cycad, *Dioonites densinervis*, which clearly foreshadow Mesozoic types. There is a mixture of the ancient and more modern plant dynasties. Halle regards the basal beds of the Shihhotse series as representing the beginning of the Permian period, though, as he points out, with undoubted Permian species are associated examples of genera which played a prominent part in Mesozoic floras. Of the upper Shihhotse series Halle says: "The most obvious evidence for a Permian age is to be found in the appearance of several forms of Mesozoic aspect, which seem to indicate the approach of the close of the Palæozoic era." The point is that the Shansi flora, probably a late Permian flora, exhibits rather a closer contact with the early Mesozoic floras than we find in contemporary floras in Europe and North America. In spite of this, Halle is disposed to think that the whole of the Shihhotse series may fall within the Lower Permian; he does not believe that even the uppermost beds "reach to anywhere near the Permian-Trias boundary."

The age of the Shihchienfang series is of special interest: the strata are conformable to those of the underlying Shihhotse series and indicate arid conditions. If the upper Shihhotse series, as Norin supposed, is Upper Permian, the overlying Shihchienfang series would be Triassic in age and equivalent to the Bunter sandstone of Europe. If, as Halle thinks probable, the upper Shihhotse beds are Lower Permian, the Shihchienfang should be correlated with gypsum-bearing Upper Permian of Europe: this correlation would afford an interesting parallel with the change from a humid to an arid climate at the close of the Carboniferous period in Europe and America.

Attention is directed without further comment to an important and valuable section in which the Chinese floras are compared with those of other parts of China and of Korea. Prof. Halle discusses at length the geographical range of the Shansi flora, which bears an intimate relationship with the northern or Arcto-Carboniferous floras of central and western Europe and North America. It is unfortunate that the rich material from American coalfields has not been more thoroughly investigated: making allowance for our relatively greater knowledge of European floras, the conclusion is that in the Shansi flora there are slightly more European than American species. On the other hand, "closely comparable but not identical species are found to a greater number in North America," and it cannot be said "that the relation to Europe is perceptibly closer than to North America."

Prof. Halle also discusses the relation of the Shansi flora to the contemporaneous floras of Angaraland. The Kusnezk flora of southern Siberia and north-western Mongolia extends as far north as lat. 71°-72° N., and it has been traced as far east as Vladivostok: its age is probably late Permian. Only one species is common to the Shansi and Kusnezk floras; the two are "almost entirely different." This is a surprising fact in view of the close relationship, both geographical and geological, between them. "There seems to remain a strong probability that China and the Siberian Angaraland belonged to regions markedly different in regard to vegetation and possibly climate at the close of the Palæozoic." It is suggested that the land of the Kusnezk flora may have been separated from that of the Shansi flora by a sea; in other words, there may have been two distinct phytogeographical regions in Asia outside the area of the *Glossopteris* or true Gondwanaland flora.

Whatever the explanation may be, it is clear that the facts recorded by Halle point to a greater range in variety of the northern floras than had previously been suspected. The discovery in Sumatra a few years ago of several species of plants that are widely distributed over the Arcto-Carboniferous province showed that the northern vegetation had penetrated far within Gondwanaland and had occupied territory which had always been considered the monopoly of the *Glossopteris* flora.

There is a close similarity between the Sumatran and the Shansi floras. It has long been known that certain members of the *Glossopteris* flora had reached Angaraland before the end of the Permian period, but it is only recently that evidence has been obtained of an equally great migration in the contrary direction. A controlling factor in the dispersal of plants has always been the nature of the geographical environment: as Halle says, "looking at the distribution of the late Palæozoic floras very broadly, it would seem that whereas the *Glossopteris* flora and, to some extent, the Angara flora with Gondwana elements are typically floras of the undisturbed continental areas, the Arcto-Carboniferous floras often have their greatest areas of uniform extension along the geosynclines."

The main purpose of this article is to direct attention to some of the many questions of general interest discussed by Prof. Halle. It must, however, be added that the greater part of the volume is occupied by admirable descriptions of the members of the Shansi flora, and there are many important floristic contributions. The author has produced a monumental work: the text is written in a clear and pleasant style which compares very favourably with that of many authors whose mother-tongue is English; the illustrations are exceptionally good. It is a pleasure to be able whole-heartedly to congratulate both Prof. Halle and the editors of the "Palæontologia Sinica" on the service which they have rendered to palæobotany.

A. C. SEWARD.

A Papuan Monograph.

The Kiwai Papuans of British New Guinea: a Nature-Born Instance of Rousseau's Ideal Community. By Prof. Gunnar Landtman. Pp. xxxix + 485 + 64 plates. (London: Macmillan and Co., 1927.) 30*s.* net.

THIS important volume constitutes a worthy successor to Dr. Landtman's previous publication on the folk-lore of the Kiwai Papuans, probably the most complete account in existence of the folk-lore of any primitive people. To collect the data for two such works is no mean test of physical and mental fortitude, as the writer of this notice knows from personal experience, having spent a few weeks in the Fly Estuary during the wet season some twenty years ago, when his visit was brought to an end by fever, which a medical colleague considered sufficiently serious to warrant his removal to Thursday Island in a pearling lugger. But he stayed long enough before being overcome to realise that the dominant qualities of the place were mud and mosquitoes. Dr. Landtman then showed decided pluck in enduring two years (1910–1912), including two rainy seasons, and he fully deserves the repute which these volumes should bring him on both sides of the Atlantic. How he came to Kiwai is explained by Dr. Haddon, who contributes a model ten-page introduction (*O si sic omnes*):

> "Many years ago my friend, Dr. Gunnar Landtman, came to see me at Cambridge, and as soon as we had greeted one another he said, 'I will go anywhere in the world you like to send me.' . . . It did not take much consideration on my part to make a suggestion. . . . I was fully aware of the fragmentary nature of many of the results we had obtained [during the Cambridge Anthropological Expedition to Torres Straits], and it was evident that a detailed study of the adjacent regions of New Guinea was necessary before the affinities of the culture of the Torres Straits islanders could be satisfactorily discussed. . . . I explained the position to Dr. Landtman, and he decided to make that area his field of research."

The successful weathering of the difficulties of the estuary did not, however, mean the end of the author's troubles. On his way back to Helsingfors his steamer sank, and irreparable disaster was only averted by a diver's skill in recovering the trunk containing the field notes, the exact position of which in the hold Dr. Landtman was able to indicate.

The Kiwai are a heavily built, muscular group of Western Papuans, whose origin is obscure, and whose culture seems in part to be derived from some distance to the west, that is, from those tribes which in New Guinea are generally called Tugeri. In physique they certainly differ from the slighter men of Strachan Island and of the lower reaches of the Bensbach River, their western neighbours in British territory.

Besides investigating the Kiwai, Dr. Landtman examined so far as possible the habits and beliefs of the Mawatta on the mainland to the west, and of the Masingle, the bush people hitherto known in anthropological literature as Masingara. All these people are totemistic; in Kiwai each person has but one totem, the great majority being plants; at Mawatta everyone has one chief totem and many subsidiary totems, and here rather more than half are animals, as are all the Masingle totems, with one possible exception. This way of stating the facts is perhaps over simple, especially as regards Mawatta—where "each person has . . . in most cases an almost indefinite number of subsidiary totems"—for a classification shows that, as at Mabuiag in Torres Straits, where the totems are divided into two groups, one all land and the other all water animals, so here the two great groups are associated with land and sea respectively, even the winds concerned being those blowing from the land related to the land animals and plants, and those from the sea with water animals and plants. It may, in fact, be suggested that to speak of an almost indefinite number of subsidiary totems is an expression in white man's language of a basic division of living things into two great categories belonging to the land and water respectively, to one or other of which every man with the exception of "a small anomalous group" must himself belong as part of what a European would call "the scheme of Nature." Such arrangements, if the term be permitted, whereby the clans of a group share the world among them, are by no means uncommon, as, for example, among the Euahlayi of New South Wales, also described as having many subsidiary totems.

No clan is considered superior to another; indeed the Kiwai are purposeful egalitarians—"no want one man he go ahead, one man he come behind, better all man he go together"—and public affairs are settled by a council of old men, who seem to agree without difficulty. Their religious ideas reflect this sociological attitude, for they have no generally accepted systematised beliefs concerning the gods or the other world. No public cult exists, and no prayers are made in communal fashion by a larger or smaller group of the population; nor is there a systematised cult of the dead, although it is recognised that something survives when the body rots. On the other hand, beings that are neither ghosts, nor in the ordinary sense of the word animals, abound, and almost everyone practises petty magic; the oldest men of each group, being considered to have most knowledge, are those who conduct the greater ceremonies and more systematised rites. In spite of this lack of religious ideas the Kiwai have a series of great pantomimic ceremonies; the ***horiomu***, connected with the dead, during part of which such wonderfully decorated turtle-shell masks as those brought back by Dr. Haddon in 1889, and now in the British Museum, are worn; the ***mimia***, in part a fire ceremony, whereby illness is kept away and the youths hardened; the *ga'era*, the occasion for the collection of a vast quantity of food from the gardens, with very much the same rivalry that occurs in the preparation of the *tabu* feast of the Melanesian-speaking peoples of the Central Division of the Territory; the ***nigori***, which has for its purpose the killing of many turtle; and, most important of all, the ***moguru*** or life-giving ceremony.

This last is the most secret and fear-inspiring rite of the Kiwai people. Dr. Landtman had great difficulty in obtaining definite knowledge, and it was only by allowing his informants to come secretly, late at night, and whisper their information, that he was able gradually to piece together its outstanding features. The ceremony takes place inside the men's long-house, and persists with intervals for sometimes so long as two months. It is difficult to follow the whole series of ideas attached to the ***moguru***, but clearly one of its two chief functions is to provide the 'medicine' which has the power to restore the languishing sago palms to full vigour. To produce this the Kiwai on this occasion (and on this occasion only) surrender themselves and their wives to promiscuous intercourse—only the closest blood relations avoiding each other—the chief ingredient in the 'medicine' being the sexual secretions, which, mixed with red paint, is smeared by every man on the trunk of a sago palm in his garden, the tree being requested to grow big and produce much food. Bananas and coconuts might also be anointed, as well as the people themselves, a small quantity taken with food being regarded as prophylactic against most physical ills. Connected with this part of the ceremony is the sexual instruction of the adolescents of both sexes.

The second principal event of the ***moguru*** is the *goro*, the ceremony of the captured wild boar, and this is more difficult to summarise. A wild boar is hunted, brought to bay, and instead of being killed is stunned and muzzled, its legs being tied together. It is painted, and ornamented with plumes of the cassowary and birds of Paradise, and laid on a litter with the legs bent beneath the body, with a bundle of arrows placed on each side. Covered with leaves so that no one shall see it, the litter is carried into the *darimo* (man-house) and deposited on a platform erected in front of the great central post, the head of the boar facing the eastern gable entrance. Beside the boar are placed bundles of arrows, clubs, beheading knives, and head-carriers. At this stage the boar is killed and its blood sprinkled on the human figures carved on the post and on the weapons surrounding it. One of the 'big fighting men' lies prostrate on top of the pig, his head pointing in the same direction; the 'new men,' that is, the initiates, now crawl on to the platform, passing astride over the prostrate man and the pig, each of them accompanied by his guardian, generally his maternal uncle, who when the boy's head is above that of the boar, puts 'medicine' into his mouth. In this part of the ceremony there seems to be room for considerable variation, but there is no doubt that the great object of the episode is preparation for war—it makes the men hot for blood so that they think about nothing but fighting—yet the pig also yields 'medicine' for the garden and for other purposes; its feet, after being dried and reddened, are buried in the sago plantation; the bones, stuck into the walls of the men's house, give protection from sickness, and so on. Naturally, women are rigorously excluded from this ceremony; but there is a notable exception—one very old woman is attached to every man-house, and with the old man who is the 'father' assists in all the rites.

It has only been possible to mention, and that briefly, some of the most striking facts recorded in this volume, but since this is the first adequate monograph on a Papuan people to be published, the reviewer may conclude by indicating a theoretical deduction of considerable interest, though only further investigation can show how far it is valid. The work of Prof. Malinowski on the Trobriand Islanders shows that to these Papuo-Melanesians the most essential part of a magical process is the spell. As indicated by Dr. Landtman, magic plays a most important part in the life of the Kiwai, but there is nothing in his record to suggest that the spell is specially important; the power of the magic seems to depend preponderantly on the actual ingredients of the 'medicine,' which are often chosen on frank *similia similibus* principles. The question then arises whether this difference is merely, as it were, accidental between two peoples inhabiting areas tolerably far apart, or whether it may be taken as the expression of a psychic and ultimately ethnic difference between true (Western) Papuans and (Papuo-) Melanesians.

Our Bookshelf.

(1) *Stellarastronomie.* Von H. Kobold. (Sonderausgabe aus der Encyklopädie der mathematischen Wissenschaften.) Pp. iii + 239-372. (Leipzig und Berlin: B. G. Teubner, 1926.) 5·80 gold marks.

(2) *An Outline of Stellar Astronomy.* By Peter Doig. Pp. viii + 183. (London: The Draughtsman Publishing Co., Ltd., 1927.) 7*s.* 6*d.* net.

These two books with somewhat similar titles are to a marked degree supplementary one to the other. Prof. Kobold's volume is an extract, 134 pages in length, from the "Encyclopädie der mathematischen Wissenschaften." It was written in 1924 and has a few references introduced up to 1926. It is very complete in its historical work, giving, for example, an excellent account of all the important star catalogues and the early work on stellar motions and on the structure of the universe. It also gives good accounts of the more recent investigations up to 1924, but to a large extent it is affected by the common fault or quality of encyclopædias, it gives both sides of a discussion and rarely offers a decisive view on controversial points.

Mr. Doig's book is, on the other hand, an attempt to give an account of the present outlook on the constitution, dimensions, motions, and distribution in space of the stars and nebulæ. Even in the short bibliography appended to each of his chapters he rarely goes back so much as ten years. His book is much more popular in style and he is rightly more dogmatic in his general statements about the nature of the stars and the structure of the universe. Both books will serve as useful sources of reference to the present-day student of astronomy—Kobold for the past and Doig for the present.

Reading the two volumes together, one is struck at the rapid change of outlook in recent years in stellar astronomy—apart from astrophysics proper, which is changing so largely from year to year with the development of theoretical spectroscopy and atomic physics. Kobold's book, with its merely occasional references to the contribution of astrophysics to the problems of the structure of the universe, reflects a period of isolation between the two halves of astronomy, an isolation which has now vanished. With Doig the interest lies on the other side—the physical rather than the statistical—though he, too, has considerable interest in the statistical application of many physical observations. His own work along these lines, much of it published in the *Journal of the British Astronomical Association*, reappears quite properly in this book, set in the framework of the recent work of Eddington, Jeans, Russell, Seares, Shapley, and others, of which he gives an interesting account in his book.

Maps, their History, Characteristics and Uses: a Handbook for Teachers. By Sir Herbert George Fordham. Second edition. Pp. xii + 83 + 8 plates. (Cambridge: At the University Press, 1927.) 6*s.* net.

All who are interested in cartography and its history will welcome the issue of a second edition of Sir George Fordham's little book, which forms such an admirable introduction to the subject. It begins with a few pages on the elementary notions which lie behind the making and using of maps, and then we have an interesting page or two on terminology. How many people who commonly make use of atlases know who first used the term 'atlas,' and what a curious, far-fetched term it is? And how many remember that the word ousted its rivals 'theatrum' and 'speculum'?

After a concise and clear account of the history of map production, the author devotes a section of his book to art in cartography. This is a matter which deserves more study by cartographers than it sometimes receives. The use of colour in modern maps has led, in some instances, to a kind of carelessness in design; as if it were possible to smash one colour down upon another, and trust that all would come right in the final printing. It is sometimes forgotten that the use of five or six colours imposes upon the cartographer not less, but more, care in the design of the map than when dealing with a map in black and white.

The remarks on the graphic expression of the surface forms appear, on the whole, to be sound; it might have been mentioned that the Dutch surveyor who in 1729 first drew contours—in connexion with sea-bed soundings—was called Cruquius, and that Hutton used them in Great Britain in 1777, and that they were in use in military sketches in England probably so early as 1793. The author refers favourably to the Army "Manual of Map Reading and Field Sketching," edition 1914; but it is doubtful if the student could now obtain a copy. The latest manual of the kind was published in 1921, and is larger, more difficult, and more 'professorial' than its predecessor. In conclusion, we can heartily recommend this little book to all who use maps, especially to teachers of geography.

Romani Versions. By Sir Donald Macalister. (Gypsy Lore Society Monographs, No. 5.) Pp. 67. (London: Bernard Quaritch, Ltd., 1928.) n.p.

Sir Donald Macalister, like other noted scholars, has given some of his leisure hours to the making of translations from English poetry. But whereas these have often been made in the long-cultivated tongues of Greece or Rome, the Principal of the University of Glasgow has chosen a less known medium, that strange Indian dialect which was brought to British shores some five or six centuries ago by wandering Gypsy tribes.

These versions are ingenious; often, so far as the non-Gypsy can judge, they attain beauty; certainly they testify to their author's knowledge of Romani. The poems are aptly chosen: "The Raggle-Taggle Gypsies," "The Princess and the Gypsies," "The Gypsy King," Scott's "The Lochmaben Harper," Kipling's "A Smuggler's Song," are suitable in their substance and spirit, and do not strain too much the limited, but genuine, Gypsy vocabulary. It is perhaps different with the polished artifice of 22 quatrains from FitzGerald's Omar, to which are added 22 translated with equal skill by Dr. J. Sampson.

Translation is not so difficult, perhaps, as it might at first sight seem. For while Romani has preserved something of the vocabulary and grammatical forms of its Indian original, its syntax is largely modelled on the language of its hosts. Also, as Dr. Sampson remarks in his introduction, even the real Gypsy songs collected in Greece by Paspati are imitations, both in metre and material, of popular Greek poetry.

Beyond the page or two of this introduction, the collection cannot, of course, claim to be of any scientific interest to the linguist or the student of folk-lore. But that was not the author's purpose. He made these versions to amuse himself; and without doubt they will bring as much pleasure and amusement to that band of Romani Rais whose delight in all things Gypsy is perhaps as intelligible as it is real.

"All I ask, the heaven above
And the road below me."

"Mangi muk o tem oprál
Ta o drom te java."

R. L. T.

Organic Chemistry for Advanced Students. By Prof. Julius B. Cohen. Fifth edition. Part 1: *Reactions.* Pp. vii + 427. Part 2: *Structure.* Pp. vii + 487. Part 3: *Synthesis.* Pp. vii + 440. (London: Edward Arnold and Co., 1928.) 18*s.* net each vol.

THE fifth edition of this familiar work contains a good deal of new matter, but as the result of a judicious condensation of some of the less important sections, the complete work contains only 58 pages more than the fourth edition, which was published in 1923. No alterations have been made in the titles of the chapters. In Part 1, a revision of Chapters ii. and iii., on the nature of organic reactions and their dynamics, has afforded an opportunity of dealing with recent studies based on the electronic theory of chemical combination. In Part 2, a brief reference to the parachor theory has been incorporated in Chapter i., while Chapter v. has been amplified by the insertion of a short account of recent work on optically active derivatives of sulphur, boron, beryllium, zinc, and copper, and on the stereochemistry of metalammines. In Part 3, the account of the carbohydrates has been remodelled in accordance with new experimental data; we are glad to note, in passing, that the author has abandoned the term "monosaccharose" in favour of "monosaccharide." Part 3 includes, in addition, short accounts of recent advances in the chemistry of anthocyanins, terpenes, and sesquiterpenes; syntheses of glutathione, spermine, and thyroxine are other new features of this volume.

Altogether, the value of Prof. Cohen's book has been appreciably enhanced by the revision. It is well printed, the new sections having been reset in a particularly clear type. We suggest that the spacing of the formulæ in the synthesis of thyroxine (p. 178), and the unprefaced representation of glutathione at the stage of hydrogen acceptor (pp. 160 and 170), may prove somewhat confusing to the student at the first reading.

The Date of Easter and other Christian Festivals. By the Rev. David Ross Fotheringham. Pp. xv + 56. (London: Society for Promoting Christian Knowledge; New York and Toronto: The Macmillan Co., 1928.) Cloth, 2*s.* 6*d.* net; paper, 1*s.* 6*d.* net.

THIS book is largely taken up with a study of the evidence for the dates of the Nativity and Crucifixion. Much of this evidence is familiar to all, but some new points are introduced, including recent work on the moon's motion and the ancient calendar by the author's brother, Dr. J. K. Fotheringham, and by Mr. C. Schoch. The suggestion is made that the star of Bethlehem may be the planet Mars, rising heliacally. The author decides on December, 4 B.C. for the Nativity, and April 7, A.D. 30, for the Crucifixion. He then goes on to recommend the rule for determining Easter, that it should be April 9 if Sunday, or the first Sunday after this. This suggested rule is supported in the preface, which is written by Lord Desborough.

A. C. D. C.

The Annual Register: a Review of Public Events at Home and Abroad for the Year 1927. Edited by Dr. M. Epstein. Pp. xiv + 318 + 168. (London: Longmans, Green and Co., Ltd., 1928.) 30*s.* net.

THIS valuable record of the year, with its impartial survey of the world's history, is again planned on the lines which have long been familiar. Half of Part I., which is a narrative under the headings of various States, is devoted to the history of Great Britain and half to other countries, including all in which events of importance occurred. Part II., in addition to a chronological list of events and an obituary with short biographies, has the usual survey of literature, science, art, finance, and law. Science receives fourteen pages, of which more than half is devoted to biology in its various aspects, and the remainder to the physical sciences. The public documents printed in full are the treaties with Iraq and the Hejaz, and the Italian Labour Charter.

Letters to the Editor.

The Nature of Clay, and its Significance in the Weathering Cycle.

THE characteristic constituent of the natural substance, clay, has been the subject of numerous investigations both by chemists and by pedologists. It is generally believed to be colloidal, and the residual product of the hydrolytic decomposition of mineral silicates. Whilst attempts have been made to study this complex by methods of acid extraction, the most promising line of advance has been the study of the finest fraction obtained in mechanical analysis—the so-called colloidal clay. Although this fraction, as isolated by some workers, may contain small proportions of unweathered material, we shall probably not err greatly in equating it with the weathering complex, particularly if a critical settling velocity of less than 10^{-4} cm./sec. has been used in its separation by means of sedimentation.

Considerations of space in the present communication preclude a full reference to recent work, but I would direct particular attention to an important investigation by W. O. Robinson and R. S. Holmes (*U.S. Dept. Agr. Bull.*, 1311, 1924). In this work, the authors report the composition of the colloidal clay from a number of North American soils. Perhaps their most important conclusion is that iron compounds, other than hydrated ferric oxide, are present as an essential part of the clay. Much of the confusion in the study of clay has arisen from regarding the clay complex as essentially an aluminium silicate or alumino-silicic acid, with hydrated ferric oxide present as an adventitious constituent. Robinson and Holmes examine the possibility that the clay complex is a mixture of an aluminium silicate of the kaolinite type ($Al_2O_3 . 2SiO_2 . 2H_2O$) and a ferric silicate of the nontronite type ($Fe_2O_3 . 2SiO_2 . 2H_2O$). Actually, only a minority of their clays fit this hypothesis. On one hand there are clays with excess of silica, and, on the other hand, clays with excess of sesquioxides—the latter clays being generally of a reddish or brownish colour.

The hypothesis examined by Robinson and Holmes could, however, only be verified by the examination of clays obtained from material which had originated directly from crystalline rocks and had, further, not been subjected to those leaching processes which cause a differentiation of the silica–sesquioxide complex. These changes result, in humid temperate climates, in the impoverishment of the surface in sesquioxides and the enrichment of a subsurface layer in these constituents. In extreme cases, in the so-called podsols, acid leaching gives rise to a bleached *A* horizon and a reddish brown, sometimes indurated, *B* horizon, which is relatively rich in sesquioxides. It is somewhat difficult to obtain material in which the silica–sesquioxide complex has not undergone some alteration, but I obtained, through the courtesy of Dr. Edward Greenly, three samples of clay from Anglesey which had originated from Mona Complex schists at a depth far below that at which the ordinary leaching processes operate. The clay fraction from a white clay gave a molecular ratio of silica to sesquioxides of 2·16; for a yellow clay the ratio was 2·09; and for a red clay 1·96. These figures are in fair agreement with the 2·0 ratio demanded by the kaolinite–nontronite hypothesis.

I have also examined a number of North Wales soils, derived from crystalline or consolidated rocks, in which it can be assumed that the clay is of primary origin. The average silica–sesquioxide ratio for the clay fraction of 17 such soils was 1·90, the individual ratios ranging from 1·51 to 2·22. Bearing in mind the tendency, under the conditions of North Wales, for sesquioxides to be leached down to lower levels, and also remembering that superficial erosion attacks the more siliceous *A* horizon, the fact that the ratio is less than 2·0 is in harmony with the hypothesis that the primary weathering product is a mixture of silicates of the kaolinite and nontronite type.

The figures of Robinson and Holmes and of other workers were then inspected in the light of what information was available as to their mode of origin, and it was evident that soils derived from crystalline rocks in humid temperate climates tend to give a weathering complex with a silica–sesquioxide ratio rather less than 2·0. It may be suggested that samples of such soils, collected without reference to considerations of profile, would probably be enriched in sesquioxides at the expense of eroded superficial horizons. I hope to elaborate this point in its significance for the regional study of soils in a further communication.

An investigation was also made of the clay fractions from a number of soils in which the parent material was alluvium or unconsolidated sediments. In these cases, the silica–sesquioxide ratio was always greater than 2·0, the average being actually 2·67 for 15 samples, with the individual ratios varying from 2·12 to 3·37. The published figures of other workers for the clay fractions from alluvial and unconsolidated deposits agree with these results. The more siliceous character of the clay fractions of such soils is not difficult to explain. One of the principal features of the hydrolytic decomposition of minerals is desilicification, and this is reflected in the appreciable content of silicic acid in river waters. Sea water, on the other hand, contains only traces of silicic acid. F. W. Clarke, in "Data of Geochemistry" (*U.S. Geol. Survey Bull.*, 770), places silica among the most important oceanic chemical sediments. The silica–sesquioxide ratio in the estimated contribution of rivers is of the order of 8·0. It is reasonable to suggest that the silicic acid present in river water undergoes precipitation together with estuarine and other littoral deposits, the clay complex of which is thereby enriched in silica relative to sesquioxides. Where these deposits again become exposed to atmospheric influences without intervening heat metamorphism, we obtain soils the clay fractions of which have a silica–sesquioxide greater than 2·0.

Summarising these results, I venture to put forward the view that the primary residual product of the chemical weathering of silicates is a mixture of kaolinite and nontronite, or of hydrated silicates having the same silica–sesquioxide ratio, namely, 2·0. Variations from this ratio may occur as a result of the differentiation consequent on soil profile development, leading in humid temperate climates to the production of a more siliceous *A* horizon and a less siliceous *B* horizon, and in humid tropical climates to the formation of laterite. Enrichment of the clay complex in silica takes place in estuarine and other littoral sediments owing to the concomitant precipitation of the silicic acid present in river waters.

The significance of the composition of the clay fraction has been recognised by many workers, notably by A. F. Joseph and his collaborators, who have shown that clay properties are most strongly developed in the most siliceous clays. Hall and Russell, many years ago, attempted to correlate soil fertility with the composition of the clay fraction. It is evident, therefore, that students of the soil are likely to obtain results of the highest importance, both for the natural study of the soil and for the elucidation of problems of soil fertility, by giving attention to the composition of the clay fraction, particularly in its vertical variation in the soil profile.

Insects and Potato Virus Diseases.

IT has long been a matter for conjecture as to what insect or insects are responsible in Great Britain for the dissemination of the 'virus' diseases affecting the potato plant. Experiments carried out by myself over a period of years show beyond doubt that, out of the normal insect potato fauna, one particular insect is a most efficient vehicle for the transmission of the serious disease known as 'leaf-roll.'

The insect in question is a small aphis, *Myzus persicæ* Sulz., and it attacks both the plant in the field and the sprouts of the tuber in the store. Under certain conditions I have been able to infect with fair regularity between ninety and one hundred per cent of the experimental plants with leaf-roll by means of this aphis. Further, I have proved, under glass-house conditions, that healthy potatoes, on the sprouts of which *Myzus persicæ* carrying the virus of leaf-roll has been feeding, will produce plants so badly 'rolled' within two months of the date of the first infection, as to give little or no crop. In the glass-house a number of known healthy potato tubers, with sprouts thus infected at the beginning of March, produced plants in an advanced stage of leaf-roll by the end of April.

It will thus be understood how it is possible for 'seed' potatoes, stored in a healthy condition, to give rise to a negligible crop in the ensuing season. Attempts to induce nine other species of insects which normally inhabit the potato plant to transmit the virus of leaf-roll under varying conditions have so far proved abortive. It is, however, unwise to deduce from these negative results that such insects are unable to transmit leaf-roll under any conditions. Suffice it to say that as yet they have not done so under conditions which gave positive results with *Myzus persicæ*.

As regards the disease known as 'mosaic,' the transmitting power of *Myzus persicæ* appears to be much less, and the percentage of experimental infections has been small. However, in experimenting with the virus of potato mosaic on another Solanaceous host, some curious facts relating to the behaviour of this virus have come to light. By infecting tobacco plants with the virus obtained from mosaic-affected 'Arran Victory' foliage by means of leaf mutilation inoculation, a very characteristic disease, known as 'ringspot' is produced in the tobacco. The chief symptom of this is the formation of clearly defined whitish concentric rings, each having a central spot (Fig. 1).

On transferring this virus by needle inoculation back to healthy potatoes, a mosaic-like disease is produced in which the symptoms of the original mosaic are intensified and its infective nature very greatly increased. Its symptoms consist of a very characteristic and strongly marked mottling of the leaves, which later may become crinkled at the edges, accompanied by large numbers of small necrotic spots. It is, in fact, very similar to the potato virus disease known as 'crinkle,' with the exception that true crinkle is very much less infectious, so far as my experience goes. This altered virus can be passed by needle inoculation from potato to potato and from tobacco to tobacco or from one to the other with the utmost regularity, the symptoms developing in the former in eight to eleven days according to the temperature, and after a somewhat longer period in the latter.

It is now possible to induce the aphis *Myzus persicæ* to disseminate this virus to potatoes where it would not do so before its passage through the tobacco, and successful transmissions have been performed in periods ranging from 14 to 24 days. This transformed or 'ringspot' mosaic in potato has not, however, adapted itself to dissemination by the aphis proportionately to its greatly increased infectivity to the plant, and aphis infection is still a matter of uncertainty. Inoculations into healthy tobacco plants with the juice of healthy potatoes or with viruses other than mosaic, have up to the present failed to produce ringspot, but when mosaic has been a component part of a virus complex ringspot has developed.

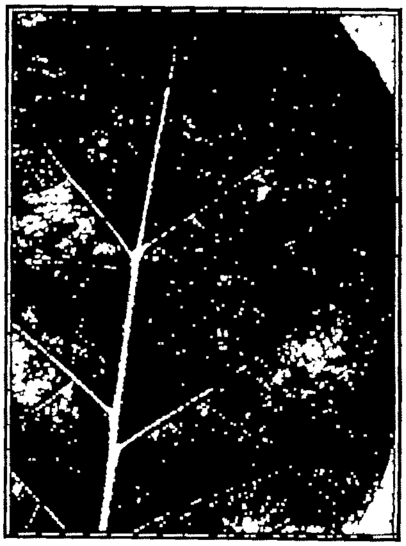

FIG. 1.—'Ringspot' on tobacco caused by inoculations with potato mosaic.

The Excitation of the *D* Lines by the Green Sodium Band.

IN a recent paper (*Phys. Rev.*, May 1928) Prof. Wood and the present writer have discussed the conditions under which it is possible to excite the *D* line fluorescence in sodium vapour by light which is free from wave-lengths absorbed by the atom. A band in the green at 5200 A., 50 A. in width, was found to produce a maximum *D* line fluorescence when a foreign gas at a few millimetres pressure was mixed with the fluorescing vapour. The presence of a foreign gas seemed essential for the production of the *D* lines in this way, and the most obvious explanation seemed to be that the excited molecule collided with a foreign gas molecule and dissociated into one normal and one excited atom. But the dissociation potential as calculated by Pringsheim (*Zeit. f. Phys.*, **44**, 651; 1927) and Loomis (*Phys. Rev.*, **31**, 323; 1928) from the analysis of the band spectra is much too high for this process to occur, as has been pointed out, and the alternative explanation was offered that the *D* lines were emitted when an atom was raised to the $2P$ levels on collision with an excited molecule. The molecule would then be left with but 0·3 volt energy, which would be distributed as part vibrational and part kinetic. The presence of a foreign gas would prevent rapid diffusion of the vapour to the cooler parts of the resonance tube, and allow the atomic and molecular densities to increase, thus increasing the probability of collision.

If this is the process occurring, it should be possible, then, to excite the atomic lines by the green molecular band in pure vapour of the proper vapour density. I have recently repeated these experiments, using an electrically heated resonance tube equipped with a thermocouple in order to obtain accurate temperature control, and have found that the green band does excite the *D* lines in pure vapour, but only in a narrow temperature range. The atomic lines appeared somewhat below 400°, rose to a sharp maximum at 410°, and disappeared again above 450°. The existence of a maximum intensity at 410° was very marked and could be determined within 5° or 10° very easily. Now, in the previous experiments no adequate temperature control was purposely employed, but it was found in the present work that the introduction of gas at a few millimetres pressure caused temperature changes of 10°-20°, the temperature rising on the introduction of the gas. Experiments showed this to be due entirely to the fact that the gas reduced the diffusion of the vapour to the cooler parts of the tube. The rapidly diffusing vapour, in the absence of gas, keeps the heated section at a lower temperature than it would attain if the diffusion were absent. Although the *D* lines were obtained in this way in the presence of gas, they were much less intense and appeared as before, only in a narrow temperature range.

An attempt was made to explain the phenomenon quantitatively. The intensity of the atomic lines formed in this way will be proportional to the number of collisions of excited molecules and atoms occurring per second, provided every excited atom so formed radiates. This, however, will not be the case, for a certain proportion of them is removed by collisions. Actually, the *D* line intensity will be measured by the number of excited atoms lost by radiation per second, and it is seen that collisions are operative both in increasing the number formed per second and in decreasing the number radiating per second, so that a balance between these factors may produce a maximum intensity at a definite temperature. Calculation showed, however, that for the *D* lines to be produced in this way, it is necessary to assume that the excited and normal molecules have diameters of the order of magnitude of 100×10^{-8}, or else to assume that the lifetime of excited molecules and atoms is 100 to 1000 times the accepted order of magnitude (10^{-8}).

In the course of the calculation it became necessary to know approximately the per cent dissociation of the molecule at 410°, the temperature at which the *D* line fluorescence was a maximum. To obtain this, the reaction isochore as modified by Fowler and Darwin (*Phil. Mag.*, **45**, 1; 1923) to include vibrationally and rotationally quantised systems was used, together with the constants of the green sodium band as given by Watson and Fredrickson (*Phys. Rev.*, **30**, 429; 1927). Assuming the vibrational levels to be fully excited at this temperature, which seems very probable, it turns out that the molecules are only 55 per cent dissociated at 410°, and that the per cent association increases with the temperature. This fact is pointed out for two reasons. One is that the per cent association has been generally considered to be small at this temperature, and this is not the case for molecules having a dissociation potential so high as 1 volt. The other is that it may be significant that the maximum intensity of the *D* lines, excited by the molecular band, should occur in a mixture of 50 per cent atoms and 50 per cent molecules.

The Pulmonary Circulation of the Whale.

WHALES are remarkable not only for the time they remain under water, but also for the depth to which they descend. In my letter on the depth to which they descend (NATURE, Aug. 20, 1927, p. 263), I gave reasons for believing that the Greenland whale descends to the depth of a mile. The ability to reach that depth implies on the part of the whale the possession of certain attributes, namely:

1. It must be able to remain long enough under water to dive to that depth and make the return journey to the surface.
2. Its buoyancy must not depend on a compressible substance like air to such an extent that when it is at the end of its dive its negative buoyancy or tendency to sink is so great that its muscular powers are unable to cope with it.
3. Its natural orifices must be provided with valves to prevent the water entering the hollow viscera.
4. Its lungs and chest must be elastic and capable of contracting as the air in them is compressed and absorbed.
5. Its circulation must be so arranged that at times the venous blood can reach the aorta without having to pass through the lungs.

The Greenland whale appears to possess these attributes in a marked degree; when attacked it descends at the rate of seven or eight miles an hour, and after an interval of from a half to three-quarters of an hour reappears at the surface in an exhausted condition and is easily dispatched. It depends mainly on its blubber for its buoyancy, and only to a small extent on air, and as the former is incompressible it has a buoyant effect at all depths. Its blubber reaches a thickness of 22 in.; its great thickness is well shown in a photograph appearing in Cook's recent volume, "Pursuing the Whale."

As in other whales, the blow-holes of the Greenland whale are protected by valves which, in the undilated condition of the openings, prevent the entry of water without any effort on the animal's part. Knox, speaking of the blow-hole valves of a fin-whale, says: "The mechanism is admirable, and would sustain any pressure from above although the animal descended to thousands of fathoms." The blow-hole valves of the Greenland whale are described by Scoresby. In this whale even the small opening leading to the ear has its little valve.

The lungs and heart of the adult Greenland whale do not appear to have been examined, but they are doubtless at least as suitable for deep diving as those of other whales. Hunter, speaking of a fin-whale, says: "The lungs are extremely elastic in their substance, so much so as to squeeze out any air that may be thrown into them and become almost at once a solid mass, having a good deal the appearance, consistence, and feel of an ox's spleen."

As regards the existence of a channel through which the venous blood can reach the aorta, that is a patent condition of the ductus arteriosus. Murie, referring to a fin-whale, says: "The ductus-arteriosus existed as a thick rounded elastic cord. Its circumference was 7 inches. Its canal was sufficiently closed to prevent the passage of blood by reason of the elasticity of its walls, but a probe the size of a quill could be pushed through the entire distance." Turner and Knox also found the vessel patent, although contracted in fin-whales.

In whales, owing to the peculiar lives they lead, the pulmonary circulation must often be carried on with considerable difficulty unless there is some arrangement against it. In the intervals between the respirations, the lungs, as Delage suggests, are probably used for hydrostatic purposes and the air in them is consequently often more or less compressed. When they descend to great depths, owing to the pressure of the water, their lungs must be in a very contracted state.

In view of these facts I venture to advance the following hypothesis concerning the heart of the Greenland and of other deep-diving whales: that in the intervals between the respirations when the air in the lungs is in a compressed state and at the times the animal is deep in the water and its chest greatly compressed, the venous blood reaches the aorta mainly via the ductus arteriosus instead of via the lungs as at other times; that the ductus is elastic and possibly contractile; and that it opens and allows the blood to pass as occasion requires.

Astrophysical Estimates of Ionisation Potentials of Iron, Yttrium, and Lanthanum.

THE work of Saha, Fowler, and Milne has shown how the intensities of ionised lines in stellar spectra are dependent upon temperature, pressure, ionisation, and excitation potentials. By studying the changes in intensity of a line from stars of one spectral class to another, astrophysical estimates have been made of the ionisation potentials of certain of the elements by several investigators.

In the case of a *Cepheid variable*, we have a star the luminosity of which changes slowly from maximum to minimum, then rises steeply to maximum again, with a regularity which is remarkable. During the same period the radial velocity goes through a cycle of changes as though the star were in a state of pulsation, expanding and then contracting, with consequent cyclic changes in the pressure and temperature of its outer portions giving rise to periodic variations in spectral classification.

Dr. F. C. Henroteau recently enlisted my interest in the variations in intensity of certain ionised lines, and in the course of an investigation of more than seventy spectrograms of η Aquilæ taken at the Dominion Observatory during the last few years, the behaviour of some twenty lines due to ionised atoms of scandium, titanium, iron, strontium, yttrium, barium, lanthanum has been studied. Microphotometer graphs of each spectrogram were made. An arc line insensitive to the periodic changes was selected closely adjacent to each of the spark lines under consideration and the ratio of the enhanced line to the arc line measured in each case. Plotting these ratios against phase (in η Aquilæ the period is 7·176382 days) the resulting curves exhibit general resemblance to one another but certain differences in position of maximum and spread of high values which must be attributed mainly to differences in ionisation potential. Taking the following known ionisation potentials:

At. No.	Element.	Ionisation Potential.
21	Sc	6·7 (Russell and Meggers)
22	Ti	6·5 (Kiess and Kiess)
38	Sr	5·67 (A. Fowler)
56	Ba	5·19 (A. Fowler)

as the basis, *the ionisation potentials of iron, yttrium, and lanthanum are estimated to be as follows:*

At. No.	Element.	Estimated I.P.
26	Fe	6·6 (5·5)
41	Y	6·6
57	La	4·9

In the case of iron, the alternative estimate (5·5 volts) is got by comparison with the graphs for strontium and barium, while the estimate 6·6 volts is the value relative to scandium and titanium. Spectroscopic values have been given as 5·9 and 8·15 by Sommerfeld, Gieseler, and Grotrian, while astrophysical estimates by Menzel are 7·5 and 13·0.

As regards yttrium, a spectroscopic determination has just been announced at the Washington meeting of the American Physical Society (April 20), by Meggers and Russell, agreeing with the above, 6·6 volts. This is of interest because the astrophysical estimates are certainly subject to large probable error.

For lanthanum I am unaware of any previous determination, and in confirmation of this and the other estimates, further study of the behaviour of sensitive lines in the spectra of Cepheid variables will be carried out. I am indebted to the Director of the Dominion Observatory for permission to utilise data taken from spectrograms belonging to that institution.

Active Nitrogen.

IN some recent experiments it has been possible to show that metastable molecules of nitrogen are present in active nitrogen. A preliminary report of these experiments has been made by one of us (J. K.) before the April meeting of the American Physical Society. The absence of a spectroscopic transition from the first or *A* electronic level of the molecule to the normal level has been reported by Miss Sponer, who also suggested that this level may be a metastable one. Also the transition from the normal level of the molecule to the *A* level has not been observed in absorption. The long life of active nitrogen cannot, however, be explained on the hypothesis that active nitrogen is a metastable molecule. Its long life and its behaviour in the presence of catalysts suggests with certainty that active nitrogen is atomic and that metastable molecules are formed under the influence of the recombination of nitrogen atoms to molecules.

In order to account for the excitation of the first positive bands of nitrogen in the afterglow with abnormal intensity distribution, we assume that in addition to metastable molecules, metastable atoms of nitrogen are formed during the recombination of atoms to molecules. These metastable atoms excite the metastable molecules to the upper level of the first positive bands by collisions of the second kind. The lowest three terms of atomic nitrogen are predicted by the Hund theory to be ^4S, ^2D, and ^2P, where the ^4S term is a normal one and the ^2D and ^{2}P terms are metastable. The difference $^2D - {}^4S$ is found from Hopfield's data on the ionisation limits of N I to be 2·37 volts. The difference $^2P - {}^4S$ has been extrapolated from the spectrum of O II and found to be 3·56 volts. Collisions between nitrogen atoms in the ^2P state and metastable nitrogen molecules yield, as the most probable result, nitrogen molecules in the 11th vibrational state of the *B* electronic level. This is the upper level of the strongest afterglow bands. We make use here of the principle of resonance that has been so successful in collisions of the second kind.

Other experiments show that more than one active entity is involved in the excitation of the first positive bands in the afterglow. This was done by destroying the visible afterglow by heating, and then showing that the 'dark modification' of active nitrogen could still excite the D lines of sodium. The NO bands, requiring about 6 volts for their excitation, are also quenched by heating. This seems to show that the metastable molecules are quenched by heating and the metastable atoms are undisturbed. Willey showed that when a mild electric discharge was passed through active nitrogen and the visible glow destroyed, the remaining gas was still active and was capable of exciting chemical reactions in which the energy was about 45,000 cal. This, it is seen, is in agreement with the present experiments.

The absence of absorption in active nitrogen between 3000 A. and 6500 A. has been reported by several observers. On the hypotheses presented here, the absorption, if present, should be either in the far ultra-violet or in the far red. The far ultra-violet corresponds to atomic absorption and the far red to the absorption of first positive bands, from the low A vibrational states in which most of the metastable molecules are likely to be.

A detailed account of this work will be presented later.

Square Roots and the Decimal System.

IN NATURE of Mar. 3 is an obituary notice of the late Alexander Siemens. The last two sentences of this obituary suggest that possibly there is a misprint or a misunderstanding.

These sentences referred to are as follows:

"There was one thing said at this meeting which the writer never saw contradicted, and that was that without the decimal system it would not be possible to extract square roots. It is quite easy, however, to turn the square root of any number or fraction into a continued fraction and then find its value to any required degree of accuracy as a vulgar fraction."

I am sure Mr. Siemens never advocated the adoption of the decimal system in arithmetic or anything else but weights and measures. Any other application of the decimal system would be quite equal to the American Congressman that tried to get a bill through Congress enacting that π should be proclaimed by law to be 3·000.

C. E. W. DODWELL.

46 Coburg Road,
Halifax, N.S.,
May 4.

I HAVE read Mr. Dodwell's remarks with interest. It will be noticed that I did not say that it was my friend Mr. Siemens that made the statement, but merely that it was said at the meeting. My recollection is that he asked a rhetorical question somewhat as follows: "How were the square roots of numbers such as 6 to be found if we had no decimal system?" I am certain that I was only prevented from speaking on this question by my desire not to help the opponents of the decimal system. I did not attribute it to Siemens in my obituary notice, because I looked up the account of the meeting in the *Journal of the Institution of Electrical Engineers* and found that it had been deleted, probably by the person who said it.

A well-known method of extracting square roots without using decimals is that first given in English in the "Arithmetic" of James Thomson, the father of Lord Kelvin, which was published in 1819. It is interesting to remember that by 1880, when Lord Kelvin and his brother James edited it, it had run through seventy-one editions. Using this method, we get

$$\sqrt{6} = 2 + \sqrt{6} - 2 \qquad = 2 + \frac{2}{\sqrt{6}+2}$$

$$= 2 + \frac{1}{2 + 1/(\sqrt{6}+2)} = 2 + \frac{1}{2 + \frac{1}{4 + \dots}}.$$

The 2 and the 4 repeating. Thus we get as convergents to $\sqrt{6}$,

$$2,\ \frac{5}{2},\ \frac{22}{9},\ \frac{49}{20},\ \frac{218}{89},\ \frac{485}{198},\ \dots$$

The last convergent equals 2·449495 approximately, and the true value is 2·449490 approximately. The successive convergents are alternatively less and greater than the true value. In this connexion something may be said in favour of vulgar fractions. The method is still set in school examination papers.

New Regularities in the Band Spectrum of Helium.

THE letter (NATURE, May 19) of Messrs. Takamine, Dieke, and Suga, reporting certain results in connexion with the analysis of the band spectrum of helium, was of peculiar interest to me, in view of the fact that I was proposing shortly to incorporate many of them in Part V. of a series of papers dealing with this subject. Mr. A. Harvey, working in collaboration with me, has measured and interpreted a number of new bands, chiefly in the less refrangible region, and, so far as can be gathered from the letter in question, has arrived at substantially similar conclusions. There appears to be at least one important difference of interpretation, but discussion of this had better await detailed publication. Meanwhile it may avoid confusion to remark that in all probability the band $3X \rightarrow 2P$ ('ortho-He') of Takamine, Dieke, and Suga, is that near λ5885 already described in Part IV. (*Proc. Roy. Soc.*, A, **118**, p. 157), whilst one designated $4Z \rightarrow 2P$ by Dr. Jevons and myself in a paper at present awaiting publication is actually the next series member to their $3Z \rightarrow 2P$. It is remarkable, and fortunate, that the same symbols X and Z have been respectively chosen in both cases for the new levels. The latter was employed in our case because of the large and unusual Zeeman effect exhibited by the lines of this band.

The effective electronic quantum numbers of these new levels will be of interest to theoretical workers and are as follows, those of several known atomic and molecular levels being included for comparison:

	S.	*P.*	*D.*	*X.*	*Z.*
ortho He	1·689	1·937	2·997	—	—
par He	1·850	2·009	2·998	—	—
ortho He_2	1·788	1·928	3·013	2·958	2·935
par He_2	1·853	1·964	3·015	2·972	2·952

It will be noted that the $p\mathrm{He}_2$ values are throughout higher than the corresponding $o\mathrm{He}_2$ values, and it is significant that the atomic parhelium and orthohelium quantum numbers differ consistently from one another in the same sense. We have here, probably for the first time, quite unambiguous evidence for the existence of molecular electronic levels which are additional to the ordinary atomic system of levels. Such additional levels constitute an important feature of Hund's recent theoretical work on band spectra. Briefly expressed, his view is that whereas in atoms the term type is determined by the total orbital angular momentum (l) of the outer electrons, in molecules it is determined by the component (i_l) of this parallel to the line of nuclei. Thus in atoms we have only one S sequence ($l=0$) of a given multiplicity, but in molecules more than one may exist, corresponding to $i_l=0$ ($l=0, 1, 2 \ldots$). The characteristics of the X level, for example, strongly suggest that it is related to the S level in some such way as this.

The Sligo Artefacts.

FOR some years past, in my researches upon the Norfolk coast, I have made a close study of the alleged hurling of large flints against each other during storms, and as, after much observation, I have not seen such collisions take place, I am unable to believe in their occurrence in the area I have investigated. So far as my knowledge extends, the capability of waves in picking up stones is limited to comparatively small specimens. These, when they fall, may strike others lying upon the beach, but such impacts, especially as they occur in water—a medium which definitely lessens the force of the blow—cannot remove, in ordinary circumstances, flakes of large dimensions (see *Science Progress*, No. 87, Jan. 1928). It is known that stones of considerable size are sometimes thrown by the action of the sea on to promenades, but these stones are apparently being rolled towards the shore, and by the uprush of the water when it meets a more or less vertical sea-wall, are carried on to the promenade. There cannot, of course, be any doubt that bulky masses of flint are propelled up the beach, sometimes aided by the buoying effect of attached seaweed, and I have witnessed such movements while storms were in progress upon the east coast. But the travel of the flints is very gradual, as it is only certain waves which are capable of moving them, and the extent of each stage of advance is generally small.

I am not familiar with the capabilities of the Atlantic in moving blocks of limestone upon the Sligo coast, but, for the reasons mentioned above, I would regard it as improbable that masses of this rock of the size described by Profs. Jones and Boswell in NATURE of June 2 could ever have been hurled to their present position by wave action. I can, however, imagine that such blocks could by slow degrees be transported by the sea to where they are now found. Actual observation during storms is what is needed for the elucidation of this question, and until this is carried out erroneous views regarding it may be prevalent.

Since Mr. Burchell's last letter to NATURE he has again visited Sligo and found *in situ* in ancient deposits, two more artefacts. One of these, made of quartzite, is a remarkable specimen, which is, I imagine, sure to be enthusiastically received by those who, like myself, by reason of the evidence already to hand, believe in the greater antiquity of man in Ireland. The other specimens, found previously by Mr. Burchell *in situ* in boulder clay, are, in my opinion, clearly of human origin, and of very great importance.

J. REID MOIR.

A Voracious Pike.

THE photograph here reproduced (Fig. 1) shows the attitude of two pike as they were washed ashore dead in the lake here a few days ago. The smaller fish, weighing 7½ lb., had bitten off a good deal more than he could chew of the larger—8 lb. I suppose the two fishes met head on, so that neither could discern the size of the other. The smaller fish, seeing something that seemed edible before him, went for it and paid full penalty for its voracity. Several years ago the late Mr. Malloch, of Perth, sent me a photograph of two pike that had been washed ashore in Loch Tay in precisely the same posture as ours. If I remember aright, they weighed 8 or 9 lb. apiece.

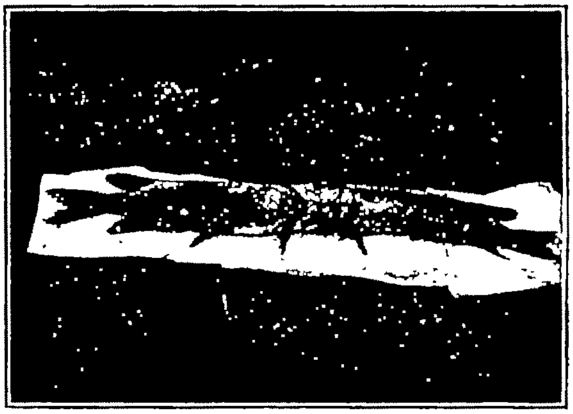

FIG 1.

HERBERT MAXWELL.

Woods and Wireless.

IN a letter in NATURE of April 7, Dr. Rolf makes some very interesting comments on the subject of absorption of wireless waves by trees, and refers to a paper in which I directed attention to this phenomenon. It is quite clear, as Dr. Rolf points out, that the capacity effect of the tree ought to be taken into account as well as its conductivity effect. It appears to me, however, to be a little doubtful whether such a simple modification of Sommerfeld's theory as Dr. Rolf proposes, is all that is required. The constants of conductivity and S.I.C. employed by Sommerfeld are for an isotropic medium, whereas used in connexion with trees they refer only to the vertical axis. Again, if we increase the conductivity of the tree we clearly increase the energy absorbed, and therefore the attenuation will be greater, whereas by Dr. Rolf's method, an increase of the conductivity leads to the opposite conclusion.

Dr. Rolf seeks to explain by the capacity effect of trees the curious phenomenon of negative damping (which, by the way, was first discovered not by myself but by Messrs. Ratcliffe and Barnett), but I am inclined to doubt whether this is the cause in the case of the curve obtained for Daventry, since this region is one of comparatively few trees, and further, the departure of the attenuation from its ideal value (assuming a bare surface) has been found to be small. The explanation, however, should not be abandoned without further investigation.

Radio Research Station,
Datchet, Windsor,
May 16.

Coal-mining Explosives.

THE dangers due to the presence of inflammable gas and dust in the working atmosphere have led to the development of a special class of explosives for use in coal mines. In general these are detonating explosives, to which have been added 'cooling salts' (for example, sodium chloride) or into which have been introduced a 'cooling agent' (ammonium nitrate), the object of which is to reduce either the amount or the temperature of the flame the explosive gives on detonation. An increased margin of safety in the presence of firedamp has been secured by these means. A rather serious drawback has been that the efficiency of the explosive has, naturally, been decreased, and as a result detonation has been made less certain; that is, the possibility of misfires has been increased. A limit is thus set, beyond it is not advisable to proceed. In the opinion of some observers, this limit has already been passed.

None of the present coal-mining explosives is a true safety explosive, and all are capable of igniting mixtures of firedamp and air in certain circumstances. On the other hand, many explosives, the use of which would rightly be considered dangerous in coal-mining work, may be fired under carefully controlled conditions in the presence of an inflammable firedamp–air mixture without causing ignition. It would appear that it is the conditions under which the explosive is fired that are of prime importance in deciding whether an ignition of firedamp or coal dust can take place or not, and the comparative immunity of the coal mines of Great Britain from ignitions due to the use of explosives is stated to be quite as much to the credit of the shot-firer for the care taken by him in carrying out his duties, as to that of the manufacturers of the explosives used.

As a basis for the researches on coal-mining explosives which are being carried out at the Safety in Mines Research Station at Buxton, it is therefore considered that the rational lines on which to proceed are to concentrate on the effects of methods used underground in firing explosives, in order to help the shot-firer to use them safely, rather than on the effects of the materials of which explosives are made in the hope of producing an inherently safe explosive. An outline of the methods used and of some of the results already obtained has been given recently by Dr. W. Payman.[1]

One of the difficulties of these researches is due to the fact that it is not possible to devise a single test which will give satisfactory information of the behaviour of an explosive under all the very varied conditions met with in mining operations. The main feature of the present official test, as recently modified by the Explosives in Mines Research Committee, consists of firing the explosive from a steel cannon, untamped, into an explosive mixture of firedamp and air. This gives a measure of the relative safeties of different explosives under one set of conditions, but though many of the explosives on the present 'Permitted List' have been fired under the conditions of the official test and 30 to 40 ounces have been used without causing ignition, yet some of these explosives have caused ignition of firedamp underground with so small a charge as 4 ounces.

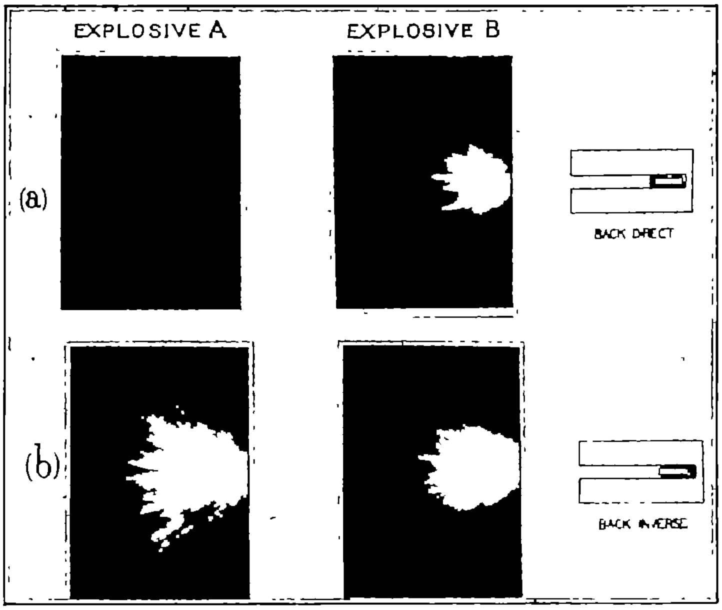

FIG. 1.

A method of test sometimes used to supplement the official test in Great Britain and other countries is to measure photographically the amount of flame given out by an explosive on detonation. This method, on which great reliance is often placed, is of no real value taken alone, as is shown by the photographs reproduced in Fig. 1. Two explosives were used for these photographs, and those at (*a*) show the amount of flame produced on firing the explosive as in the official test. In the official test, Explosive A is more dangerous than Explosive B, although it gives less flame. For photographs (*b*) the experiment was repeated, except that the detonator was placed at the back of the charge instead of at the front. Though this makes no apparent change in the safety of either explosive in the official test, it will be seen that it results in much more flame being sent out by the explosive.

It is evident from these photographs that the modern coal-mining explosive, or 'permitted' explosive, as it is called, is by no means a flameless explosive. If we are to learn anything about the mechanism of ignition of a firedamp–air mixture by an explosive, it will be necessary to find the answer to two questions. The first is not why do explosives cause the ignition of a gas mixture, but why do not these large, apparently hot, flames produced by 'permitted' explosives during official test always ignite firedamp–air mixtures when they are fired into them? Secondly, when ignition does result—for example when the charge is increased—is the flame then the cause, or if not, what is? The attempts to answer these questions are regarded by Dr. Payman as the most important part of the research work on explosives which is being carried out at Buxton.

---

[1] "The Problem of the Safe Use of Coal-mining Explosives." W. Payman. Midland Institute of Mining Engineers, General Meeting, Leeds, April 17, 1928.

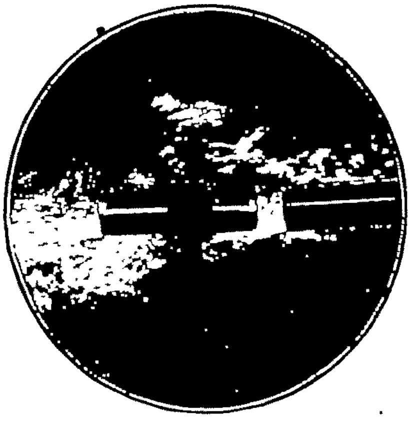

FIG. 2.

When an explosive is detonated, it is converted into gaseous products at high temperature and pressure. When fired untamped, as in the official test, there is projected from the mouth of the shot-hole the flame of the explosive accompanied by the gaseous products of explosion. Further, the shattering effect which makes itself evident in practice by breaking down the coal must have a similar effect on the air outside the shot-hole. This is the concussion effect apparent to a greater or less degree by its effects on the ear whenever a shot is fired. Since it is known that nearly all flames will cause the ignition of an inflammable gas mixture, it is convenient to consider the flame as the chief potential source of ignition of firedamp when explosives are fired. The effects of the hot gases and shock and pressure waves can then be considered separately, not only with regard to the possibilities of their causing or aiding ignition, but also with regard to the likelihood that they may lessen or remove entirely the igniting power of the flame.

A method has been developed at Buxton, based on an old German optical device, which enables photographs to be obtained of the invisible detonation gases and waves sent out by an explosive in addition to photographs of the visible flame. This method depends essentially on the refraction of a beam of light at the edges of the detonation gases and at the surface of the shock wave. The method has been used to give both 'snapshots' and moving film records, the former using the spark produced on the almost instantaneous discharge of a Leyden jar, the latter using a powerful arc lamp to give the beam of light.[1] The utility of the method may be appreciated from Fig. 2, which shows a photograph of a normally invisible stream of compressed air passing through a glass tube.

In order to obtain a photograph of a shock—or concussion—wave independently of any flame or products of detonation, such a wave was produced by bursting a small celluloid disc by means of compressed air, the record reproduced in Fig. 3 being obtained. The front of the shock wave, which is approximately spherical, is shown as a circle, the wave resembling somewhat a soap-bubble blown from the end of a tube.

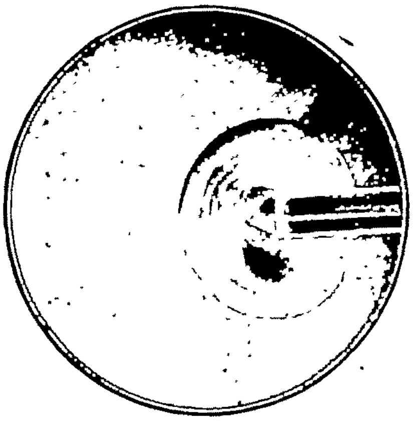

FIG. 3.

The next photograph (Fig. 4) shows the wave and the gaseous products of detonation when a No. 6 fulminate detonator is fired in an iron tube open at both ends. Here again we see the approximately spherical shock-wave, but now it is closely followed by the gases evolved on detonation. The shock-wave marks the boundary of disturbance, and the air outside this at the instant the photograph was taken is quite unaffected. The air which was formerly enclosed within the space defined by the spherical shock-wave has now been compressed into the space between the shock-wave front and the front of the gaseous products of detonation.

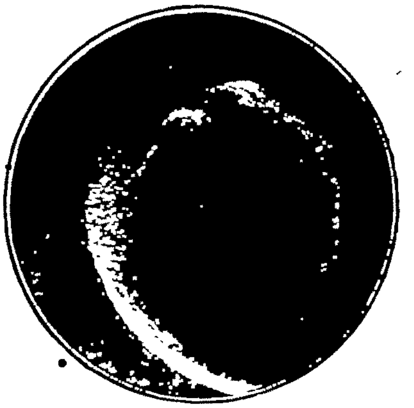

FIG. 4.

Moving film records have enabled the speed of the shock-wave to be determined, and have also given the relative position of flame, waves, and gases as they travel away from the shot-hole.

In addition to the purely scientific examination of the formation and spread of explosive gases, flames, and waves away from an explosive, these photographic methods are being linked up with experiments designed to examine the ignition process under actual conditions of mining practice.

---

[1] A full description of the method is given in "The Pressure Wave Sent out by an Explosive," Part 1, by W. Payman and H. Robinson. Part 2 by W. Payman and W. Shepherd. *Safety in Mines Research Board Papers*, No. 18 and No. 29.

The Sun's Outer Atmosphere.[1]

By Prof. E. A. Milne, F.R.S.

Astronomers are accustomed to divide the outer regions of the sun into four parts: (1) the photospheric layers, (2) the reversing layer, (3) the chromosphere, (4) the corona. In this address I wish to deal particularly with the chromosphere, but before doing so I should like to dwell a little on certain aspects of this fourfold division. Meteorologists make a similar subdivision of the earth's atmosphere. We have the troposphere, the stratosphere, the conducting layers, the auroral layers, and so on. But meteorologists have at least one advantage over solar physicists—meteorologists know where the earth's atmosphere begins. It may leave off very indefinitely, but it certainly begins quite definitely—it begins at the solid and liquid crust of the earth. It is sharply bounded below. But on the sun, and indeed on any star, no such sharp base exists. Whether the sun is wholly gaseous, or whether with Dr. Jeans we suppose it to be ultimately in a liquid state in the far interior, we are at least certain that owing to the high surface temperature and the positive temperature gradient implied by the outflow of heat, the entire outer layers, down to a depth much greater than the furthest depth we can see, are in the gaseous state. We therefore have no datum line for the base of the solar atmosphere.

It is true that, as seen in the sky, the sun has a sharp edge. But we have to remember that at the sun's distance one second of arc corresponds to 700 km., and that a line of sight passing one second of arc inside the sun's limb traverses 64,000 km. of the solar sphere. Thus the sharpness is to some extent illusory. We can, however, assert that above the level corresponding to the 'sharp edge' the gases are practically transparent as regards their continuous spectrum, whilst below this level they are practically opaque. If we knew the intrinsic opacity (per unit mass) of the solar material, we could calculate the pressure at which the transition from practical transparency to practical opacity takes place, for a line of sight nearly tangent to the sun. Assuming that general opacity arises from the ejection of photo electrons, the various unknowns may be estimated. We find that the opacity of a column of given length varies as the square of the pressure, and hence falls off rapidly outwards. It appears that practical transparency along a tangential line of sight occurs at a pressure of about 10^{-6} atmospheres. When we view the sun's surface normally, at the centre of the sun's disc, we see to a deeper level. Calculation shows that all but one per cent. of the light originates at depths where the pressure does not exceed 10^{-3} atmospheres. This change of pressure, 10^{-6} atmospheres to 10^{-3} atmospheres, appears to take place in a range of depth of some 50 km. These limits serve to define the 'photospheric layers'—the layers within which originates the light of the continuous spectrum sent to us by the sun.

Superimposed on the sun's continuous spectrum is an absorption line spectrum. Some of these lines show in their fine structure reversals, but we may ignore these and state that for the undisturbed solar disc we have, broadly speaking, a spectrum composed entirely of absorption lines. We are not compelled to assume that the layers producing *these lines are entirely exterior to the photospheric* layers. Theory shows that, provided the temperature decreases outwards, an absorption spectrum will be shown if the gas has a general coefficient of absorption and superimposed on this certain selective absorption coefficients associated with particular wave-lengths. Thus if the general coefficient of absorption remained definitely constant at all levels up to the sun's boundary, we should still have a Fraunhofer spectrum. Actually, if we accept the photoelectric origin of the general absorption, the general absorption coefficient per unit mass decreases with the pressure, and thus as we pass outwards the general absorption coefficient *becomes practically zero whilst* the selective absorption coefficients are still large. There is therefore a region effectively transparent except in the lines themselves. Nevertheless, within the photospheric range of pressures already mentioned, selective line absorption will also be occurring. The term 'reversing layer' is used to denote in a general way those layers which contribute to the Fraunhofer spectrum, but we now see that there is no precise delimitation between the reversing layer and the photospheric layers. The two shade into one another. The photospheric layers are also giving rise to line absorption, though this absorption will be weak; in other words, the *residual intensities* of the lines produced in this region will not be much below the intensity of the continuous background. The upper reversing layer, transparent except in the lines, will give rise to stronger lines, that is, lines with smaller residual intensities.

As evidence for this we have that the stellar sequence of spectra indicates a pressure of the order of 10^{-4} atmospheres for the layer in which absorption lines of excited atoms originate, but a pressure of the order of 10^{-7} atmospheres for the layer in which absorption lines of normal atoms originate. The former pressure lies inside our photospheric range of pressure, the latter pressure *lies outside it.*

In the upper reversing layer a new feature begins to present itself—the selective effect of radiation pressure near a wave-length of selective absorption. Now it must be supposed that selective absorption is occurring to some extent at all depths throughout the sun; in the far interior, the X-ray levels of the atoms will be giving rise to selective absorption. We may, therefore, pause for a moment to inquire how it is that selective radiation pressure only arises on the fringe of the sun. The pressure of radiation at any particular wave-length is proportional to two factors. One is the net outward stream of radiation—the difference between the inward and outward streams; the other is the selective absorption coefficient in that wave-length—the degree of obstruction offered. But the selective absorption has itself an influence on the net stream. Where the selective obstruction is high, neither an inward nor an outward beam can go very far without being absorbed, and consequently the average distance (from a given atom) from which either an inward or outward beam originates is very small. When the state is one of 'local thermodynamic equilibrium,' as can be shown to hold provided the density is not too low, this has the effect of making the inward and outward beams very nearly equal at a wave-length of strong selective absorption. They originate from places so close to one another, both in space and in temperature, that they are only slightly unequal. They accordingly very nearly cut one another out. Thus in the product (selective absorption coefficient) × (net stream) the effect of the large selective absorption coefficient is neutralised by the small net stream, and we get no appreciable effect of selective radiation pressure; the radiation pressure is the same at a wave-length of selective absorption as at a wave-length where there is no selective absorption.

---

[1] Discourse delivered at the Royal Institution on Friday, Mar. 9.

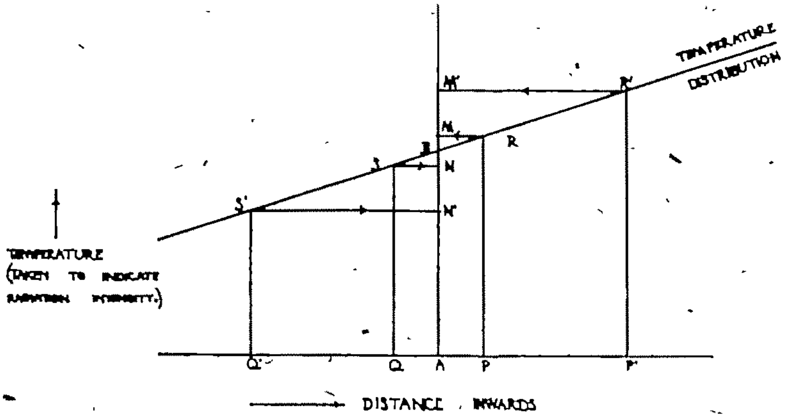

FIG. 1.—Diagram to illustrate the absence of selective radiation pressure in local thermodynamic equilibrium in interior. AM and AN represent the outward and inward fluxes at A in ν-radiation, AM' and AN' the outward and inward fluxes at A in ν'-radiation, where $k_\nu > k_{\nu'}$ (k = absorption coefficient) These fluxes originate at the mean positions P, Q, P', Q' respectively, where $AP < AP'$ because $k_\nu > k_{\nu'}$. The following relations hold:

i. Large absorption coefficient k_ν.
Net flux at $A \propto AM - AN = MN \propto PQ \propto 1/k_\nu$.

ii. Small absorption coefficient $k_{\nu'}$.
Net flux at $A \propto AM' - AN' = M'N' \propto P'Q' \propto 1/k_{\nu'}$.

Hence ($k_\nu \times$ net flux in ν-radiation) = ($k_{\nu'} \times$ net flux in ν'-radiation), or radiation pressure due to ν-radiation = radiation pressure due to ν'-radiation.

Thus no selective effect in the interior.

Let us now see what happens near the boundary of the star, assuming local thermodynamic equilibrium holds up to the boundary. Near the outer confines of the star the inward stream is small, and there is little to neutralise the outward stream. The net stream is almost equal to the outward stream, and a big selective absorption coefficient will give rise to a big selective radiation pressure.

We can look at the matter at a slightly different angle. At the outside of the star, the big selective absorption coefficient, combined with such outward stream as exists, gives rise to a big selective radiation pressure, even though the big selective coefficient has itself cut down the outward stream to a value below the photospheric value. As we go inwards, an inward stream is generated by the back radiation from the atoms traversed, and this soon nearly balances the outward stream, giving a small net stream in the interior.

At all depths selective absorption cuts down the intensity of each stream. The difference between the interior and the surface is that in the interior the two streams are cut down to nearly the same amount and balance one another, whilst at the surface the outward stream, though cut down, is unbalanced.

The consequence of this is that in the upper reversing layer the gases are pushed outwards by selective radiation pressure, and so the layer is less compressed than the lower reversing layer and photospheric layer beneath. It is not easy to make an exact calculation, but it appears roughly that for calcium atoms the pressure decreases from 10^{-5} atmospheres to some very small pressure in a range of about 100 km. This estimate is not to be pressed—it may perhaps be an under-estimate. But we shall not go far wrong in attributing a thickness of the order of some hundreds of kilometres to the upper reversing layer.

In this region, in a steady state, the atoms are maintained in equilibrium under gravity, the gradient of gas pressure and selective radiation pressure. As we go outwards selective radiation pressure steadily increases in importance. The question arises, what happens at the upper boundary of this layer? Actually, it cannot have a definite upper boundary, but we will suppose we are endeavouring to trace the pressure upwards by the same principles as govern the equilibrium of the earth's atmosphere, selective radiation pressure only being added. Two possibilities arise: either selective radiation pressure, though increasing, remains steadily less than gravity, or it attains a value greater than gravity. It may do the former for some kinds of atoms, the latter for other kinds of atoms. In the former case nothing particular happens; the atoms of this particular kind simply thin out moderately rapidly. In the latter case, we arrive at a contradiction. When radiation pressure exceeds gravity, equilibrium is no longer possible unless the gradient of gas pressure becomes reversed. As it is difficult to see how the gas pressure could ever begin to decrease again once it began to increase—and it must ultimately decrease because the sun's atmosphere is finite—we reject this possibility. But if equilibrium is no longer possible, since we have assumed equilibrium all the time, something must be wrong with our assumptions. We could only now keep the atoms in equilibrium if we assumed some kind of hypothetical net which caged the atoms down. Let us suppose that the atoms are, in fact, kept in equilibrium by a net of this kind, and that then the net is suddenly removed. What will happen?

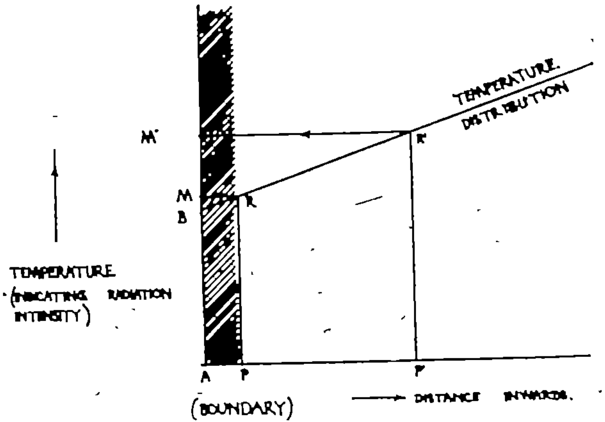

FIG. 2.—Diagram to illustrate existence of selective radiation pressure at boundary (chromosphere absent). AM and AN represent the emergent fluxes at the boundary in ν and ν'-radiation ($k_\nu > k_{\nu'}$). They originate at depths P′ and P′ respectively, and so correspond to temperatures PR and P′R′. Since k_ν is large, P is practically at A, and the emergent flux in ν-radiation corresponds closely to the boundary temperature AB. The following relations hold:

i. Large absorption coefficient k_ν.

$\text{Net flux} \propto AM = AB + BM = AB + a/k_\nu$.

ii. Small absorption coefficient $k_{\nu'}$.

$\text{Net flux} \propto AM' = AB + BM' = AB + a/k_{\nu'}$.

ν – Radiation pressure $\propto k_\nu AM = k_\nu AB + a$.

ν' – Radiation pressure $\propto k_{\nu'} AM' = k_{\nu'} AB + a$.

Hence $k_\nu > k_{\nu'}$ implies ν-radiation pressure > ν'-radiation pressure.

The atoms, being acted on by a radiation pressure exceeding gravity, will be ejected from the layers below. An outer atmosphere will come into being. But the ejection of atoms will not proceed indefinitely. As this new outer atmosphere becomes thicker and thicker its back radiation will begin to be appreciable; it must be constantly returning to the layers below some fraction of the radiation incident on it. The back radiation will exert a downward pressure, which will go on increasing with increasing thickness of the outer atmosphere until finally its back pressure is equal to the pressure exerted by our hypothetical net. After that no more atoms will be ejected, and the outer atmosphere will be permanent, and will exist in a state of equilibrium.

In the case of the sun we identify this outer atmosphere with the chromosphere, observed at times of total solar eclipse and spectroscopically at other times. About a century ago, Canning called a New World into existence to redress the balance of the Old. For millions of years the sun has been calling a new atmosphere into existence to redress the balance of the old.

(To be continued.)

Obituary.

DR. CHARLES H. GILBERT.

IN the passing of Dr. Charles Gilbert, America has lost one of her most trusted fishery authorities and a zoologist of wide reputation. He had retired from his professorial duties at Stanford University, California, some three years ago, and was devoting his whole energies to the working out of salmon problems on the Pacific coast, and specially in Alaska, where the most productive salmon fisheries of the world now exist, when a sharp attack of bronchitis terminated his career.

A native of the State of Illinois, Dr. Gilbert early came under the spell of that famous ichthyologist, David Starr Jordan, and in a short time was his most prominent pupil and then his associate in various expeditions. Ere long, papers were appearing on the fishes of southern California and the Pacific Islands over their joint names. When the Stanford University was created in 1891, Jordan became the principal and Gilbert the professor of zoology. At the age of sixty-five he retired, after occupying the chair for thirty-four years. His published work during this long period, as shown in Dr. Bashford Dean's "Bibliography of Fishes," was almost exclusively on systematic ichthyology. He described many new species—in one paper 32, and in another 25—in a search of American waters. He studied the fishes of Panama when de Lesseps was engaged upon his unsuccessful effort to construct the canal, and he also wrote on the fishes of the inhospitable Galapagos Islands, and of Hawaii and Japan.

It was in 1880 that Dr. Gilbert first became associated with the U.S. Fisheries Commission, and from that time forward much of his work had practical application to fishery problems on the Pacific Coast. The interests of the salmon began to claim him from the year 1912, and it may be said without much fear of contradiction that his best and most useful work was carried on in the elucidation of the great runs of salmon in British Columbia and Alaska, and that in this branch of investigation he became the leading authority. Salmon research in Scotland had already revealed not only the importance of marking fish, but also the great value of salmon scale study, and Gilbert was the first in America to appreciate the insight into the life history of fishes which this branch of study can yield.

The runs of salmon in the famous Fraser River, which since the days of the Hudson's Bay Company had been regarded as inexhaustible, had begun to decline in a rather alarming manner, and a great fall of rock into the Hell's Gate cañon during the making of the Canadian Northern Railroad had blocked the river and wiped out the 'big run' which occurred every fourth year. The extensive canning industry became seriously alarmed. Gilbert came to the aid of British Columbia and produced a series of admirable papers on the life history of the most valuable species (*Oncorhynchus nerka*), the Sockeye, and laid the foundation for the scientific study of the other species found in the rivers of the coast.

Since the salmon interests of the State of Washington and of British Columbia were inextricably linked in any scheme of regulative treatment, it was clear that only by the creation of a joint body representing both the United States and Canada could satisfactory results be attained. Dr. Gilbert was one of those who actively urged the calling of a conference for the consideration of this proposal, and in the spring of 1925 a representative body assembled at Seattle. From this there sprang into being the International Pacific Salmon Investigation Federation under the chairmanship of Mr. Henry O'Malley, the U.S. Commissioner of Fisheries. One of the important lines of investigation decided upon was the migrations of salmon to Alaska and an estimate of the spawning stocks necessary for the maintenance of the fisheries, and this work was naturally put into Dr. Gilbert's hands. The biological work generally is in charge of Dr. Willis Rich, of the U.S. Bureau of Fisheries, a worker who has repeatedly collaborated with Dr. Gilbert in recent years.

The Federation has suffered a great loss in the death of one of its most thorough and trustworthy investigators. W. L. C.

DR. HIDEYO NOGUCHI.

WE much regret to see the announcement that Dr. Noguchi died at Accra on May 21, of yellow fever contracted in the course of his investigation of the cause and mode of transmission of that disease. Our readers will recall that Prof. Adrian Stokes died in the same way in September last, and some of them may remember the death of that brilliant young man, Walter Myers, when he went to Para on the same errand so long ago as 1901.

During the last ten years Dr. Noguchi has been extensively engaged on the parasitology of yellow fever as it occurred in Central and South America, working in conjunction with the sanitary campaign by which the International Health Board have very nearly succeeded in eradicating the disease in those parts. In Ecuador in 1918 he found a spirochæte which could be grown in pure culture and with which a disease resembling yellow fever could be produced in guinea-pigs and some other animals. The organism had been seen in the kidney of a fatal case some years before by Stimson, but his account was published briefly in an official report, and no particular importance was attached to it. Noguchi produced cumulative evidence that his *Leptospira icteroides* was distinct from other similar organisms and etiologically related to yellow fever, which was very strong if not entirely conclusive: a convenient summary by him will be found in the *Lancet* (1922, vol. i. p. 1185). The well-established facts that the disease can be transmitted by an ultramicroscopic agent either by injection or through the mosquito are quite in harmony with his thesis, for other spirochætes are known to have invisible phases. With his cultures he prepared vaccines and sera, but there has, we believe, been no satisfactory opportunity for getting a conclusive test of their value in prevention and treatment. The American commission which for the past two years has been investigating the disease as it occurs in West Africa, to which Prof. Stokes was attached, found that the indigenous monkeys and other animals were quite immune to the disease, but by the use of highly susceptible *Macacus* imported from India they have provided further experimental proof that the disease is transmissible by mosquitoes, and that the virus is invisible. Of the *Leptospira* they could find nothing, possibly because yellow fever in Africa is not the same thing as yellow fever in the Americas. It was doubtless this discrepancy which led Dr. Noguchi to Accra last November with such unhappy results.

Dr. Noguchi was born in Japan in 1876, and educated at Tokyo University and the Institute for Infectious Diseases. He went to the United States in 1901 as lecturer on pathology in the University of Pennsylvania, and afterwards worked at the Carnegie Institution. Since 1914 he has been one of the most distinguished members of the staff of the Rockefeller Institute. Apart from yellow fever, he will be remembered for his pioneer work on the cultivation of spirochætes outside the body and their specific differentiation, for his demonstration of the *Spirochæta pallida* in the brain which gave the final proof that general paralysis was syphilitic, and for his work on vaccine virus. The successive volumes of the *Journal of Experimental Medicine* are good enough evidence of his fertile brain and clever hands. Lately he has been working out the cause of oroya fever in Peru, which seems to be due to a minute parasite inside the red blood corpuscles.

WE regret to announce the following deaths:

Mr. A. R. Bennett, a well-known telephone engineer who was responsible for many inventions connected with the telephone in its early days, on May 24, aged seventy-eight years.

Dr. William F. M. Goss, past president of the American Society of Mechanical Engineers and formerly professor of railway engineering and dean of the college of engineering at the University of Illinois, on Mar. 23, aged sixty-eight years.

Dr. John Horne, F.R.S., formerly assistant director in Scotland of the Geological Survey, on May 29, aged eighty years.

Prof. C. W. Howard, director of the Government Bureau for the Improvement of Sericulture in Kwongtung Province, who had recently been appointed head of the Department of Biology at Wheaton College, Illinois, and was an entomologist of wide experience in the United States, South Africa, and China, on Mar. 1, aged forty-six years.

Prof. Otto Nordenskjold, an honorary corresponding member of the Royal Geographical Society, leader of the Swedish Antarctic expedition of 1902–3, on June 2, aged fifty-eight years.

News and Views.

THE King's Birthday honours list includes the names of the following men of science and others associated with scientific work: *Order of Merit*—Sir George Grierson, in recognition of his eminent position as an Oriental scholar and of the value to the Empire of his work on Indian languages and dialects. *Baron*—The Right Hon. Sir Alfred Mond, Bart., chairman of Imperial Chemical Industries, Ltd. *Knights*—Dr. J. H. Jeans, secretary of the Royal Society; and Capt. G. H. Wilkins, the distinguished Australian aviator and explorer, who recently flew an aeroplane across the Arctic Ocean from Alaska to Spitsbergen. *Companion of Honour*—Prof. J. S. Haldane, Director of the Mining Research Laboratory of the University of Birmingham. *G.B.E.*—Sir John Dewrance, past president of the Institution of Mechanical Engineers. *C.B.E.*—Dr. C. H. Lander, Director of Fuel Research, Department of Scientific and Industrial Research; and Mr. H. E. Wimperis, Director of Scientific Research, Air Ministry. *O.B.E.*—Prof. A. V. Bernard, professor of hygiene and preventive medicine in the University of Malta, and Medical Officer of Health, Malta; Mr. R. S. Cooke, Inspector-General, Ministry of Auqaf, and Honorary Director of Antiquities, Iraq; Mr. E. R. Sawer, Director of the Department of Agriculture, Palestine; Dr. W. S. Tucker, Director of Acoustics at the Air Defence Experimental Establishment, War Office; and Mr. R. McK. Wood, principal scientific officer, Royal Aircraft Establishment, Farnborough. *M.B.E.*—Mr. W. R. Black, assistant principal, Ministry of Agriculture and Fisheries; Dr. J. F. Corson, assistant bacteriologist, Medical and Sanitary Department, Tanganyika Territory; and Mr. G. Maclean, Sleeping Sickness Officer, Medical and Sanitary Department, Tanganyika Territory.

THE Institution of Civil Engineers has had the good fortune to be served by a succession of secretaries of outstanding ability, the name of one of whom, James Forrest, is commemorated by the James Forrest Lecture, while the name of his predecessor was given to the Manby Premium. Charles Manby (1804-1884) was the son of Aaron Manby, and helped his father construct the first iron steamer to go to sea, and also worked under him at the Paris Gas Works and the Charenton Ironworks. Establishing himself in London as a civil engineer, in 1839 he became secretary to the Institution, in the duties of which James Forrest (1825–1917) assisted him. On retirement in 1856, Manby was presented with a sum of money "as a token of personal esteem and in recognition of the valuable services" he had rendered to the members individually and collectively. During the early 'fifties, Forrest had been assistant secretary to the Society of Arts, but on Manby's retirement he returned to the Institution of Civil Engineers and continued to hold that important post until 1896. During his tenure of office the names on the roll had risen from between 800 and 900 to 6900, inclusive of the student class, while the annual income had grown from £3000 to more than £20,000. Various marks of respect were shown Forrest. His portrait was presented to the Institution in 1890, an endowment fund for the James Forrest Lecture was raised in 1891, while Forrest himself, after retirement, established in 1897 the James Forrest medal, to be awarded annually to the writer of the best student's paper. On retirement, Forrest was succeeded by Dr. Tudsbery, who in turn has been succeeded by Dr. Jeffcott.

ON the eve of his elevation to the peerage, Sir Alfred Mond was able to announce to the first ordinary general meeting of the shareholders of Imperial Chemical Industries, Ltd., that the profits for the year had exceeded the estimate by half a million pounds, a result he attributed to the improvement of trade consequent upon a less disturbed labour position, the uniformly good relations prevailing between the management and employees in the various firms absorbed in the merger, the continually increasing demand for heavy chemicals in the artificial silk industry, in agriculture, etc., to the increased capacity of the combine to be adventurous in research and in applying its results, and to the negotiating power which its capital resources conferred upon it. Referring to negotiations with chemical interests in other countries, Sir Alfred said the merger has laid it down as a cardinal point of policy that it must regard itself as the guardian of the national safety in the way of production of chemical products, and many of its research activities are based upon the need for carrying that policy into effect. It expects shortly to put into operation a plant to manufacture methanol, an important raw material of the dye industry for which Great Britain is at present dependent on foreign sources of supply, and the Billingham factory hopes to make the production of petrol from coal a commercial proposition. Impetus has been given to the researches into this chemical engineering problem by the import duty on oil fuel. The tradition of the associated firms of the essential necessity of research and its continuous application has been strengthened by the formation of a consultative research council representative of the academic and industrial world.

THE Commission for Synoptic Weather Information met in London during the week May 29–June 2, under the presidency of Lieut.-Col. E. Gold, Assistant Director of the Meteorological Office, Air Ministry. The Commission deals with the international exchange of the meteorological reports on which weather forecasts are based. It specifies the codes in which the reports shall be abbreviated and the time-table according to which the different radio services shall transmit the reports. Representatives from the meteorological services of Denmark, Holland, Belgium, France, Germany, Norway, Sweden, Finland, Russia, Poland, Czecho-Slovakia, Iceland, Portugal, Spain, and Great Britain attended the meeting, as well as the Director of the Meteorological Service of Canada and the Chief of the United States Weather Bureau. The meeting in London was preceded by a meeting in Paris of a sub-commission appointed to formulate proposals in regard to the collection and distribution of meteorological reports from the ocean. This sub-commission met under the presidency of General Delcambre, the Director of the National Meteorological Office of France. The British representative at the meeting at Paris was Commdr. L. A. Brooke-Smith, superintendent of the Marine Division of the Meteorological Office, Air Ministry. During the meeting in London the delegates were entertained by H.M. Government to luncheon, at which Sir Philip Sassoon, the Under-Secretary of State for Air, presided. They also paid a visit to the aerodrome at Croydon, when they inspected the meteorological service which provides for the requirements of aviation between London and the Continent.

By permission of the Air Ministry, a special meeting of the Royal Meteorological Society was held at the Croydon Aerodrome on Thursday afternoon, May 31. About two hundred fellows and their friends were present, including representatives from the International Commission for Synoptic Weather Information who were attending a conference at the Air Ministry. After a brief address of welcome by Sir Richard Gregory, president of the Society, supported by Dr. G. C. Simpson, Director of the Meteorological Office, a lecture on the "Development of Meteorological Services for Aviation" was given by Capt. F. Entwistle, Superintendent, Aviation Services Division, Meteorological Office. Capt. Entwistle explained the organisation by which pilots are not only informed of the weather conditions over the route they are flying at the time of the commencement of the flight, but also of the changes likely to occur and the prevailing conditions at neighbouring stations, so that an alternative route can be taken in the event of bad conditions on the normal route. Tea was provided at the Aerodrome Hotel, and afterwards guides conducted parties to the various points of interest in the aerodrome. These included the recently opened booking and waiting rooms, customs' offices, emigration department, control tower, etc. A popular feature of the afternoon was the opportunity provided by Imperial Airways, Ltd., to make short flights at a reduced charge in commodious air liners specially detailed for this purpose. About one-third of the company took advantage of this opportunity to make an ascent.

The last news from General Nobile in the *Italia* was received on the morning of May 25, when the airship was approaching Spitsbergen on the way back from the Pole in bad weather. Various relief measures have been taken in the hope that the explorers have reached land in safety. The *Città di Milano*, the *Italia's* base ship, made a cruise from King's Bay to Amsterdam Island, where heavy pack-ice forced her to return. The *Times* reports that Norway has sent Lieut. L. Holm with an aeroplane by sea to Spitsbergen, where Capt. R. Larsen will probably join him. The Store Norske Spitsbergen Coal Co. has arranged to put at the disposal of the search a team of sledge dogs with experienced dog-drivers. They will be sent overland from Advent Bay. The Italian and Swedish Governments also propose to send aeroplanes, and the Soviet Government has dispatched an ice-breaker from Archangel to the Barents Sea. The most probable place for the airmen to be found is the northern coast of Spitsbergen. There they may have found a few Norwegian trappers wintering. Sea communication with the north coast is not yet open, and the explorers, in want of sledge equipment, may have decided against an overland journey to King's Bay or Advent Bay. On the other hand, if the *Italia*, by want of fuel, or by damage to the envelope, was forced down on the drifting ice, there is less hope of the explorers having been able to reach safety. But the lack of news for some weeks need not be taken to imply disaster to all on board. The *Italia* may even have been carried as far as Novaya Zemlya.

The Samuel Augustine Courtauld Institute of Biochemistry will be opened at the Middlesex Hospital on June 14 by H.R.H. Prince Arthur of Connaught. At the ceremony, Sir Archibald E. Garrod will give an address on "The Place of Biochemistry in Medicine." The Institute, which is part of the scheme for the new Middlesex Hospital, was made possible by the generosity of Mr. S. A. Courtauld. It occupies a site at the back of the present Hospital and is six stories high, with a basement and sub-basement, connected to the main building by underground passages and a bridge across Union Street. Below ground is the boiler-house, designed to meet the needs of the whole of the new Hospital; on the ground floor is a well-designed restaurant for students of the Medical School; the upper five floors are given over entirely to biochemical work, and consist of four large fully equipped laboratories, one for students, another for clinical routine work, and two for research. There is also a series of small rooms for special purposes, such as the incubator room, the dark room, large-scale preparation room, library, office, and private room. Besides these, on the top floor there is some space that has not yet been allotted, and two large well-ventilated animal houses. The whole Institute is fully equipped with the most up-to-date apparatus, and everything has been done to ensure that the best possible means are at the disposal of the professor and his staff for the furtherance of biochemical research.

At the thirty-seventh annual general meeting of the Institution of Mining and Metallurgy, held at Burlington House, Piccadilly, on May 17, Mr. R. E. Palmer, president of the Institution, occupied the chair. In the course of the proceedings, the Hon. Peter Larkin, High Commissioner for Canada, presented to the Institution on behalf of Canadian friends and admirers of the late Dr. Willet G. Miller, Provincial Geologist for Ontario, a replica of the portrait of Dr. Miller which is now hanging in the Ontario Parliament Buildings. The president received it on behalf of the Institution. Dr. Miller was the recipient of the Gold Medal of the Institution in 1915, "in recognition of his eminence as an economic geologist, and of the important part played in mining by economic geology." Mr. Palmer then presented the Gold Medal of the Institution to the Right Hon. Sir

Alfred Mond, "in recognition of his scientific and industrial services in the development of the mineral resources and metallurgical industries of the British Empire." Sir Alfred Mond acknowledged this award of the highest honour the Institution can confer in a speech of considerable interest, in which he reviewed the advances made in the mining and metallurgical industries more particularly from the Empire point of view. Mr. Palmer delivered his presidential address, having for its subject "The Institution—its Objects, Aims, and Value, not only to the Members, but to the Profession and Mining Industry as a whole," after which he inducted the new president, Prof. S. J. Truscott, into the chair.

The coming congress of the International Astronomical Union at Leyden on July 5–12 offers every prospect of being an important and interesting meeting. Between two and three hundred delegates, representing more than twenty countries, so far removed as Japan and Mexico, will meet to discuss programmes of work which either require international co-operation or are best forwarded by general agreement in many details. For the first time since the War, representatives of the Central Powers and of Russia will be present; this year they come as visitors, but it is to be hoped that at the next conference their countries may have seen their way to enable them to come as full members. The main work of the Union lies in the meetings of some twenty-seven standing committees devoted to special lines of astronomical work. Resolutions adopted by the various committees will, after any financial implications have been examined, be placed before a general assembly of the Union at the close of the meeting. A visit to the Zuider Zee reclamation works is among the functions on the lighter side of the programme of the Union. The president is Prof. W. de Sitter, Director of the Leyden Observatory, and the local secretary is Dr. Hins, of the Observatory staff.

The effects of recent electricity legislation in Great Britain on the status and salaries of the engineers employed in the electricity supply industry is producing new difficulties which will have to be overcome if the community is to benefit. According to the Act, if a station fails to generate electricity at a price less than that at which it can be supplied to it by the Central Board, it is liable to lose its status as a generating station and be converted into a distributing station. Now the price which a station charges for electricity depends on the salaries and wages of the engineers it employs. If these are too low, it may be flourishing at the expense of other stations which pay their workmen higher wages. It seems necessary that some special legislative machinery be employed which will adjust salaries and wages, and so prevent strikes. It looks as if the electricity supply industry has become, or is on the point of becoming, the most vital industry in Great Britain. As the machines for producing the electric energy needed for electric lighting and industrial purposes are being concentrated in a few very large stations, the whole system will be very vulnerable to labour disturbances and a very brief stoppage would inflict most serious loss on the country. Formerly, railway transport could claim to be the most vital industry, but the general strike which happened a few years ago proved that road motor transport, its formidable competitor, could greatly mitigate the damage that would otherwise have fallen on the public. The objection to legislative machinery to prevent strikes and lockouts is that there are always some employers and trade unions who will ignore the proper channels for ventilating grievances.

Sir Ernest Rutherford, Cambridge, and M. Jean Perrin, professor of physical chemistry at the Sorbonne, have been elected associates of the Royal Academy of Belgium.

Sir William J. Pope has been elected Prime Warden of the Goldsmiths' Company in succession to Sir John Mullens. Other fellows of the Royal Society who have been Prime Wardens of the Company are Mr. George Matthey, Sir Frederick Bramwell, Sir Frederick Abel, Sir J. Wolfe Barry, Mr. C. T. Heycock, and Sir Dugald Clerk.

Mr. E. A. Reeves, map curator and instructor in practical astronomy and surveying to the Royal Geographical Society, has been awarded the Society's Victoria Medal. Mr. Reeves was president of Section E (Geography) at the Newcastle meeting in 1916 of the British Association, and is a distinguished cartographer. The Victoria Medal is given occasionally for purely scientific attainments, the last award being in 1927, to Sir Charles Close.

Mr. H. Richardson, Principal of the Bradford Technical College, has been made Officier d'Académie by the French Government. Mr. Richardson, who was formerly a Beyer fellow of the University of Manchester, was, before he received his present appointment, director of university studies in the College of Technology, Manchester, and secretary of the Board of the Faculty of Technology in the University. He has been closely concerned with the development of technical education in the textile industry. The French order 'Palmes Universitaires,' designed "to honour eminent talent and to reward services rendered to education," comprises two grades, Officier d'Académie and Officier de l'Instruction Publique. It is the former decoration which Mr. Richardson has received.

An earthquake of moderate intensity was recorded at Kew Observatory on June 1, at 13 hr. 24 min. 51 sec. G.M.T. The epicentre is estimated to have been 5770 miles away, but the records are too small to give any indication of the direction.

The Royal Danish Research Ship *Dana* is to leave Copenhagen about June 8 on a two years' world cruise under the command of Dr. Johannes Schmidt. We understand that both physical and biological work will be undertaken, and as regards the latter, it is expected to include much more pelagic than bottom work. All the oceans of the world will be visited, but special attention will be given to the western part of the Pacific Ocean.

Owing to numerous requests on the part of archæologists, Mr. Reid Moir will make an exhibit in London, during June and July, of specimens illustrative of all the phases of prehistoric man as revealed in recent years in East Anglia. The exhibition, which, through the kindness of the Society of Antiquaries, is being held in its rooms in Burlington House, will open on Monday, June 18, and close on Saturday, July 7. There will be no charge for admission. The specimens will be on exhibit from 10 A.M. to 6 P.M. daily, with the following exceptions: Tuesday, June 19 and 26, 10 A.M. to 1 P.M.; Saturday, June 23 and 30, and July 7, 10 A.M. to mid-day. The exhibit will be explained by geological sections, and each group of specimens will be carefully labelled.

THE Advisory Committee recently appointed by the president of the Scottish Board of Health—the Right Hon. Sir John Gilmour, Bart., Secretary of State for Scotland—held its first meeting on Friday, June 1, at the offices of the Board, 121A Princes Street, Edinburgh, under the chairmanship of Sir John Findlay, Bart. Sir John Gilmour, who received the members of the Committee, referred to the difficulty and complexity of the problems on which the Committee has been called upon to advise, and gave an assurance that any practical proposals put forward for reducing the pollution of rivers would receive sympathetic consideration. The Committee considered the general scope of the terms of reference given to it, and resolved to carry out, as a preliminary measure, an investigation of the extent, nature, and effect of pollution on the River Tweed and its tributaries and of the administration of the Rivers Pollution Prevention Acts in that area. Evidence is to be invited on behalf of the various interests concerned.

A REMARKABLY cheap geological map of Europe has been made available by the Oxford University Press. It is not new, but is a re-issue of the map, well known to older geologists, that was prepared by Topley and Goodchild for Sir Joseph Prestwich. The size is 22 in. × 16 in., and as the map is durably mounted on linen to fold, it should, at the modest price of half-a-crown, appeal to students all over the world. Although more detail may have been presented in later and more expensive maps, the Oxford map has the very real advantage of clearly displaying the major structural features by means of a simple but effective system of colouring. Despite its age there is no reason to regard it as out-of-date, for within the limited scope of its small scale it still remains a trustworthy guide to the salient features of a continent which, in the west and south, is too complicated for detailed representation on a map of any reasonable scale. Thus, even apart from the low price, it may be confidently recommended as a most useful adjunct to the study of the geology of Europe.

THE List of Second-hand Scientific Instruments (No. 92) which has recently been issued by Messrs. C. Baker, 244 High Holborn, W.C.1, is larger than usual, for the customary January list was held over. The catalogue, which contains nearly sixty pages of matter, contains a big selection of apparatus, mainly optical in character. More than a third relates to microscopes and accessories, and the short electrical section contains instruments which were the property of the late Sir David Salamons. Photographic apparatus is now brought together in a separate catalogue, so it does not appear in the general list. Intending purchasers of microscopes or fittings, and surveying and electrical instruments, should certainly see Messrs. Baker's List No. 92.

APPLICATIONS are invited for the following appointments, on or before the dates mentioned:—A head of the mechanical and civil engineering department of the Technical College, Sunderland—The Chief Education Officer, Education Offices, Sunderland (June 12). An assistant librarian at Birkbeck College—The Secretary, Birkbeck College, Breams Buildings, Fetter Lane, E.C.4 (June 12). Three forest officers, on probation, under H.M. Forestry Commissioners—The Secretary, Forestry Commission, 22 Grosvenor Gardens, S.W.1 (June 14). A professor of electrical engineering under the Egyptian Ministry of Education—The Director, Egyptian Education Office, 39 Victoria Street, S.W.1 (June 14). A lecturer for production engineering at the County Technical College, Wednesbury—The Director of Education, County Education Offices, Stafford (June 16). A junior technical officer in an Admiralty Experimental Establishment—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (June 16). A temporary assistant lecturer in the training department (women) of the University College of South Wales and Monmouthshire, with special qualifications in biology and nature study—The Registrar, University College, Cardiff (June 19). An assistant in the library of Bedford College for Women—The Secretary, Bedford College for Women, Regent's Park, N.W.1 (June 20). Professors of civil engineering, mechanical engineering, and electrical engineering, at the College of Engineering, Guindy, Madras—The Secretary to the High Commissioner for India, 42 Grosvenor Gardens, S.W.1 (June 23). An assistant lecturer in physics at the University College of Wales, Aberystwyth—The Secretary, University College of Wales, Aberystwyth (June 24). A lecturer in textile physics in the department of textile industries of the University of Leeds—The Registrar, The University, Leeds (June 25). A temporary reader in organic chemistry in the University of Dacca, East Bengal—The Registrar, University of Dacca, East Bengal (June 26). Two lecturers at the Municipal Technical College, Swansea, with qualifications in two of the following subjects—chemistry, botany, and pharmacy—The Director of Education, Education Office, Dynevor Place, Swansea (June 28). A research student in the department of medical entomology of the London School of Hygiene and Tropical Medicine—The Secretary, London School of Hygiene and Tropical Medicine, 23 Endsleigh Gardens, W.C.1 (July 7). An assistant in field husbandry at the Massey Agricultural College, New Zealand—The High Commissioner for New Zealand, 415 Strand, W.C.2. A lecture assistant and laboratory steward in the chemistry department of the Royal Technical College, Salford—The Secretary for Education, Education Office, Salford. A lecturer in geography, botany, and zoology at the Bedford Training College—The Principal, Training College, 14 The Crescent, Bedford.

Research Items.

Beisan.—Some additional particulars of the cult objects found in the temples of Tell el-Hosn at Beisan by the expedition of the Museum of Pennsylvania to Beth-shan, are given in an account of the excavations by Mr. Alan Rowe, Field Director, which appears in the *Museum Journal* (Philadelphia) for the last quarter of 1927. Two new Canaanitish temples were discovered, bringing the total up to six, a door jamb showing a portrait of Ramesses-Weser-Khepesh, the actual builder of the temple of Dagon of I Chronicles x. 10, and the blackened trunk of a palm tree, proving that the date, now entirely absent from Beisan, flourished there 3400 years ago. It is known also to have been plentiful in Byzantine and early Arabic times. In the inner sanctuary of the southern temple of Thothmes III. was found the shoulder blade of a young bull, part of the animal sacrifice which was offered in the adjoining room. In this room were the altar of sacrifice, the channels for the blood, and the hole containing the remains of the wooden post to which the victim was attached. At the south end of the altar were two horns of a bull that had been slaughtered upon it, and to the west, a collar bone of a bull with a sacrificial dagger of bronze and wood. The bull was about three years old, recalling the bullock of three years offered by Hannah in Shiloh. A hole near by with small pieces of wood and a semicircular piece of plaster, suggested that here was a pole on which the carcase was suspended for dressing, as shown in the papyrus of Anhai. A heavy bronze pendant showing a lion seizing a bull (?) was probably an amulet which hung on the neck of the victim. In the southern corridor were found hundreds of cigar-shaped clay objects, 8½ inches in length, which were doubtless votive offerings representing rolls of bread or cakes for the Queen of Heaven. Of two round objects of clay, one showed a seal impression containing the Egyptian word *imenyt*, 'daily offering,' which is here compared with 'shewbread' of Israelitish usage.

Liver in Pernicious Anæmia. — Pernicious anæmia is a disease characterised by progressive blood destruction and usually terminating fatally within three or four years whatever the treatment. In 1925, Whipple and Robscheit-Robbins observed that in the treatment of experimental hæmorrhagic anæmias in dogs, a diet rich in liver exerted a remarkable regenerating effect. A little later, Minot and Murphy applied this observation to the treatment of pernicious anæmia in man, and announced last year that they had treated 125 cases of this disease, with success in practically all the cases. A number of reports by other observers has now appeared which fully substantiate the curative effect of liver treatment in pernicious anæmia (*Lancet*, April 28). The liver must be given raw, or very lightly cooked, 200 grams, or thereabouts, daily, and the diet has to be continued for weeks or months. Some individuals fail to tolerate the diet, and it needs careful regulation. Certain liver extracts may be substituted for the liver itself. The beneficial effect of the treatment is seen both in the general improvement in the patient and in the regeneration of the blood.

The Birds of China.—In spite of the troubles in which its country has been plunged, the Peking Society of Natural History has been able to issue a new part of Volume I. of its *Bulletin*, containing a second and final instalment of a tentative list of Chinese birds by Messrs. Wilder, Gee, and Moffett. The part shows evidence of difficulties in production: it bears no date (the copy before us arrived at Nature office on April 10), but the many errata might have been much reduced by careful proof-reading. The present part deals with the Passeres, and has followed modern precedent in splitting many of the older genera. The number of species in the completed list is 1028, or, if sub-species be added, 1468 forms. The list is intended to be a real guide to Chinese birds, for all the information is repeated in Chinese and the genuine colloquial names of species, as well as Chinese translations of the English names, have been inserted.

Copepods and Hydrogen Ion Concentration.—Mr. A. G. Lowndes, in a paper entitled "Freshwater Copepoda and Hydrogen Ion Concentration" (*Annals and Magazine of Natural History*, Ser. 10, vol. i, April) embodies the results of several years' continual observations undertaken in order to find out the connexion (if any) between the distribution of freshwater copepods and the hydrogen ion concentration of the water in which they lived. The method was very simple, the *p*H of various pieces of water being taken directly in the field and the copepods collected being carefully identified in the laboratory. The localities studied, besides many in England, include the Island of Skye and Spitsbergen, and a large number of genera and species is recorded. The *p*H varies from 3·0 to 9·8, and although no species occurs through the whole range, yet all those studied are capable of living within a very wide margin. Thus a variety of *Cyclops longvidus* can live between *p*H 3·0 and 7·2. This copepod, selected for special observation and reared from egg to adult under the widest possible variation of hydrogen ion concentration, showed that provided calcium and magnesium salts were not present in too great a quantity, a high value of *p*H is not injurious. It bred freely, and there was no alteration in structure so far as direct measurements could show. Individuals taken from ponds with low and high *p*H showed no more variation than those taken from the same pond. It is shown from these observations and experiments that the hydrogen ion concentration can have no direct influence on *Cyclops longvidus*, and its influence on other species is probably small.

The Shell of Tortoises.—It has been shown that plates of bone, superficial to the true bony skeleton, occur in the carapace and plastron of certain tortoises, and Oliver P. Hay has suggested that these represent the relics of a primitive superficial armour, which still remains almost complete in the leather-back turtle, *Dermochelys*. In a second contribution on the subject (*Proc. U.S. Nat. Mus.*, vol. 73, art. 3) Hay describes these epithecal bones in another specimen of the South American "matamata," *Chelys*. He considers that primitively the horny scutes upon the surface of a tortoise's armour coincided with epithecal ossicles, but that in the highly developed thecophorous turtles the coincidence no longer exists. This leads him to suppose that, contrary to the usual view, the horny shields had primarily no relation to the costal plates, but were intimately related to a more superficial series, the epithecal plates. As a result of the ultimate suppression of the latter in the course of ages, the horny shields were brought into contact with the more deeply lodged thecal bones. The shields themselves do not grow at their edges merely, but a new layer of horn is laid down upon the whole inner face.

Flowering Plants of the Panama Canal Zone.—The Smithsonian Institution of Washington, D.C., has just published a handbook on the flowering plants of the Panama Canal Zone. It is the work of Paul C. Standley, of the National Herbarium, and is the result of co-operation of the Smithsonian Institution, the U.S. Department of Agriculture, and the Canal Zone Authorities. The handbook is on the popular plan and will be found useful to lumbermen, horticulturists, and casual visitors. Since many of the plants of the Canal Zone are common to all Central America and the West Indies, the usefulness of the book is correspondingly increased. Besides a brief description of each plant, the author discusses its history, gives all the vernacular names so that the plant can be readily identified locally, and a résumé of its uses.

COLOUR VARIETIES OF RICE.—A study of colour inheritance in rice has been made by Messrs. Mitra, Gupta, and Ganguli (*Memoirs Dept. Agric. India*, Bot. Series, vol. 15, No. 4) in Assam. The amount of natural crossing is found to be so low as 0·5 per cent, perhaps owing to the heavy rains and morning dew preventing the aerial transference of pollen. The colours of different parts of the rice plant are inherited independently, although there may also be correlation of colour in these parts, which include the leaf-sheath, pulvinus, ligule, auricle, internodes, outer and inner glume, stigma, and kernel. The pigmented cell sap may give red, yellow, brown, purple, and black colours, but they usually disappear from the mature plant except in the spikelet. Purple is dominant over green or white, red over white, green or yellow over brown, and black over green or yellow, and dominance may also be incomplete. Purple, pink, brown, yellow, red, and black colours appear in a series of shades determined by independent colour factors. When coloured and non-coloured factors were crossed, a Mendelian 3 : 1 ratio generally resulted, but in more complicated cases 9 : 7, 9 : 3 : 4, 9 : 6 : 1, etc. Thus the pulvinus is white or purple, and when certain forms with white-green pulvinus were crossed together, the F_1 was light purple (intermediate), while the F_2 gave a ratio of 9 purple : 7 green. In one case white × white stigma gave 15 white : 1 purple stigma in F_2. A detailed study of the colour inheritance in various organs is useful in delimiting the many varieties of cultivated rice.

NEW CALIFORNIAN MIOCENE MOLLUSCA.—New species of mollusca, and one *Serpula*, from the Vaqueros and Temblor formations of the Californian Miocene are described by L. W. Wiedey (*Trans. San Diego Soc. Nat. Hist.*, vol. 5), no attempt, however, being made at present to monograph the faunas as a whole. The material has been collected from widely scattered localities in the State south of the San Francisco Bay region. A historical view of the two formations precedes the systematic description of 34 new species (including the *Serpula*) illustrated on 13 very good plates. The faunas of both present warm-water aspects in their assemblages of genera. While the preceding Upper Oligocene fauna was predominantly of cool-water nature, an invasion of many truly tropical genera took place during the Vaqueros, which was succeeded by somewhat cooler conditions during the Temblor formation, when a warm temperature type is indicated as having prevailed.

THE LUNAR PERIODICITY OF EARTHQUAKES.—During the year 1927 the seismographs at the Hawaiian Volcano Observatory recorded 1149 local earthquakes (*Volcano Letter*, No. 170, Mar. 29). Among them, the regular recurrence of times of increased seismic activity was too noticeable to be set aside as accidental. These epochs of greater activity occur at intervals of about two weeks and near the times of the first and last quarter phases of the moon. According to Perrey's first law, similar epochs coincide nearly with the times of new and full moon, but it should be remembered that Perrey's law relates to ordinary earthquakes, while most of the Hawaiian tremors are of volcanic origin.

EXPLORATION IN NOVAYA ZEMLYA.—The exploration of Novaya Zemlya, in spite of a Norwegian expedition a few years ago, was far from complete when in 1921 the Russian Institute for the Exploration of the North begun a series of systematically planned expeditions. The work has continued year by year up to the present, under the direction of Dr. R. Samoilovitch, who gives a summary with map in *Arktis* (Heft 1/2; 1928). The most important part of the work lay on the survey and geological examination of the east coasts, particularly of the northern island, which were previously imperfectly known. A great deal of oceanographical work was also done, including an examination of the fauna of the shore waters and the currents of Kara Strait. Favourable ice conditions in 1927 allowed a cruise to Franz Josef Land and back, on which many oceanographical stations were made. When the results are available, they should fill some of the gaps in the knowledge of the Barents Sea.

COAL-SEAMS OF NORTHUMBERLAND AND DURHAM.—During the past few years, Dr. Wm. Hopkins has been collecting evidence bearing on the correlation of the coal-seams of the north-east coalfield of England, and his results and conclusions, now published (with a very full discussion) in the *Trans. Inst. Min. Eng.* (vol. 74, pp. 221-241; 1927; and vol. 75, pp. 49-59; 1928), constitute an important contribution to our knowledge of a field which until recently has been unduly neglected. Dr. Hopkins has modified the hitherto accepted correlations of some of the more important seams, and the scheme which he advocates is illustrated by two plates of vertical sections. The sources of evidence collected from pit to pit include the thickness, lithological characters, and sequence of the beds intervening between the seams, and in particular the characters of the fossil bands associated with the seams. Some of the mussel bands can be used to confirm or modify the tentative conclusions based on other lines of evidence, and the 'ostracod band' above the Harvey seam, comprising a unique assemblage of mussels, annelids, and ostracods, affords a particularly valuable datum plane, since it can be traced over the greater part of the field, and is everywhere stamped with a succession of characters not simulated in any way by the other fossil bands of the area. Dr. Hopkins has brought into order a confused mass of data, and has established a general framework which itself suggests new problems for future investigations.

RYDBERG TERM TABLES.—Rydberg's tables of $N/(m+a)^2$, which have been invaluable in the analysis of the series spectra of neutral atoms, contained several errors as they appeared in the standard "Seriengesetze der Linienspektren" (Paschen-Götze). They have been reprinted in a corrected form in the April number of the *Journal of the Optical Society of America*, together with the four-, nine-, and sixteen-fold numbers appropriate to the spectra of singly, doubly, and trebly ionised atoms respectively. The computing has been done partly by Prof. Paschen himself, and partly by Messrs. C. J. Humphreys, J. E. Mack, and R. A. Sawyer. The last-mentioned author, who was recently associated with Prof. Paschen in the analysis of the first spark spectrum of aluminium (Al II), has translated a short article by the latter describing the method of use of the tables.

Oil and Gas at Bell Springs, Wyoming.—The enterprise of the American people in continuing their detailed search for oil in the Rocky Mountain region, despite the excessive over-production of this commodity which that country, hence the world at large, is experiencing, is in many respects remarkable. It is attested periodically by the appearance of appropriate bulletins of the United States' Geological Survey, of which No. 796—D, the work of Messrs. C. E. Dobbin, H. W. Hoots, and C. H. Dane, is the latest example. Perusal of this account of the Bell Springs region does not encourage the belief in any ultimate discovery of a second Salt Creek, the one really big oilfield which this State, incidentally the whole Rocky Mountain region of the United States, has produced. On the contrary, save for the striking of dry gas at the top of the Cloverly formation (Cretaceous) on what is known as the Separation Flats structure, little of economic interest seems to have eventuated from some eight years of exploration. Technically this dry gas, in really large quantities, presents some interesting problems, both to the geologist and to the engineer. In this case, the first yield was at the rate of 11,000,000 cubic feet per day, which was afterwards increased by drilling 30 feet deeper to 15,000,000 cubic feet, at a pressure of 860 lb. per square inch. Ordinarily, it might have been presumed with reason that further drilling would reveal the presence of some petroleum, but, instead, the well in question went to water, and all attempts to shut it off by plugging back to the gas zone, failed. The moral seems to be that in this Rocky Mountain region large quantities of *dry* gas (in itself entirely a commercial proposition providing it occurs in accessible areas and/can be economically fed to centres of civilisation, as in Alberta, Canada) tend to be indicative of the absence of petroleum in any magnitude. The literature is full of similar examples from this region, and the chief problem raised is that of the genesis of the gas: how it comes about that such enormous quantities of dry gas are formed without the accompanying achievement of mineral oil. Alternatively, if petroleum was formed initially, what has become of it?

Standardisation of Silver Nitrate Solutions for use with Sea Water.—For more than twenty-five years standard sea water obtainable only from the Hydrographic Laboratories of Copenhagen has been used for the standardisation of silver nitrate solutions used in oceanic investigations. Several criticisms of this standard have appeared recently, and in the *Journal of the American Chemical Society* for March, T. G. Thomson describes experiments from which he concludes that the use of pure sodium chloride solutions and ordinary standard apparatus gives equally accurate results. Two solutions of silver nitrate were estimated, with both pure sodium chloride solutions and standard sea water from the Hydrographic Laboratories. The results obtained with each standard closely agreed within the limits of experimental error. The empirical formula $\mathrm{Cl}_w = 0.008 + 0.99980\ \mathrm{Cl}_v - 0.001228\ \mathrm{Cl}_v^2$, was derived for the conversion of the chloride per litre at 20° C. to the chlorine per kilogram; Cl_w represents grams of chlorine per kilogram and Cl_v grams per litre.

Coal Carbonisation Tests.—In accordance with the established scheme of the Department of Scientific and Industrial Research, a test has been carried out on another type of plant for carbonising coal at low temperatures (Department of Scientific and Industrial Research. Report of Test by the Director of Fuel Research on the Crozier Retort installed by Mineral Oils Extraction, Limited, at Wembley. (London: H.M. Stationery Office, 1928. 9*d.* net.). This retort was designed primarily for the treatment of shale. It is a vertical retort of elongated cross-section externally heated, but having as a special feature cross flues at five levels, whereby the heating gases are carried through the body of the charge. The retort is operated intermittently, but might conceivably be worked continuously. Owing to the elaborate internal construction, it cannot be used with coking material and the actual test was made on a Scotch splint coal with scarcely any tendency to fusion. The yields (per ton) were: coke 15·4 cwt., gas of low calorific value 23·9 therms, tar 16·4 gal., crude spirit 0·8 gal., ammonium sulphate 9·1 lb. From the results given, it is clear that the plant has a limited field of service so far as coal is concerned, and from the account given of the test, it seems as though there is room for considerable perfection in details of design.

The Quantum Yield in the Photochemical Decomposition of Nitrogen Dioxide.—From the pressure changes which occur when nitrogen dioxide is exposed to the radiation from a mercury vapour lamp, Norrish concluded that to a certain extent nitric oxide and oxygen are produced by photochemical decomposition of the dioxide. In the *Journal of the American Chemical Society* for March, R. G. Dickinson and W. P. Baxter describe experiments which confirm this view and afford measurements of the quantum yield of the reaction with monochromatic radiation. The conditions were arranged so that the pressures of the reaction products were sufficiently low (less than 0·1 mm.) for their rate of recombination to be very slow. The reaction could thus be considered simply as a decomposition rather than a photochemical equilibrium. After exposure, the nitrogen peroxide was frozen out with liquid air and the pressure of the residual gas measured by means of a quartz fibre gauge. The yield was found to be largely independent of the pressures of NO_2 and N_2O_4, but was greatly influenced by the wave-length of the radiation. It is assumed that the first step in the reaction is the absorption of a quantum by a molecule of NO_2, which then reacts with an unactivated molecule: $NO_2 + h\nu \longrightarrow NO'_2$; $NO'_2 + NO_2 = 2NO + O_2$. In the absence of degradation to heat or other loss of energy, the yield should be unity. The most effective wave-length used was 3660 A., which gave a yield of 0·77.

Theory of the Autogyro.—An autogyro obtains remarkably high lift forces from a system of freely rotating blades, and it is important to develop a theory which will explain the behaviour of an autogyro and will provide a method of estimating the effect of changes in the fundamental parameters of the system. In R. and M. 1111, Aeronautical Research Committee (London: H.M. Stationery Office, 1928. 1*s.* 6*d.* net) Mr. H. Glauert develops a theory depending on the assumptions that the angles of incidence of the blade elements are small, that the interference flow is similar to that caused by an ordinary aerofoil, and that only first order harmonics of periodic terms need be retained in the equations. An alternative method of analysis by considering the energy losses of an autogyro is developed in an appendix to the main report. The maximum lift coefficient of an autogyro, using the disc area as fundamental area and the forward speed as fundamental speed, lies between 0·5 and 0·6 in general, and the best lift-drag ratio is of the order of 6 or 8 at most. Moreover, since it is necessary to maintain a sufficient ratio of tip speed to forward speed, the stalling speed of an autogyro must rise with the maximum speed of level flight, and so the principal merit of the autogyro system, the low landing speed, would disappear in the case of high speed aircraft.

The Cracking of Lead Cable Sheathing.

A PAPER on the important practical subject of "The Deterioration of Lead Cable Sheathing," by Messrs. S. Beckinsale and H. Waterhouse, read at the spring meeting of the Institute of Metals, represents work done in the Research Department, Woolwich, for the British Non-Ferrous Metals Research Association. The authors have examined a large number of lead cable sheaths which have failed in service by inter-crystalline cracking, and it was found in all cases that the material which had failed was lead of a high degree of chemical purity. It has been suggested that this type of cracking may have resulted from overheating during the extrusion of the sheath. It is shown, however, in the present paper that for lead of the composition generally used, working can be done from room temperature up to within a few degrees of the melting point without leading to cracking, and the only difference observed in the lead rolled at different temperatures was that the grain size tended to increase as the temperature was raised. It was not found possible to reproduce any cracking corresponding with that observed in service by variations of the working temperature.

It has been observed previously that the structure of the same cable sheath varies very appreciably so far as the size of the crystals is concerned. This point has been taken up with considerable care by the present authors, and they have shown that there is no probability that appreciable grain growth has occurred during service. They have also failed to find any reason to believe that there is a relationship between the frequency of the cracking and the crystal size. This type of cracking has also been attributed to allotropic changes in the lead, but careful work, both pyrometric and mechanical, has failed to reveal any evidence of such allotropic change, and it is considered that the possibility of such things being in any way responsible for the cracking must be dismissed.

Cracking is well known to occur in brass which is subjected to the simultaneous effect of stress and corrosive action. Similar cracking in lead has been obtained under the combined action of tensile stress and corrosion with solutions of acetic acid or lead acetate. It is not believed, however, that such corrosive attack can have any important bearing on the present subject, since it was observed that the cracking in service commenced on the inner surface of the sheath and spread outwards, and that it was not until the cracks had reached the exterior surface that the slightest evidence of local corrosion of the inner surface could be detected. It was shown, however, that while silver, copper, bismuth, and nickel all diminished the resistance of lead to corrosion in soluble acetates, arsenic, cadmium, and particularly tin and antimony, all rendered lead more resistant. There are cases on record where acetic or some other organic acid appears to have played an important part in the failure by corrosion of lead sheet and cable sheathing which had been in contact with oak, though pitch pine and deal appear to be without action. Creosote, if free from acetic acid, also has no influence in the production of inter-crystalline cracking.

The failure of the sheathing occurs generally in situations subject to vibration, or where the metal is subject to changes of length due to fluctuations of temperature, and the view that the cracking is due to 'fatigue' is one for which there is considerable support. Fatigue tests have been carried out which indicate a range of stress at the fatigue limit of approximately only 0·18 ton per square inch, and cracks were found in the fatigue test pieces which bear a striking relationship to those in the cable sheathing which had failed.

Since the cracking in service was thus in all probability due to fatigue, experiments were carried out with lead alloys in which the fatigue limit was higher. Even very small amounts of metals, such as bismuth and silver, which are regarded as undesirable impurities in certain respects, have a beneficial effect in raising the fatigue limit. The most satisfactory method of doing this, however, is to use the binary or ternary alloys of lead containing tin, antimony, or cadmium; 0·5 per cent of cadmium increases the fatigue limit to more than three times that of pure lead, while similar increases can be obtained by using ternary alloys containing cadmium and either tin or antimony. These ternary alloys have not only a high fatigue limit, but they also have a permanence of composition during melting and a resistance to oxidation at raised temperatures which are superior to those of the binary alloys, while in addition they possess good corrosion-resisting properties. F. C. T.

University Statistics,[1] 1926–27.

SINCE the acceptance by Oxford and Cambridge of annual parliamentary grants and the consequent inclusion of these two universities in the University Grants Committee's returns, these statistics have presented a fairly comprehensive survey of university work in Great Britain. For five years now the returns have comprised all universities and, with few exceptions, all university colleges in Great Britain, and it seems a pity that they are not supplemented by others, in identical form, for the excepted institutions.

The total number of full-time students of both sexes in 1926–27 was 42,354. The proportion of women to men has risen during the past five years from 14 : 36 to 15 : 35. In England as a whole women formed, in 1926–27, 28·3 per cent of the total number; in Wales, 39·3 per cent; in Scotland, 34 per cent; in London institutions, 35·7 per cent. Since the War the large body of students aided under the government scheme for the higher education of ex-service men has obscured the situation in regard to student enrolments. As this large body has gradually passed out of the universities the total number of men students has continuously fallen until 1925–26, when only 17 of the ex-service scholarship holders remained. Now for the first time the actual tendencies of student enrolments to increase are exhibited in the returns, which show an increase of 748 (men 658, women 90) over the number of full-time students in the preceding year. If from the figures shown in the returns for preceding years the number of ex-service scholarship holders are deducted, the decreases shown in 1925–26 and 1924–25 are converted into increases of 58 and 360 respectively, and the decrease in 1923–24 is reduced to 113. Similarly, the increase in the proportion of women is converted to a slight decrease.

---

[1] Returns from Universities and University Colleges in receipt of Treasury Grant. 1926–27. (London: H.M. Stationery Office, 1928.) Pp. 24. 3s. net.

Since 1922–23 a very remarkable change has taken place in what may be called the balance of university studies—the distribution of full-time students among the main subject groups. Between 1913–14 and 1922–1923 the returns (in which, as already stated, Oxford and Cambridge were not included) showed a fall of more than five per cent in the percentage of the total represented by students in the arts group (including theology, fine art, law, music, commerce, economics, and education), whilst the percentage represented by the medical group rose by more than three, and the percentage of the other three groups, pure science, technology, and agriculture, rose very slightly. Since 1922–23, on the other hand, the returns, including now Oxford and Cambridge, show a rise in the percentage of the arts group from 40·8 to 51·7, whilst the number of students in that group has risen by above 3500, despite a fall of more than 2000 in the grand total of students. The position of the pure science and agriculture groups has remained fairly steady, but for the medical and technology groups both percentages and actual numbers have markedly decreased, namely, from 11,866 (26·6 per cent) and 5567 (12·5) to 8415 (19·9) and 3970 (9·4) respectively. The greatest changes were in Scotland, where the percentage of the medical group fell from 35·2 to 22·7, while the percentage of the arts group rose from 38·9 to 56·1.

This extraordinary rise in favour of the arts group of subjects is attributed by the University Grants Committee to the attraction exercised, during a period of bad trade and restricted opportunities in other professions, by the improved prospects offered by the profession of teaching. This explanation is supported to some extent by statistics of teachers in grant-aided secondary schools in England and Wales. Between 1922 and 1927 their total number increased by 676, while the number of those of them who were university graduates increased by more than two thousand,—from 11,937 to 14,019—the increases year by year being 241, 419, 552, and 870. Clearly the teaching profession has been absorbing a largely increasing proportion of the universities' output of graduates. The falling off in the number of the technological students is, the Committee considers, due to the continuance of serious depression in many industries.

A similar rise in favour of the arts group of subjects and decline in number of students of technology are disclosed by recent statistics of university education in Prussia. The years 1924 to 1927 have seen in Prussia a steady decline in the student enrolments of the Technischen Hochschulen from 8603 to 7936, whilst most of the subjects grouped under the heading of arts show an increase, which is most noticeable under modern languages. Of interest in this connexion are the following extracts from the United States Bureau of Education's biennial survey of higher education, 1924–26: "Immediately after the War . . . the idea gained ground that educational institutions should emphasize training to very specific objectives. The two-year period under review gives many indications that there has been a decided reaction . . . a returning faith, if not in the disciplinary value of the so-called cultural subjects, at any rate in their practical value and in the habits of application developed by the exertion required to master them."

A new table, introduced for the first time last year, classifies research and other advanced students under the branches of study in which they were engaged. Under certain branches of science it gives the following numbers of full-time advanced students: chemistry 511, engineering 141, physics 132, botany 83, geology 52, mathematics 47, zoology 43, metallurgy 42, agriculture 35, physiology 33. Commenting on the dominant position of chemistry, the Committee suggests that the other sciences, and especially the biological sciences other than medicine, have been far too much neglected by advanced students at the universities. It observes also in regard to chemistry that the immediate demand is more for men who have combined a study of this subject with such other subjects as engineering, agriculture, bio-chemistry, and botany than for men whose special knowledge is confined to the ordinary branches of pure chemistry.

Annual Visitation of the Royal Observatory, Greenwich.

THE visitation of the Royal Observatory, Greenwich, took place on Saturday, June 2, and was attended, as usual, by a large gathering of astronomers and their friends. The Astronomer Royal presented his report for the year ended on May 10 last.

The usual observations of sun, moon, planets, and stars were made with the transit circle. The moon's longitude was 6·2″ in advance of that given by Brown's tables. The residual has been diminishing by 0·2″ per annum since the new tables were introduced in 1923. The latitude is systematically south of the tables by ¼″. It will be remembered that Brown removed the constant term of 1″ which Hansen had applied to the latitude, but the observations show that some such term is needed. The catalogue of 11,000 stars between declination 32° and 64° is making good progress, and should be finished in 1930. The stars selected as comparison stars for Eros in 1931 are also being observed; they are so closely packed that it is difficult to get sufficient observations of each of them.

A re-discussion of the declinations of stars near the pole shows that there is no evidence of secular change of latitude since the erection of the transit circle in 1851. The observations would scarcely permit of a greater change than 0·1″ per century. The observations with the Cookson floating zenith telescope have been discussed both for latitude variation and aberration. The aberration constant for the seven years 1919–26 is 20·447″; that for the previous seven years was 20·442″; the corresponding values of the solar parallax are 8·814″ and 8·816″. The parallaxes of 39 stars were determined from photographs with the Thompson equatorial, bringing the total up to date to 369 stars.

Spectroscopic observations of the 'colour-temperature' of early-type stars have been continued with the 30-inch reflector; the spectroscope has been modified by the substitution of a mirror for the lens; this enables the investigation to be carried farther towards the red end of the spectrum, which previously was in bad focus. The micro-photometer has also been modified to permit shorter sections of the spectrum to be measured, thus avoiding regions of absorption. The 30-inch reflector was also used for the photography of comets Grigg-Skjellerup and Pons-Winnecke. The latter was photographed when very near the earth, its angular motion being nearly equal to that of the moon. Its nucleus at that time was quite small and stellar, permitting accurate measures to be made.

The astrographic equatorial is being used for determining proper motions in the Greenwich zone, by re-photographing fields taken twenty-five to thirty years ago. The zone from declination 73° to 77° has been under observation during the year. Special attention has been paid to stars measurable as double stars on the plates; Dr. Groot published a paper on these stars in the *Mon. Not. R.A.S.* for last November.

The egress of Mercury at the transit of last November was observed both visually and photographically. Three consecutive transits of Mercury (those of 1914, 1924, and 1927) have been well observed at Greenwich; the first of the present century, that of 1907, was also seen by glimpses, but the contacts could not be observed.

The mean area of spots on the sun in 1927 was practically the same as in 1926. The first four months of 1928 show no appreciable change. The indications at present point to a flat maximum like that of 1907 and lower than that of 1917. The curve for the last four cycles supports the result obtained from magnetic polarities of spots, that the complete cycle comprises two eleven-year periods. An interesting album was exhibited showing photographic traces of the more remarkable magnetic storms in juxtaposition with photographs of the sun's disc at the time; in most cases there was a large sunspot near the central meridian, or a region that had been active not long before. The subject is under further investigation.

The Astronomer Royal refers with satisfaction in his report to the successful results obtained at Giggleswick in the solar eclipse of June 29. One investigation that failed at that time, the comparison of the calcium doublet in the infra-red with the *H* and *K* lines, was afterwards carried out at Greenwich with a larger dispersion. The line at 8542 A. was found to be somewhat more intense than *K*. Preparations are being made for observing the eclipse of 1929, total in the Malay peninsula; Dr. Jackson and Mr. Melotte are going, and will make further investigation of the gravitational bending of light.

Magnetic observations are now made at Abinger. The results for the last three years are:

	Decl. W.	Hor. Force.	Vert. Force.	Dip.
1925	13° 22·7′	0·18597	0·42946	66° 35·1′
1926	13 10·4	0.18581	0·42947	66 36·3
1927	12 58·4	0·18575	0·42932	66 36·2

The result for 1925 is the mean of the ten months February–November. The greatest daily movement of the air was 1003 miles on Feb. 11. Interesting traces of the sudden variations in temperature, direction of wind, and barometric pressure on this day, due to the passage of a 'line-squall,' were exhibited. The rainfall for 1927 was 27·78 inches, being 3·54 above the average. There were 82 entirely sunless days, the total bright sunshine being 27·4 per cent. of the possible amount.

The time service is now based on weekly observations with a small reversible transit instrument; it is found that the results of this differ in the mean by 0·09 sec. from those with the transit-circle. The Shortt clocks are so reliable that their rate can be trusted for a week. With reference to the distribution of Greenwich time from the broadcasting station at Rugby, the Astronomer Royal notes that the distribution of time by galvanic signals was suggested by Airy in his report for 1849 and carried out on a small scale in 1852. Note is made of the indebtedness of the time department to the enthusiasm, care, and patience of Mr. Bowyer.

A. C. D. Crommelin.

University and Educational Intelligence.

Cambridge.—Dr. A. E. Barclay, Christ's College, has been appointed lecturer in medical radiology and electrology. Mr. W. N. C. van Grutten, King's College, has been appointed an assistant secretary to the Appointments Board.

Prof. G. H. Hardy gave the Rouse Ball lecture on June 6 on the subject "Mathematical Proof."

The chair of astrophysics was partially endowed by an anonymous donor in 1913, and it is reported that this donor has now paid over £12,000 to the University, a sum greater than the money originally offered to the University.

London.—The title of reader in physics in the University has been conferred on Miss M. O. Saltmarsh as from May 17 last, in respect of the post held by her at Bedford College. Dr. Saltmarsh studied at Girton College, Cambridge, and for two periods was engaged on research work in physics at the Cavendish Laboratory. Since 1910 she has been respectively demonstrator, assistant lecturer, and lecturer at Bedford College. She was granted leave of absence by the College Council to give visiting lectures to the department of physics at Vassar College, Poughkeepsie, N.Y., U.S.A., in 1920–21. Her recent published work has been on spectrum analysis.

Applications are invited for the Graham Scholarship in pathology, value £300 per annum, and tenable in the first instance for two years, founded to enable "a young man to continue his pathological researches and at the same time to secure his services to the school of advanced medical studies connected with University College Hospital as a teacher under the direction of the professor of pathology." Applications must reach the Academic Registrar, University of London, South Kensington, S.W.7, by June 26.

The following post-graduate studentships are being offered by the Council of Bedford College for Women: Amy Lady Tate research scholarship, value £125 for two years, and an anonymous research studentship, value £100 for one year. Candidates must be graduates of Bedford College in the faculty of arts or science. Applications must reach the Secretary of the College, Regent's Park, N.W.1, by June 27.

The Research Prize awarded by the Scientific Club of Winnipeg for the best research work done in the University of Manitoba during a period of three years by a recent graduate, has been divided between Leonard B. Clark and Charles F. Goodeve, whose work was carried on in the Departments of Zoology and Chemistry respectively.

The Streatfeild Research Scholarship in medicine and surgery, the annual value of which will probably be £250 and the tenure three years, will shortly be awarded. Applications, which should state the nature of the proposed research, the place where it will be carried out, and the status of the applicant, should be sent to the Registrar, Royal College of Physicians, Pall Mall East, S.W.1, by, at latest, June 29.

Vacation courses in glass-blowing and instrument-making have been arranged for by the Society for the Advancement of the Training of Instrument Makers (Vereeniging tot Bevordering van de Opleiding tot Instrumentmaker), for the latter half of August, in the Physical (Cryogenic) Laboratory of the University, Leyden, Holland, particulars of which are obtainable from Dr. C. A. Crommelin of that laboratory.

Calendar of Customs and Festivals.

(Addenda to May) May 29.

Restoration or Royal Oak Day.—Established by Act of Parliament and first celebrated in 1665 as a day of general thanksgiving for the restoration of Charles II. to the throne. It was, and still is, marked in popular observance by the wearing of an oak leaf, which at one time used to be gilded, associating the day with the story of the king's escape from the Parliamentarians by hiding in an oak. The alternative name "Oak Apple Day" was justified by the requirement in some localities that the sprig of oak should bear galls, and at Northampton, when the corporation went in procession to All Souls' Church, the charity boys and girls each wore a gilt oak apple on a sprig of oak, for which gilded potatoes were substituted if no oak apples were obtainable.

The simple form of celebration by wearing an oak leaf has been supplemented in various localities by other observances, which, it is most probable, must be regarded as transferences derived from the May Day celebrations. In Derbyshire, for example, oak boughs were hung over the doors of houses; at Basingstoke, and in the neighbouring towns, bands of men gathered oak sprigs which they hung on knockers, latches, and other parts of the doors of houses, a service for which they expected gifts of beer, etc. Garlands were sometimes hung on the doors of houses. At Durham, May 29 was one of three days on which the Dean and Chapter caused twenty shillings in copper to be scrambled for, a custom known as 'push penny,' which antedated the Restoration and went back to monastic times. The choir sang anthems from the large tower, also a May Day custom.

In Devonshire, at Starcross, the connexion with May Day was indicated by the children's custom of carrying about May babies in boxes which resembled coffins; and at Tiverton a procession included an 'Oliver'—a character dressed in black with hands and face smeared with soot, and his body bound with a strong cord, who capered ridiculously and was pelted with dirt and stones by the crowd—and a throne of oak boughs on which a child was seated.

Riding the Marches.—In Scotland, a custom analogous to that of 'beating the bounds' in England, was observed in certain districts at the end of May. At Hawick it took place on the last Friday in the month, when the standard of the town was carried by a cornet followed by the magistrates and burgesses round the boundaries, and formal demonstration of their legal rites was made. An ancient song celebrating the border contests with the English was sung by the cornet from the roof of an old tenement belonging to the town. At Inveresk this custom of riding the marches was observed once in fifty years, when a company armed with spears and including a minstrel and a fully armed champion paraded the boundaries.

June 11.

St. Barnabas.—On this feast it appears to have been the custom to decorate some churches with garlands of roses and woodruff. Entries to this effect appear in the accounts of St. Mary-at-Hill, London. For 1512 the entry runs: "Rec'd of the gadryng of the Maydyns on St. Barnabas Day vjs viijd."

A miraculous walnut tree which grew beside the holy thorn in the churchyard of Glastonbury Abbey never budded before St. Barnabas Day, but on that day shot forth its leaves. Cuttings from this tree were much in request at a high price, even after the Reformation, King James I. being among those who obtained them.

St. Barnabas Day was proverbially the longest day and shortest night, as indeed it would be under the Old Style, and storms were believed to be prevalent on this day.

At the parish of Hesket, in Cumberland, the Court of Inglewood Forest was held annually on St. Barnabas day in the open air. The suitors assembled on the highway side at a place marked by an ancient thorn, paid their annual dues to the lord of the forest and selected juries from among the twenty manors forming part of the demesne. Cumberland being one of the counties in England in which evidences of Norse influence are especially notable, it is not surprising to find here a survival of the Scandinavian institution of the open air communal assembly, the *thing*, and that it should be associated with a tree traditionally held in regard. The ash was also especially reverenced by the northern nations. In their legendary beliefs it was the ash tree Yggdrasil which supported the earth. There is ample evidence of the sacred tree in British folklore. In Irish belief there were five trees, situated in different parts of the country, which were looked upon with veneration as having magical properties. Of these one was a yew, one an oak, and two were ashes. The fall of these five magical trees was held to signify the triumph of Christianity over paganism. Down to historical times each tribe in Ireland possessed a sacred tree—which in some sort symbolised the existence of the clan, for if it were hewn down by an enemy it signified the overthrow of the clan. An oak tree near Oswestry, known as Mile Oak, was popularly associated with St. Oswald and was held inviolable. Many place names indicate a derivation from an association with a thorn, an ash, or an oak. Among the Celtic peoples, the hazel was specially venerated.

Tree worship was prevalent in early times among all Aryan-speaking peoples The sacred fig-tree of Romulus in the Forum at Rome was worshipped down to the time of the Empire, and on the Palatine Hill was a cornel tree which was esteemed one of the most sacred objects of the city. At Benevento was a sacred walnut tree which was especially noted in the popular imagination as a meeting-place of witches.

June 15.

St. Vitus Day.—This day seems to have been connected with rain in the same way as St. Swithin. If it rained on this day, according to a popular proverb, it would rain for thirty days. Offerings were made to St. Vitus on this day as a protection against disease, and in particular against the disease with which the saint's name is associated. The reason for this association is not known. The saint, who was a native of Sicily and was martyred about A.D. 303, in an entirely legendary account which confuses two different persons, is said to have cured a son of Diocletian of possession—historically an impossibility—also Diocletian had no son.

St. Vougas or Vie (sixth century), venerated especially at Treguenec in Brittany, an Irish bishop who, like many other Irish saints, sailed on a stone across the sea. A rock off the coast of Brittany is traditionally known as 'the Ship,' and it is supposed to be that which served St. Vie. He is associated with a sacred grove. When a church dedicated to him was built on the spot where his relics had been revered, a wood was cut down. His relics at Treguenec were visited by pilgrims who sought relief from fever. In Ireland, in Carn parish, Co. Wexford, are a church and well dedicated to St.Vauk or Vaak.

Societies and Academies.

London.

Physical Society, May 11.—**E. G. Richardson**: The amplitude of sound waves in resonators. After a consideration of the relations between the 'pipe' and the 'Helmholtz resonator,' graphs of the variation of amplitude, obtained by means of a hot-wire anemometer traversed through various types of resonator, are reproduced. By means of a calibrated manometer of the vibrating membrane type, some direct values of the impedance of orifices are obtained. Traverses across an orifice through which the air is vibrating in simple harmonic form are obtained with the hot wire: these show a tendency for the air to vibrate with greater amplitude in annuli remote from the centre of the orifice.—**R. E. Clay**: The focus of a gas-filled X-ray tube. Pinhole photographs of the focus obtained with various radii of curvature of the cathode and various distances from the anticathode are discussed; it is concluded that with the tubes of the type considered, a radius of about 2 cm. and a distance of 3 or 4 cm. are the best conditions.

Royal Statistical Society, May 15.—**D. Caradog Jones**: The cost of living of a sample of middle-class budgets. The budgets were divided into three groups, representing, respectively, families living in London, in large towns with a population exceeding 50,000, and in smaller towns and country places. For families of about the same type, the budgets revealed a higher level of expenditure in the small towns than in the large towns. This seems to be due in part to the higher cost of living experienced rather than to the higher standard of living enjoyed there. On an average, out of a total family expenditure of between £400 and £500 a year, in round numbers 40 per cent is spent on housekeeping and service, 20 per cent on rent, rates, fuel and light, 10 per cent on clothing, 10 per cent also on holidays, clubs, and recreation, 5 per cent on insurance. In general, the proportion of the total income spent on the necessaries of life, such as food and house-room, tends to fall as the income rises. In the normal middle-class family, nearly 40 per cent of the total food bill represented expenditure on meat, fish, bacon, etc. The dairy products, milk, butter, eggs and cheese, came next in order of importance, costing about two-thirds as much as the first group. Bread, including cakes and biscuits, and also fruit and vegetables, each accounted for roughly half as much as the dairy group. There was then a drop to 5 per cent for jam and sugar, and for tea, coffee, cocoa, etc. When this group of middle-class families is compared with the Sumner Committee group of working-class families, it is found that the middle class spend relatively more on meat, milk, and fruit, while the working class spend more on bread, tea, and sugar.

Paris.

Academy of Sciences, May 7.—**G. Bigourdan**: The various methods used for the calculation of pendulum corrections. It is usual to employ one master pendulum and several subsidiary pendulums. The most exact method implies a continuous comparison of all the pendulums in order to eliminate any temporary irregularity in any one of them. Other methods in use are adversely criticised.—**Pierre Termier** and **Eugène Maury**: New geological observations in eastern Corsica: phenomena of crushing and lamination: mylonites and tectonic breccia.—**Georges Claude**: Obtaining energy from the sea. In connexion with this project, a 50-watt turbine has been made, which, working between 15° and 35° C. gives power of 40 kilowatts.—**Louis Roy**: The intrinsic equations of elastic surfaces with three parameters.—**C. Sauvageau**: The question of *Tilopteris Mertensii*. Observations tending to prove that this alga multiplies by simple budding. There is no alternation of generations.—**Maurice Caullery** was elected a member of the Section of Anatomy in succession to the late F. Henneguy.—**V. Hlavatý**: The second fundamental form II.: generalisation of the theorem of Enneper.—**Miécislas Biernacki**: The lines of Julia of integral functions.—**D. V. Jonesco**: Some theorems of existence of the integrals of systems of differential equations.—**Vladimir Bernstein**: Concerning a formula of F. and R. Nevanlinna relative to the meromorph functions in a sector.—**Serge Bernstein**: Functions regularly monotone.—**R. Gosse**: The equations $s = f(x, y, z, p, q)$ which admit an invariant for one single system of characteristics.—**W. Gontcharoff**: Series of zeros of successive differentials.—**J. Herbrand**: The theory of the demonstration.—**D. Riabouchinsky**: Some remarks on functions of current.—**D. Gernez**: The rapid construction on the map of lines for utilising radiogoniometric bearings taken from a vessel.—**Léopold Infeld**: Maxwell's equations in the theory common to gravitation and electricity.—**R. Darbord**: The absolute measurement of coefficients of influence.—**E. Pierret**: A new method of maintaining oscillations in a triode valve. Description of a method of obtaining stable waves of wave-length between 14 cm. and 18 cm.—**M. Fallot**: The magnetic susceptibility and second supposed isoelectric point of gelatine. Determinations of the magnetic susceptibility of gelatine as a function of the hydrogen ion concentration showed only one minimum value, at $pH = 4{\cdot}7$. The refractive index and dispersion of these gelatine solutions were found to be independent of the hydrogen ion concentration.—**G. Bruhat** and **M. Pauthenier**: Remarks on the theory of electrostriction and its experimental control.—**L. Décombe**: Electrified spherical films, the photo-electric effect and the X-ray fluorescence spectrum.—**Marcel Cau**: Double refraction and dichroism of thin films of iron obtained by distillation. The films were produced on plates of glass placed over an iron wire heated electrically in a vacuum. The films, which were grey by transmitted light and presented a polished appearance, showed double refraction accompanied by dichroism. The effect is produced by the magnetic field of the current used for the distillation.—**Marc de Hemptinne**: The photolysis of benzaldehyde. A study of the absorption spectrum suggests that benzaldehyde should be decomposed under the influence of rays of wave-length less than 2500 A., and benzene and carbon monoxide should be the products of decomposition. Experiments are described confirming these predictions.—**Aubert**, **Dumanois**, and **Pignot**: The effects of antidetonants in the vapour phase. Experiments showing that antidetonants acting in the gaseous phase increased the time of combustion.—**C. F. Muttelet**: Study of the acidity of fruit juice and of jams.—**Mme. Ramart-Lucas**: The comparative stability of isomers according to their absorption spectra.—**A. Wahl** and **Lobeck**: A new reaction of the disulphisatides.—**J. A. Le Bel**: Stalactites. A description of some peculiarities of some stalactites found in a cave at Les Eyzies (Dordogne).—**F. Dienert**: The circulation of subterranean waters in alluvium. Examples of the use of dyes for following the circulation of underground water.—**J. Viret**: The Oligocene fauna of Coderet, near Branssat (Allier).—**E. Leblond**: The formation of accessory vacuoles in *Closterium lunula*.—**R. Dieuzeide**: The transformation and disappearance of certain denticles of the skin of *Centrophorus* *granulosus*.—A. **Lacassagne**: The action of the *K*-rays of aluminium on some micro-organisms. Details of the effects of varying time exposures to the rays on cultures of pyocyanic bacillus, prodigiosus, staphylococcus and entero-coccus.—F. **Holmeck**: Attempt at the interpretation from the energy point of view of the action of the *K*-rays of aluminium on micro-organisms.

CAPE TOWN.

Royal Society of South Africa, April 18.—Th. **Schrire**: On some new species of bacteria isolated from *Xenopus Lævis*. Three new organisms have been isolated from a mould-like growth on a frog (*Xenopus Lævis*). The disease could not be reproduced by inoculation with various methods, but a mixed infection with all three organisms is highly pathogenic to frogs.—J. F. V. **Phillips**: *Curtisia Faginea* Ait. ('Assegaai'): An ecological study. This tree is important sylviculturally and economically. It is best developed in the Knysna forests, although it ranges from the Cape Peninsula to the forests of Gazaland. It is very rarely a dominant, and still more occurs in pure communities. It is most at home in the medium moist forest at Knysna. In pole and later stages the species is definitely semi-light-demanding. The plant flowers regularly, fruits fairly regularly and heavily. The fruits are of moderate fertility; the greater number aggregate at the base of the parent. The rate of growth in girth is slow. —S. **Schonland**: Materials for a revision of Crassulaceæ (The South African species of the genus *Crassula* L. emend. Schonl.). A wider view than usual is taken of specific limits, but no less than 219 species of *Crassula* are recognised in South Africa.—H. G. **Fourcade**: A new method of aerial surveying: note on the determination of the verticals of a plate pair. —A. V. **Duthie**: On a terrestrial Isoetes, *I. stellenbossiensis*, A. Duthie, from the Stellenbosch Flats. This is the third species of Isoetes to be described from the Union of South Africa. It occurs in shallow depressions, which are damp in the winter but dry during the summer months, and has been found growing beside xerophytic plants.—**Margaret R. Levyns**: Veld-burning experiments at Ida's Valley, Stellenbosch. The type of vegetation covering the area is that known as 'rhenosterveld,' which is not a stable type of plant community. Burning leads to rapid increase of the rhenoster bush and certain other plants, and also induces vigorous growth among the petaloid monocotyledons and some other plants, this vigour being of a temporary nature. Clearing the ground of bush does not favour the spread of the rhenoster bush. In this case vigorous growth is more apparent among the grasses than among the petaloid monocotyledons.

GENEVA.

Society of Physics and Natural History, April 19.—S. C. **Guha**: The microcrescometer, normal type and universal type. Study of the growth of the coleoptilum of oats. The author presents two different forms of an instrument designed to measure the growth of plants, multiplying the movements up to 5000 and 20,000 times, by means of a lever which causes an angular displacement of a mirror. He gives the first results of his observations on the daily growth of the coleoptilum of oats, showing a maximum between 10 A.M. and noon.

May 3.—Gr. **Gutzeit**: A rapid method of qualitative analysis. The author has attempted to generalise the use of spot reactions, carried out on filter paper or on a porcelain plate with depressions, with the aid of various specific organic reagents. Characteristic reactions for 23 metals and 17 acid groups are given.—P. **Rossier** and G. **Tiercy**: The auxiliary chronometer *Nm* of the Observatory of Geneva and the rating of chronometers submitted to examination. This Nardin chronometer has been regulated for mean time and compared with the Riefler sidereal time pendulum. The comparisons have been made by two different methods of measurement; the maximum difference in the two cases has been 0·02 sec.—P. **Balavoine**: The tannin content of wine is influenced by the climatic conditions at the time of vinification. This fact has been proved by comparing products obtained simultaneously and working on a similar portion in the eastern Pyrenees and at Geneva. All the other characteristics remain similar; the proportions of tannin are respectively 0·17 and 0·02. Other experiments lead to the conclusion.—B. P. G. **Hochreutiner**: A new Cyrtandropsis in the Hawaiian islands. The observed facts lead to the conclusion that the Cyrtandropsis are formed from different species of the genus *Cyrtandra*, which have afterwards evolved in a convergent manner.

Diary of Societies.

FRIDAY, June 8.

Royal Astronomical Society, at 5.—W. H. Wright: Photography of the Planets in Light of Different Wave-lengths (George Darwin Lecture).—S R. Pike Note on the Separation of Gases in Prominences.—N Goryatscheff: The Definitive Elements of the Orbit of Comet 1925 c (Orkisz).

Royal Society of Medicine (Ophthalmology Section), at 5.—At 6 15 (Annual General Meeting)—M. Hine: Report on a Case of Neurofibromatosis of the Eyelid, and of a Case in which a Glass Ball burst in the Socket—F. Ridley: Lysozyme-antibacterial Body present in Great Concentration in Tears, and Especially its Relation to the Human Eye.

Physical Society (at Imperial College of Science), at 5.—L. F Richardson and others Contact Potential in the Dolezalek Electrometer connected Idiostatically—G. P. Barnard: Some Experiments on the Light-Sensitivity of Commercial Selenium Cells.—Dr. J. R. I. Hepburn. The Vapour Pressure of Water over Sulphuric Acid-Water Mixtures at 25° C. and its Measurement by an Improved Dew-point Apparatus.—Demonstration:—A simple Practical Application of the Properties of Selenium Cells, G. P Barnard.

Malacological Society (at Linnean Society), at 6.—Prof A. E. Boycott · The Habitats of *Clausilia biplicata* Montg.—R Winckworth: Remarks on Limpets and Description of New Species of *Acmaea*

Geologists' Association (in Architectural Theatre, University College), at 7 30.—Dr. T Robertson and T. N. George: The Carboniferous Limestone of the North Crop of the South Wales Coalfield—Dr R. L. Sherlock. The Alleged Pliocene of Buckinghamshire and Hertfordshire.

Royal Institution of Great Britain, at 9—Prof. G. P. Thomson: The Waves of an Electron.

SATURDAY, June 9.

Institution of Municipal and County Engineers (North-Eastern District), at 10 30 A.M. (at Municipal Buildings, West Hartlepool).—At 5 (at Grand Hotel, West Hartlepool)—F. Durkin: Municipal Work at West Hartlepool.—J H. Miers Municipal Work at Hartlepool.

Institution of Municipal and County Engineers (Yorkshire District) (at Town Hall, Wakefield), at 2—L. Ives · Municipal Work in Wakefield.

Biochemical Society (at Rothamsted Experimental Station, Harpenden).—E. Boyland and S. F. Cook · The Blood Pigment of Ascidians—R R. Morrison, P. R. Peacock, and S Wright. The Action of X-radiation on Vitamin D in Irradiated Ergosterol.—L R Bishop: A Study of the Proteins in Barley.—P H. H. Gray: Production of Indigotin from Indol by Soil Bacteria.—G. V. Jacks: The Formation of Humus.

TUESDAY, June 12

Royal College of Physicians of London, at 5.—Dr. C Bolton: The Interpretation of Gastric Symptoms (3).

Quekett Microscopical Club, at 7.30.—Prof. J. S Huxley: Some Problems of Animal Growth.

WEDNESDAY, June 13.

Geological Society of London, at 5 30.—Prof. G. B. Barbour · A Re-excavated Cretaceous Valley on the Mongolian Border—S. I. Tomkeieff: The Volcanic Complex of Calton Hill (Derbyshire): a Petrological Study.—Dr. S. H. Haughton: A Brief Account, illustrated by lantern slides, of the Arrangements in Progress for the Forthcoming XVth Session of the International Geological Congress, to be held in South Africa in July and August 1929.

Electroplaters' and Depositors' Technical Society (Annual General Meeting) (at Northampton Polytechnic Institute), at 8.15.

THURSDAY, June 14

Royal Society, at 4 30.—Prof. A. V Hill: (*a*) Myothermic Apparatus; (*b*) The Rôle of Oxidation in Maintaining the Dynamic Equilibrium of the Muscle Cell; (*c*) The Absolute Value of the Isometric Heat Coefficient Tl/H in a Muscle Twitch and the Effect of Stimulation and Fatigue; (*d*) The Absence of Delayed Anaerobic Heat in a Series of Muscle Twitches; (*e*) The Recovery Heat-Production in Oxygen after a Series of Muscle Twitches—Prof. A V. Hill and W. Hartree. The Anaerobic Delayed Heat-Production after a Tetanus—C. H Best and Ruth Partridge: The Equation of Motion of a Runner Exerting a Maximal Effort.—*To be read in title only*:—C. A Seyler: The Dictyoxylon Cortex of Lycopodiales as a Constituent of Coal—B. Sahni: On Clepsydropsis Australis, a Zygopterid Tree Fern with a Tempskya-like False Stem from the Carboniferous Rocks of Australia.—W. O James: Experimental Researches on Vegetable Assimilation and Respiration XIX.—A. W Greenwood · Studies on the Relation of Gonadic Structure to Plumage Characterisation in the Domestic Fowl IV.—Prof. T P Hilditch: Relationships between Chemical Composition of Vegetable Seed Fats and their Botanical Origin.

London Mathematical Society (at Royal Astronomical Society), at 5—Prof G. H. Hardy: A Formula of Ramanujan.—E. L. Ince. Simultaneous Linear Partial Differential Equations of the Second Order.—K. Knopp. Über Reihen mit positiven Gliedern.—Echo D. Pepper: On Density Distribution in Stellar Space.—E. G. C. Poole: Dirichlet's Principle for a Flat Ring.—T. G. Room: Notes on some Geometrical Configurations · (I)–(VIII)—W. E Sumpner · Fractional Integration.—C T. Preece: Theorems stated by Ramanujan (III.).—Prof. G N. Watson · Theorems stated by Ramanujan (IV.).

Optical Society (at Imperial College of Science), at 7.30.—Instr. Capt. T. Y Baker · The Errors of a Reflecting Prism.—W. D. Wright: A Trichromatic Colorimeter with Spectral Primaries—T. Smith. (*a*) The Theory of Aplanatic Surfaces; (*b*) The Primordial Coefficients of Asymmetrical Lenses, (*c*) Note on the Use of Lenses in Series for Sight Testing.—Demonstration:—Slides illustrating Studies in Diffraction, the late F. W. Shurlock.

SATURDAY, June 16

Royal Society of Medicine (Therapeutics Section) (at Pharmacological Laboratory, Oxford).—Annual General Meeting and Laboratory Meeting.

Mining Institute of Scotland (at Dunfermline)

PUBLIC LECTURES.

MONDAY, June 11.

King's College, at 5.30.—Prof. E. L. Stevenson: The Expansion of Geographical Knowledge in the Early Renaissance as illustrated by Contemporary Maps (1): The Geography of the pre-Columbian Period.

WEDNESDAY, June 13.

King's College, at 5 30—Prof. E. L. Stevenson. The Expansion of Geographical Knowledge in the Early Renaissance as illustrated by Contemporary Maps (2): Christopher Columbus and the Beginnings of Trans-Oceanic Discovery.

THURSDAY, June 14.

Institute of Pathology and Research (St. Mary's Hospital), at 5—Dr. P. Fildes: Principles of the Treatment of Tetanus with Antitoxin.

FRIDAY, June 15

King's College, at 5 30.—Prof. A Wildon Carr: Some Problems in Metaphysics (1): The Nature of Human Freedom.

CONGRESS.

June 6 to 9.

South-Eastern Union of Scientific Societies (at Rochester)

Friday, June 8.

Geological Section.

At 10 30 A.M.—

H. H. Milner. Geology from the Air (Presidential Address).

At 11.30 A.M.—

Dr S W. Wooldridge · The Geomorphology of the North Downs.

At 12.30—

H G. Dines: The Bapchild Palæolithic Site.

Zoological Section.

At 11 A.M.—

Prof E. W. MacBride: The Conditions for Progressive Evolution (Presidential Address).

At 12 noon—

H. H. S. Bovingdon: The Reflections of a Biologist on Food and Efficiency.

Saturday, June 9.

Regional Survey Section.

At 11 A.M.—

C. C. Fagg: The History of the Regional Survey Movement (Presidential Address)

At 12 noon—

G. B. Hutchings: A Regional Survey of the Lower Medway Valley.

SATURDAY, JUNE 16, 1928.

Emigration within the British Empire.

THE Report of the Oversea Settlement Committee for 1927,[1] while a distinct improvement on the corresponding report for the previous year, is still far from being a satisfactory production. It is inadequate to its theme, and such detailed information as it contains scarcely does justice to the magnitude of the expenditure incurred by the Home or Overseas governments. An official publication of this kind could be utilised as an effective stimulus to emigration of British stock from our over-populated island to the undeveloped fertile lands in our possession, for prospective emigrants are more inclined to rely upon statements in official publications for guidance than the alluring but too commonly reckless statements which appear in unofficial handbooks and pamphlets. Moreover, it should have an educative value: it should be so framed as to provoke comment in the press and Parliaments of the Dominions, and it is to be feared that this will not happen unless dogmatic assertion of fundamental policy is accompanied by careful statement of the grounds on which policy has been based.

For example, the report states that "The essential need of the Oversea Dominions for an increase of population to develop their resources and the desire that this increase should be effected by means of British stock, are the objectives on which all are agreed." But the Oversea Dominions are not reminded that failure to co-operate with the mother country to satisfy this need is a source of danger to them and of the gravest anxiety to those statesmen at home who realise that the resurgent coloured peoples of the world have legitimate cause for complaint if they are arbitrarily denied access to empty and potentially fertile lands in British possession upon which we are making only half-hearted efforts to settle our own people. Dominion statesmen are not forcibly reminded that their policy of discouragement of immigration of all except agricultural and domestic workers is a contributory cause of the rapidly declining birth-rate in the mother country, and that if this continues the proportion of foreign to British immigrants is bound to increase, with an inevitable lowering of the standard of living of the whole of the peoples of the Dominions. Canada, in particular, should be made to realise that the standard of living of the peoples of central and southern Europe, from the countries of which more than half its immigrants for 1927 were recruited, is very much lower than that of the people of Great Britain.

---

[1] Report of the Oversea Settlement Committee for the year ended 31 December 1927. (Cmd. No. 3088.) Pp. 44. (London: H.M. Stationery Office, 1928.) 9d. net.

The reluctance of the Dominions to foster immigration is not difficult to understand. They are not yet convinced that unrestricted immigration need not necessarily further congest an already overstocked labour market. Labour leaders overseas need more than the assurance given in this report, based upon the history of the United States, that the open-door policy would effect vast developments in agriculture and primary production accompanied by unprecedented industrial expansion, with a corresponding distinctive rise in the standard of living. They can be pardoned for thinking that Great Britain's offer of pound for pound to assist emigration under the Empire Settlement Act of 1922 is a poor bribe to the Dominions for their acceptance of the responsibility for the after-maintenance of a transferred part of our surplus population.

The statistics given on p. 15 of this report are therefore of the utmost value. They deal in convincing manner with the healthy effect of increased population between 1891 and 1921 on the external trade of Canada, Australia, and New Zealand. In this period the population of Canada increased by 80 per cent, whilst the *per caput* value of its external trade in 1921 was more than six times that of 1891: in New Zealand the population nearly doubled, while the *per caput* value of its external trade almost trebled: and in Australia, the population between 1891 and 1921 increased by 70 per cent, and the *per caput* value of its external trade by 116 per cent. It is a great pity that the report does not contain statistics of unemployment in the three Dominions for the same period, but it is more than probable that they are unobtainable. The two sets of statistics might reasonably be expected to provide overwhelming proof of the beneficial effects of the transference of Great Britain's surplus population on the prosperity of the Dominions and thus go far to overcome the present opposition of Overseas governments to schemes intended to increase the movement.

It may occasion some surprise that the report of the Oversea Settlement Committee for the year 1927, five years after the passing of the Empire Settlement Act, should contain the following passage:—

> "The problem of Empire Settlement is closely interwoven with that of Empire industry and Empire trade, and one of the first steps *to be taken* [the italics are ours] with a view to making passage assistance more widely available should be to ascertain, in consultation with the Dominions:—
>
> "(*a*) What occupations exist throughout the Empire which could be enlarged and provide increased employment if further man-power were made available locally;
>
> "(*b*) What new industries, primary and secondary, can be created within the Empire and developed by men and women of British descent;
>
> "(*c*) How far it is possible to extend the preference for British settlers in those parts of the Empire which require fresh settlers for their development."

The Committee rightly says that a satisfactory answer to these questions would go far to solve present difficulties, but it is legitimate to ask why they have not been formulated until now. It passes our comprehension how the Committee could have dealt with its task hitherto without information on these various points.

In commenting on the Committee's report for 1926, it was suggested in these columns that "the immediate need is for a comprehensive survey of the accessible and potential resources of the Empire," but we had no idea that such a survey as we contemplated would have to include the matters enumerated above. We had in mind surveys as that mentioned in Section III. of the present report, namely, a geophysical survey of the mineral resources of certain parts of Australia, upon which task Mr. A. Broughton Ede has lately embarked with the financial support of the British and Australian Commonwealth governments. Apparently, however, these wider schemes are not considered as activities proper to the functions of the Oversea Settlement Committee. Regarding the geophysical survey of Australia, it remarks: "It was decided that the effect on development and immigration was too indirect to justify a contribution to the cost of the proposed survey under the Empire Settlement Act."

Undoubtedly the Committee has a most difficult task to perform; but it is one of ever-increasing importance. There are abundant empty spaces within the Empire suitable for settlement by our own people. Great Britain, judging by our unemployment, is badly overcrowded. The nation is spending vast sums annually on the maintenance of an army of unemployed, and what is still more disastrous, the will-to-work of a large section of the population is being steadily undermined. The situation calls for almost heroic measures, but the Oversea Settlement Committee appears to be afflicted with a fearful timidity. It is true that Great Britain as a whole suffers from the same disease, but we have the right to expect that those face to face with the problem of Empire settlement, provided with all facilities for arriving at a true appreciation of the situation, should give the Empire a bold lead. So far the Committee has failed to rise more than a few steps to the height of opportunity. The schemes in operation as outlined in the report are quite inadequate to the urgent needs of our time.

What is wanted is a report dealing with the problem of Empire settlement in a thoroughly scientific spirit and couched in such language that it will command the attention of the various governments of the Empire as a whole, and provoke them to energetic action.

World Meteorology.

Manual of Meteorology. By Sir Napier Shaw, with the assistance of Elaine Austin. Vol. 2: *Comparative Meteorology.* Pp. xl + 445. (Cambridge: At the University Press, 1928.) 36*s.* net.

THE science of meteorology has had no very happy or harmonious development. After the invention of the thermometer and barometer, elementary meteorological phenomena such as expansion of air by heating, melting and congelation, evaporation and condensation, were for a time in the focus of physical investigation. But practicable experiments and personal observation did not prove sufficient for penetrating that intricate complex of physical phenomena which constitutes weather. Then the invention of the galvanometer and electrometer, which opened new worlds to the experimental physicist, became simply fatal to progress in the old field. The telegraphic weather chart seemed to open a new era, and led to the transfer of meteorological research from the individual university investigator to richly equipped offices and institutes. But the isobaric chart failed to be that 'lamp of Aladdin' which made all difficulties disappear. Disillusion and pessimism followed upon the highly-raised illusions. "Galton himself," says Sir Napier Shaw, "after twenty-five years of unparalleled effort as chairman of the Kew Committee of the Royal Society, and a leading member of the directing council of the Meteorological Office, the most powerful body of scientific men that ever directed anything, became disillusioned and discouraged at the end. He doubted that anything would come of it all." I could give many parallel examples from other countries of leading men of this science who, like Sir Francis Galton, began in enthusiasm and ended in pessimism.

Sir Napier Shaw has never shared this pessimism. Nor has he been in doubt that there is one, and only one, way out of the difficulties, namely, to see the problem in its *full universality*. This spirit of universality is the most marked feature of Sir Napier Shaw's book, and will secure it a prominent place in the history of meteorology. It marked strikingly already the first introductory volume, "Meteorology in History," which might also have been called "Meteorology and Humanity," as it gives the development of human views upon the phenomena of the weather from the most ancient times to the age of the telegraphic weather chart. The same spirit characterises still more this second volume, "Comparative Meteorology," in which the more special meteorological work is begun.

First of all, Sir Napier Shaw does not see meteorology as anything like an isolated science, bordered by the official duty of a meteorological institute. He sees it as a branch of universal physics. At every opportunity he has emphasised that the cultivation of meteorology as a science remains a university duty, in spite of all special institutes erected; and throughout his book the establishment of the full connexion between meteorology and general physics is a marked feature. It has induced his enthusiasm for the tephigram, of which he shows the universal use for bringing the principles of thermodynamics into application to meteorological processes; and it underlies his attempt to condense our general meteorological knowledge in definitions, axioms, and theorems—certainly a very brave attempt which can but react favourably upon further development.

This spirit of universality takes, however, its externally most striking form by the fact that, wherever the book is opened, we meet with maps of the *entire world*. No more eloquent expression could be given to the principle that only a map which is too great to have a *frame* is a satisfactory meteorological map. So long as a frame is there, the origin of what happens inside the frame may be looked for outside it. But when maps for all atmospheric levels go all round the earth we approach in meteorology to the conditions which have made experimental physics so relatively easy, namely, that all the variables of the problem can be brought under the control of the investigator.

It would lead too far to enter upon the many interesting details of the book, many of which may perhaps be discussed more advantageously when Vol. 3 has appeared. But I must mention Sir Napier Shaw's open-minded and, at the same time, reserved attitude towards the newest subjects of discussion in meteorology. Through his "Life History of Surface Air Currents" he is one of the chief predecessors of those who succeeded finally in formulating what is now called the "Polar Front Theory," and his diagram on p. 381, in which he represents the wind distribution in a cyclone, not by the traditional spirals, but by straight lines, will remain the most eloquent protest ever formulated against the theory of cyclones as homogeneous revolving systems. But at the same time he distinguishes carefully between the unquestionable empirical facts, as the actual existence of a polar front and certain typical phenomena related to it, and the attempts to bring these facts within the scope of theory.

In connexion with this important distinction, I must take the opportunity to mention a correction of historical order, common to Sir Napier Shaw's book and many other books and papers dealing with meteorology which have appeared in recent years. It is true that I was formally the director of the Bergen Institute at the time when the polar front got its name, and was stated to be, not a more or less exceptional phenomenon, but on the contrary a daily characteristic feature of every weather map. But this discovery is not mine. It belongs to the working young meteorologists of the Bergen school, J. Bjerknes, H. Solberg, and T. Bergeron,—the last of the three joined in the work a little later than the first two. For my own part, I have never drawn a weather map, or performed an analysis of such a map according to what is now called those 'Bergen methods,' which have made it impossible for the polar front to escape observation. Thus to state it again, the creation of these methods of weather analysis, and the empirical discoveries which are made by use of them, are due to the three young men I have mentioned, and not to me.

Parallel to and interacting with the empirical investigations of these young meteorologists, my own attempts went to bring the stated facts within the scope of theory. This led to what has been called the 'Wave Theory' of cyclones or of cyclone formation. In its origin, this theory is older than our precise knowledge of the phenomena which it should explain. General dynamical principles led me in the years 1915 and 1916 to assume that a cyclonic vortex could originate in no other way than as some kind of wave, though I was not able to see what kind of wave, or how it transformed into a vortex. I hoped, however, to get a clearer view by generalising systematically the classical wave theory. But only a first and introductory paper relating to this research appeared (Leipzig, 1916). I remained in doubt how to continue it. Sir Napier Shaw's diagram might have brought me on the right track. But I did not at that time feel sure if I should not look upon it rather as a joke than as a serious suggestion. At the Bergen Institute, however, from the summer of 1918 onward, every day brought a new and from day to day more carefully analysed weather chart, giving more and more detailed information on the life cycle of cyclones from birth to death, and the effect upon my theoretical work was an instantaneous one. There could no longer be any doubt, either concerning the character of the initial wave, or of the general dynamics of its development to a vortex of ultimately complete homogeneity. The fact that in these circumstances my theoretical comment on the empirical discoveries came to appear practically simultaneously with the publication of the latter, may explain why the whole 'Polar Front Theory,' taken as including both the now generally accepted empirical facts, and also—though perhaps still rejected by most meteorologists—the 'Wave Theory,' was credited to me, while I can take the responsibility merely for the latter.

Sir Napier Shaw's attitude towards the two cyclone theories, the 'pure' vortex theory, and the theory of the development from wave to vortex, is that of benevolent neutrality. He ends in expressing confidence that under the pressure of both of them the problem must yield. When—we hope within a short time—the next volume of Sir Napier Shaw's great "Manual" appears, we may perhaps find it to have yielded in that direction in which his historical diagram has been pointing as the first fingerpost.

V. BJERKNES.

A Popular History of Mathematics.

Histoire des mathématiques. Par W. W. Rouse Ball. Édition française revue et augmentée, traduite sur la troisième édition anglaise par Lieut. L. Freund. Tome 1 : *Les mathématiques dans l'antiquité ; les mathématiques au moyen âge et pendant la renaissance ; les mathématiques modernes, de Descartes à Huygens.* Pp. vii + 338 + 9 planches. (Paris : J. Hermann, 1927.) 40 francs.

MR. ROUSE BALL'S "Short Account of the History of Mathematics" must be one of the most successful books of its kind that has ever appeared. Originally published in 1888, it reached a second edition in 1893 and a third in 1901. The fourth edition was stereotyped in 1908, and the book has since been five times reprinted, though the preface to the stereotyped edition states that no material changes have been made since the issue of the second edition of 1893. Its success is to be accounted for by the fact that it is eminently readable and is not too technical to be easily followed by the amateur who wishes to get a general idea of the course of the history of mathematics through the ages. As the author explained in the original preface, it may serve as an introduction to more elaborate histories, but it was primarily intended to give a short and popular account of those leading facts in the history of mathematics which many who are unwilling, or have not the time, to study it systematically, may yet desire to know. Accordingly, it is not overloaded with detail or masses of references to authorities.

The greater part of the account is admittedly a compilation from existing histories or memoirs, and especially, so far as the history down to 1799 is concerned, M. Cantor's "Vorlesungen über die Geschichte der Mathematik." This fact brings with it a certain drawback, often inconvenient to the professional mathematician who makes use of the book, namely, that it is in general difficult to be sure whether, when a reference is given to some book or memoir, the author himself has consulted the original work or is merely giving a reference at second hand. This inconvenience, however, does not so much affect the non-professional reader, while the method adopted of dealing in chronological order with the lives as well as the writings of famous mathematicians gives a human interest to the narrative and so enhances the attraction of the book.

After a chapter on Egyptian mathematics, Ball divides his history into three periods: (1) Mathematics under Greek influence; (2) mathematics of the Middle Ages and of the Renaissance (Chaps. viii.-xiii.), ending with Galileo, Kepler, and Desargues; and (3) modern mathematics (Chaps. xiv.-xix.), beginning with Descartes, Fermat, and their contemporaries. In proportion to the wider range and increased complexity of the developments in mathematics as we approach recent times, the story necessarily becomes more 'sketchy,' so much so that the nineteenth chapter on the nineteenth century becomes little more than a list of names and titles of books.

The volume before us is vol. i. of the "Édition française revue et augmentée," translated from the third English edition. Arrangements were apparently made in 1903 for a translation into French, which duly appeared (in two volumes) in 1906-7, though no reference to it is made in the present edition. The translator, in an undated preface, merely states that Ball's work formed only one volume, and that it has been thought proper to complete it by additions "which clear up several important points in the history of science and show the course followed by certain illustrious savants in reaching their discoveries." These additions have, he says, made it necessary to divide the work into two parts. The first volume contains the translation of the first fifteen chapters, the second the last four, beginning with Newton; the division is an artificial one designed to make the two volumes about equal in bulk, the additions being more considerable in the second volume than in the first. We may hope that this will prove to be the case when the second volume appears, for the additions to the first are, so far as we can see, negligible. The period from 1903 until 1927 has been fruitful in new editions and fresh researches, and Ball himself added in the stereotyped edition a good number of references to such new works; it is a pity that the French translator, writing in 1927, has incorporated scarcely any of these new references or of others that might have been given, so that in this respect the new edition is much less valuable than it might have been made.

The translator has tried to keep as closely as possible to the original, but he should have exercised more care. Apart from a number of unnecessary misprints (for example, "Dialès" for "Diocles," p. 97) and incorrect spellings of names, for example, "Ænopides" for "Œnopides" and "Menœchmus" for "Menæchmus," there are several statements which will raise a smile. On p. 97 we are told that Dionysodorus found the radius of the earth to be about 42,000 stades, "ce qui correspond à environ 80,000$^{\mathrm{km}}$," whereas Ball says, correctly, "a little less than 5000 miles." On pp. 21-22 there is a story from Iamblichus about the Pythagorean pentagram, to which Ball applied the well-known remark, "Se non è vero, è ben trovato"; it will scarcely be believed that our French translator gives for this: "Si elle n'est pas vraie, elle est tout au moins intéressante" (!). The sense of a passage is sometimes destroyed by the mistranslation of a word, as when "partially" becomes "particulièrement." But the most glaring lapse is on p. 45, where we are told that Plato visited Egypt "in company with Eudoxus and Strabo," a remarkable feat, seeing that Eudoxus lived from about 408 to 355 B.C. and Strabo from about 66 B.C. to A.D. 24! The explanation is found on reference to the original, where Ball observes that "Plato visited

Egypt with Eudoxus, and Strabo says that in his time the apartments they occupied at Heliopolis were still shown." For the second clause the translator substitutes "On raconte que, de son temps . . .," regardless of the fact that this leaves "in his time" completely in the air.

Incidentally, we cannot but express regret that advantage is not taken of some re-issue to correct mistakes which in places disfigure the original work. Thus we are told that "Archytas taught that the earth was a sphere rotating round its axis in twenty-four hours, and round which the heavenly bodies moved." The second clause of this sentence is difficult to reconcile with the first; but in any case there is no ground for thinking that Archytas anticipated Heraclides of Pontus in holding that the earth rotates on its own axis in twenty-four hours. The error may perhaps be due to a confusion of the name of Archytas with that of an otherwise unknown person, Hicetas of Syracuse, to whom, alternatively with Heraclides, the discovery in question is attributed.

T. L. H.

Sex and the Gene.

The Genetics of Sexuality in Animals. By Dr. F. A. E. Crew. (Cambridge Comparative Physiology Series.) Pp. x + 188. (Cambridge: At the University Press, 1927.) 10*s.* 6*d.* net.

THE chromosome theory of heredity has been of considerable value in advancing our knowledge of how characters are transmitted through the germ cells from one generation to another, but there is an important gap yet to be filled. We have little knowledge of the developmental processes involved. It is Dr. Crew's aim to place before the reader material derived from the study of sexuality in animals "in the hope that someone may be sufficiently stirred as to decide to devote himself to a subject which has always fascinated me . . . how the gene in its action produces its end result, the character." If the solution of this problem were the main end in view, the physiologist, to whom the book is primarily addressed, might question the advisability of selecting such a complex subject rather than one with more immediate prospect of quantitative treatment. However, sexuality is in itself of sufficient importance to justify extensive treatment, and much can be said in favour of it as a subject for the study of developmental physiology.

Goldschmidt, whose own contributions play a primary rôle in the theory developed by Crew, has already dealt extensively with the same subject in "The Mechanism and Physiology of Sex-Determination" (English Translation. Methuen, 1923). Some similarity of treatment was therefore to be expected, but it is disappointing to find in many passages how closely the two books resemble one another. This resemblance diminishes in places the value of Crew's book as an independent critique of the subject. In a work dealing largely with experimental material, more space might perhaps have been devoted to the exposition of original data. For the most part, general inferences only are given, and one gets little information on the relative significance of the actual results from which the inferences are derived. References are, however, amply given, and extensive bibliographies are a valuable feature. The book requires attentive reading, since not infrequently the writing is somewhat involved. On the other hand, the book gains considerably by the style being both emphatic and provocative.

The first two chapters give a compact account of the genetic evidence bearing on sex determination. The third is mainly devoted to Goldschmidt's work on *Lymantria* and his 'time law of intersexuality.' In extending this 'law' to amphibian development, Crew contributes to the simplification of the subject, but a similar extension to mammals in explanation of hermaphroditism is not so successful. The material described shows varying degrees of abnormality, and it is not unreasonable to assume that a time relationship is involved, but the genetic and embryological evidence seems insufficient to support the elaborate and somewhat lengthy treatment. Many very arbitrary assumptions are made, and the discussion, although not without interest, lacks objectivity.

In Chap. iv. it is shown that in a number of animals extrinsic changes may result in a deviation or reversal of the sexual characterisation primarily established by the genotype. In discussing plumage characterisation in the fowl, Crew abandons the orthodox theory of hormonic specificity of the gonads and advances the hypothesis that male and female types of plumage are expressions of different metabolic levels. The hypothesis accommodates many of the known facts and provides perhaps the simplest explanation of the henny-feathered cock which has yet been advanced, but the term 'metabolic level' is indefinite and allows considerable elasticity of interpretation. A critical test would be found in the results of gonadectomy and transplantation. Crew groups a series of 'results' in tabular form, but no specific references are given to the actual data. The majority of the groups can be accommodated by either hypothesis. No detailed account whatever is given of those groups which are really crucial. It is claimed that the case of a single bird described by Greenwood and Crew cannot be accommodated by the orthodox hypothesis, but apart from the numerical inadequacy of the material, it is not free from objection on theoretical grounds. Since the publication of the book, Domm in America has obtained similar results with adequate material but does not consider it necessary to abandon the theory of hormonic specificity as applied to the normal animal. As the account stands in the book, Crew's hypothesis, although provocative of careful consideration, can only be regarded as highly speculative or intelligently prophetic.

Chap. v., on "Sex Reversal in the Adult," contains some interesting material. In the main the theoretical interpretation is similar to that advanced in earlier sections. The short chapter on the "Mode of Inheritance of Sex Dimorphic Characters" suggests that further work might be done on this subject. The book closes with a chapter on the "Sex Ratio." Differential mortality *post conceptionem* will in part explain the significant deviation from equality at birth and later stages, but an entirely satisfactory explanation has not been found to account for the deviation at conception which has frequently been assumed.

As one of the first of the Cambridge Comparative Physiology Series, the general editors are to be congratulated on the format. The printing maintains the high standard of the University Press.

ARTHUR WALTON.

London and Londoners.

The Earlier Inhabitants of London. By Prof. F. G. Parsons. Pp. 240. (London: Cecil Palmer, 1927.) 10*s.* 6*d.* net.

FOR the nonce, Prof. F. G. Parsons has laid aside his calipers and turned historian. These forty years and more he has sought to meet the needs of professional anthropologists by supplying them with data relating to the races and peoples who have lived in England in all periods of its history—from Palæolithic times to the present. He has now written a book to please himself on "The Earlier Inhabitants of London"; he has set down, in easy narrative, with many a sly allusion and pleasant digression, all he has succeeded in learning concerning the founders of his native city, London. Nor will readers have to proceed far to discover that their guide to ancient London is a frank outspoken Saxon whose inborn sympathies are enlisted in favour of that element of the British people which is fair in colouring and long in skull. He brings his history of London to a close just before the coming of the Normans; at that time he estimates that seven-eighths of the inhabitants of London "were of Nordic blood."

We have no direct testimony concerning the beginnings of London; all we know, or can hope to know, concerning its earlier history is, as Prof. Parsons reminds his readers time and again, circumstantial and inferential. He accepts the belief now current, that London began to come into existence between the landing of Julius Cæsar, 54 B.C., and the coming of the legions of Claudius, A.D. 43, and that it began as a port for the midland tribe—the Catuvellauni, whose capital town was the present St. Albans. Having accepted this much, he then infers that its earlier inhabitants must have been recruited in the main from the peoples who occupied adjoining regions—the Cymric Belgæ. His search for evidence bearing on the racial constitution of the people which Cæsar found in possession of England, takes Prof. Parsons far afield. He finds that they were in the main a Celtic-speaking people of Nordic origin, which had absorbed the still older racial elements of England—the round-headed 'beaker' people, the long-headed people of the chambered barrows, and a still older strain derived from Palæolithic times.

Nevertheless, on the evidence obtained from cemeteries of a pre-Saxon date, Prof. Parsons concludes that in the earlier days of London the home countries were inhabited by a people essentially Nordic in its racial constitution. The Saxons who began to invade England in the fifth century of our era found its eastern and south-eastern parts occupied by a people who, like themselves, were Nordic, or north-west European, in origin. No doubt merchants from abroad settled in London and brought their families with them; it may be, as Prof. Parsons hints, that foreign legions stationed near London did leave their mark on the 'earlier' Londoners, but if one may rely on the evidence of skulls of Romano-Britons preserved in the Museum of the Guildhall, the predominant Londoner in Roman times was, as Prof. Parsons suggests, of Belgic or Nordic origin. But the round-headed Gaul from central and southern France was not negligible.

After the departure of the Roman legions, the history of London is darkness, but Prof. Parsons gives reasons for his belief that the Saxon invaders left the city alone until the seventh century, when the Saxons of Essex began to settle in it. In the ninth century, Alfred Saxonised it more effectually. Later still came the Danes and the Norse, to swell the North Sea element in the racial constitution of the Londoner.

Some day, perhaps, Prof. Parsons will give us a racial analysis of the modern Londoner. It is certainly very difficult to find a native of London who can claim that all four grandparents were born in or near London. London draws people to-day, just as it did in its earlier history, from all parts of Europe, and yet, we believe, when full inquiry is made, that even to-day London is still essentially a Nordic city. However this may be, there can be no doubt of our present indebtedness to Prof. Parsons; the book is manifestly a labour of love—a rebound from the repression that our modern methods of investigation impose on all anthropologists. Who has not wished, in the midst of the dry narration of facts—just for a glorious hour in which to set down what is surmised, as well as that of which we have proof? It is just because Prof. Parsons has 'let himself go' that he has succeeded in writing a book which is at once interesting and stimulating.

Our Bookshelf.

Reports of the Progress of Applied Chemistry. Vol. 12, 1927. Issued by the Society of Chemical Industry. Pp. 743. (London: Society of Chemical Industry, 1928.) Members of the Society of Chemical Industry, 7*s.* 6*d.*; Others, 12*s.* 6*d.*

WITH the exception of the chapter on explosives, on which it is evidently intended to report in alternate years, the present issue of the "Annual Report on the Progress of Applied Chemistry" again constitutes a reasonably complete and most valuable survey of a year's achievement. The general form of the reports, with their copious references to the original information on which they are based, their name and detailed subject indexes, is of course perfectly familiar to chemists the world over. This year the chapter on non-ferrous metallurgy is perhaps noteworthy in two respects: it gives the impression of being based to a special degree on experience (although the inclusion of literature references wherever possible is always much to be desired), and, being written by Prof. G. A. Guess, of Toronto, it originates from outside Great Britain. The chapters on plant and machinery, fuel, gas, etc., electrochemical industries, rubber, soils, and sanitation are also provided—with every success—by authors who did not report last year.

Discussion of any part of the subject matter would be of doubtful profit, so great is its wealth of detail and diversity of interest. Since, however, the chemical control of food must so closely concern everyone, whether chemist or not, and since the reviewer's copy has fortuitously been opened at the page dealing with this subject, the contents of this section of thirty-one pages may be indicated. Vitamins, from the chemical, biological, and industrial points of view, are first considered (8 pages), their origin, production, and evaluation being discussed; then follows an account of milk and dairy products (5 pages), in which not only new and modified analytical methods, but also the results of surveys and researches on dairy troubles are recorded. Sections on fruit and vegetable products (3 pages), canning and storage (5 pages), cereal products (4 pages), preservatives and colouring matters (3 pages), and miscellaneous information (3 pages) complete the chapter, in the course of which 161 references to original papers are quoted.

It is unlikely that many chemists, either in the British Empire or the United States of America, are unaware of the existence of this series of reports; so much general information is brought under review, however, that industrial chemists will not be alone in welcoming the appearance of yet another annual volume. A. A. E.

(1) *Methods of Applied Geophysics: for the Exploration of Oil, Ores, and other Useful Deposits.* By Dr. Erich Pautsch. Pp. iv+82. (Houston, Texas: Gulf Publishing Co., 1927.) 6.50 dollars.

(2) *Die magnetischen Verfahren der angewandten Geophysik.* Von Dr. Hans Haalck. (Sammlung geophysikalischer Schriften, herausgegeben von Prof. Dr. Carl Mainka, Nr. 7.) Pp. viii+150+3 Tafeln. (Berlin: Gebrüder Borntraeger, 1927.) 12 gold marks.

(3) *Elektrische Bodenforschung: ihre physikalischen Grundlagen und ihre praktische Anwendung.* Von Dr. Walther Heine. (Sammlung geophysikalischer Schriften, herausgegeben von Prof. Dr. Carl Mainka, Nr. 8.) Pp. xi+223. (Berlin: Gebrüder Borntraeger, 1928.) 18 gold marks.

(1) THE rapidly growing importance of geophysical methods of prospecting for oil, ores, and other deposits is stimulating the production of numerous books on the subject. Of the three here noticed, that by Dr. Pautsch attempts to cover the whole field, and has chapters on the various classes of method, gravitational, seismic, acoustic, magnetic, electric, and radioactive. The treatment is very cursory. The book deals with the subject rather after the manner of an engineer's pocket-book or collection of formulæ; it seems scarcely likely to be of serious use to anyone desiring to apply geophysical methods in practice.

(2) (3) The two German books are in a different category; each deals carefully and in detail with the underlying principles, the practical applications, and the instrumental equipment connected with a single class of geophysical methods, electric or magnetic. They should be of real value to applied geologists, but it need scarcely be said that success

in the use of geophysical methods of prospecting depends very largely on the possession of sound judgment and experience in interpreting the physical measurements in the light of the geological data for the district.

A Descriptive List of the Printed Maps of Norfolk, 1574–1916: with Biographical Notes and a Tabular Index. By T. Chubb. *And a Descriptive List of Norwich Plans, 1541–1914.* By Geo. A. Stephen. Pp. xvi + 289 + 26 plates. (Norwich: Jarrold and Sons, Ltd., 1918). n.p.

THIS is a useful and scholarly handbook for the geographer, antiquarian, and historian to retain for reference on their shelves. Norfolk was favoured by the old cartographers; moreover, the pioneer work on soils and geology which emanated from the county at a later date helped to maintain contemporary interest in its maps. After an interesting introduction, in which due credit is given to the work of John Norden and others in the sixteenth century, when Norfolk was an active manufacturing county, Mr. Chubb gives a catalogue of Norfolk maps from 1574 until 1916. Each entry is accompanied by informative notes which are bibliographically valuable. Well-selected examples of maps published at intervals of about twenty years help the reader to visualise the advance in the art of cartography, and in the development of the county. But for the fact that reference has been made to geological maps (for example, Samuel Woodward's early map of 1833) and to soil maps, it might be invidious to point out that the first map showing Glacial Drift, that of part of Norfolk and Suffolk, by S. V. Wood and F. W. Harmer (Mon. Palæontograph. Soc., 1872), has not been mentioned. As it was the first of its kind in the world, it is certainly worthy of a note.

The latter half of the book is contributed by the City Librarian of Norwich, who has catalogued and added notes on the various plans of Norwich contained in the Norwich Public Library, Castle Museum, and the British Museum. A compilation of this kind for so ancient and ecclesiastical a city as Norwich was worth doing, and the author has done it well. The tabular index of the whole book, arranged under the cartographers' names, is to be specially commended for its usefulness.

Lehrbuch der analytischen Geometrie: Grundlagen, Projektive, Euklidische, Nichteuklidische Geometrie. Von Prof. L. Heffter und Prof. C. Koehler. Band 1: *Grundlagen, Grundgebilde I. Stufe, Euklidische Ebene.* Zweite wesentlich umgearbeitete und vermehrte Auflage. Pp. xvii + 477. (Karlsruhe: G. Braun, 1927.) 20 gold marks.

THIS is a book for which there is not likely to be any great demand in Great Britain. Yet it may be questioned whether more attention ought not to be paid to this kind of work in the ordinary honours course. For example, there are students who specialise in geometry without learning anything about the modern theory of its foundations. Perhaps some knowledge of the subject matter of the introduction of this volume might be required of them. Again, projective geometry is a subject of increasing reputation, in that its foundations are secure against some of the attacks which are destroying our confidence in anything that depends upon measurement. Lastly, the physicist can no longer afford to regard the non-Euclidean systems as an idle fancy of the mathematician's brain. It is not suggested, of course, that this particular book could be adopted for general use in Great Britain; but rather that something of the same kind, perhaps less elaborate, may before long be considered as part of the general education of the mathematician. A. R.

The Statesman's Year-Book: Statistical and Historical Annual of the States of the World for the Year 1928. Edited by Dr. M. Epstein. Sixty-fifth Annual Publication: Revised after Official Returns. Pp. xxxvi + 1538. (London: Macmillan and Co., Ltd., 1928.) 20*s.* net.

WITH the exception of the usual careful revision in fact and figures, this valuable publication in its present issue has undergone few changes. The plan of the book, with its many subheadings and full index, greatly facilitates its use. Although it is some twenty pages larger than last year, the volume has been slightly reduced in bulk. Iraq has now been removed from the mandated Territories in the section on the British Empire and added to the independent States. A new paragraph on the Saar, and a much-expanded section on the Ægean Islands of Italy, have been added. There are the usual introductory tables of statistics and sections on the International Institute of Agriculture and the League of Nations. Two coloured maps show respectively French, Spanish, and International zones of influence in Morocco, and the new boundary between Canada and Labrador in terms of the Privy Council's report.

Hand-List of Catalogues and Works of Reference relating to Carto-Bibliography and Kindred Subjects for Great Britain and Ireland, 1720 to 1927. By Sir Herbert George Fordham. Pp. 26. (Cambridge: At the University Press, 1928.) 2*s.* 6*d.* net.

SIR GEORGE FORDHAM has laid students of cartography under an obligation by the publication of this volume. In the list he gives the titles of ninety-one works, from "The English Topographer" of Dr. Rawlinson, printed in 1720, to Mr. H. A. Sharp's "Historical Catalogue of Surrey Maps," of 1928. The stream of publication seems to have been fairly continuous during the two hundred year period in question, except for gaps of no publication from 1736 to 1768; from 1780 to 1814; and 1840 to 1870; gaps curiously equal. There seems no probability of the stream drying up now, for no fewer than sixty-seven of the works catalogued have been published during the present century. Sir George Fordham himself, and Mr. Thomas Chubb, have an honourable pre-eminence amongst the modern workers at this subject.

Letters to the Editor.

Helium and the Genesis of Petroleum.

VARIOUS hydrocarbons, but more especially methane, are common constituents of the natural gas effusions in many parts of the world, and another very common constituent is helium, though in relatively small quantities, which vary from simple traces to about 1 per cent or more. In the mid-United States of America, where large oilfields exist, and for which more complete information is available, it appears that the region in close proximity to the oil field is also a region of relatively high helium content in the gases (G. S. Rogers, *Professional Paper*, 121, U.S. Geological Survey, Washington, pp. 68-91; 1921).

Lind and Bardwell have investigated the effect of alpha particles upon hydrocarbons, and have found that these hydrocarbons undergo chemical change when subjected to such bombardment, the hydrocarbon molecules becoming more complicated. They have found that for methane two molecules undergo change per ion pair formed, or M/N is 2, whilst for acetylene $M/N = 20$, for ethylene 5·1, and for cyanogen 7·4 (*Jour. Amer. Chem. Soc.*, vol. 48, pp. 2335, 2351; 1926). The effect of alpha rays upon methane was to produce the higher saturated hydrocarbons and liquid olefines, whilst from ethylene a colourless liquid resulted, and acetylene gave rise to a white solid.

It will be assumed that helium arises from alpha particles ejected by radioactive substances. Since each alpha particle produces 2×10^5 ions approximately, one cubic foot of alpha particles ionises 2×10^5 cubic feet of gas. Now each alpha particle eventually becomes a helium atom, and therefore one cubic foot of helium is, in its process of formation, capable of ionising this amount of gas. Taking Lind and Bardwell's result that for methane M/N is 2, each cubic foot of helium may alter 4×10^5 cubic feet of methane (weighing 8 tons) into higher and more complicated hydrocarbons.

The action follows the equations

$$2CH_4 = C_2H_6 + H_2$$
$$\text{or } 2CH_4 = C_2H_4 + 2H_2$$

(Lind and Bardwell, loc. cit.).

Considering liquid hydrocarbons more specifically, it has been calculated from the results already mentioned, that 1·2 milligrams of these resulted from the formation of 0·000015 c.c. of effective helium, or nearly two tons of liquid per cubic foot of helium.

The average helium content of 142 Canadian sources of natural gas is about 0·25 per cent (R. J. Elworthy, Canadian Dept. of Mines, 1926), and from 325 United States sources it is about 0·5 per cent (Rogers, loc. cit.). Since many of these gas wells produce enormous volumes of gas, it is to be expected that radioactive disintegration as measured by the helium produced during long periods of geological time may have played an important part in the formation of petroleum. It is true that, owing to the paucity of experimental results, the figures arrived at may be to some extent a matter of opinion, and it is also a long way from 1·2 milligrams to millions of tons, yet it would seem (if the results of Messrs. Lind and Bardwell are to be relied upon) that in the Petrolia gas field, where the original helium has been estimated at 10^9 cubic feet (cf. Rogers' Report, p. 62), millions of tons—indeed, according to the above calculation, two thousand millions of tons—of liquid hydrocarbon may have resulted in this area.

In view of these figures the question of the origin of petroleum naturally arises. The percentage of helium content in the prolifically oil-bearing tertiary series is generally small, but Lind states (*Nat. Acad. Sci.*, vol. 11, p. 772; 1925) that recent then unpublished estimates show that helium is confined to no particular age of strata but depends rather on the retentiveness of the sands. It might also be mentioned here that the helium in the atmosphere, assuming it to be entirely of subterranean origin, corresponds, under proper conditions of production, to 4×10^{15} tons of liquid hydrocarbons.

The presence of dense compounds in petroleum and of bitumen in meteorites, the high solubility of radon in petroleum, and the wide distribution of the radioactive elements, together with the formation of both paraffins and olefines in the experiments quoted, seem to make these questions worthy of further investigation.

If the reactions quoted above are in progress, it might be expected that hydrogen would be a common constituent of natural gas in some other form than as simply appearing in the hydrocarbons.

Active Nitrogen.

THE function of impurities which seem necessary to the formation of the afterglow in active nitrogen has been interpreted as being in the poisoning of the surface to the combination of nitrogen atoms. Experiments were commenced to study the rôle of the impurity oxygen. It was felt that the possibility could not be entirely excluded that oxygen was necessary in some physical action to induce the afterglow in the gas phase. Accordingly pure *glowless* nitrogen was introduced into a litre bulb, into the centre of which pure oxygen could be admitted more or less uniformly in all directions. In impure nitrogen the active species which eventually give rise to the glow are created in the discharge and remain for some time after cessation of the latter. If the same occurs in pure nitrogen, and if merely the presence of ordinary oxygen is required for the afterglow formation, then the afterglow may be expected to appear if oxygen is introduced into glowless nitrogen immediately after discontinuing the discharge (electrodeless). Pure nitrogen was prepared by two methods: (1) from bromine water and ammonia (Kenty and Turner, NATURE, 120, 332; 1927; also, Waran, *Phil. Mag.*, 42, 246; 1921); (2) from sodium trinitride (NaN_3).

For some time it was impossible to produce absolutely glowless nitrogen (although the afterglow was very weak and of very short duration), even though the utmost precaution had been taken to ensure the complete absence of oxygen and other impurities. Only after continued baking out of the bulb at high temperature and under high vacuum was glowless nitrogen obtained. Upon the introduction of pure oxygen (1 per cent) in the manner described above, *no glow was produced.* This was repeated several times with nitrogen from both sources with the same results. Furthermore, after the oxygen had been admitted and the mixture now subjected to the discharge, little or no glow was discernible. This seemed very strange indeed. I publish these results in view of the recent work of Herzberg (*Z. fur Physik*, 46, 878; 1928), whose investigations offer an explanation of these effects. Herzberg, in some very pretty experiments, finds that freedom of the walls from gases such as water vapour or hydrogen is a factor in the elimination of the afterglow. Even with nitrogen containing more or less oxygen, he reports no afterglow if the vessel has been well baked out. The addition of a small quantity of hydrogen to pure or oxygenated nitrogen, which cannot be made to glow itself, again produces a very intense afterglow. In this connexion Bonhoeffer and Kaminsky's observations (*Z. fur phys. Chem.*, **127**, 385; 1927) that impurities, whatever they are, have no effect on the character of the afterglow spectrum, suggests that the impurities as such take no part in the excitation process which produces the luminosity. This is in agreement with conclusions to be drawn from the experiments described above.

The optimum amount of oxygen for production of the afterglow has been given as about 0·23 per cent, while 2 per cent completely obliterates it (Bonhoeffer and Kaminsky, *loc. cit.*; Strutt, *Proc. Roy. Soc.*, **88**, 539; 1913). I have been able to obtain very intense nitrogen afterglows in air (21 per cent oxygen), and even in mixtures up to about 57 per cent oxygen (although with decreased intensity but observable with a spectroscope), in the electrodeless discharge at a pressure of about 0·2 mm. Hg and below. At higher pressures the type of afterglow changes until at about 1 mm. and up to 2 mm. (in air) only the continuous afterglow spectrum of oxygen first noticed by J. J. Thomson (*Phil. Mag.*, **32**, 321; 1891) is observable. The nitrogen and oxygen afterglows were so strong as to be easily distinguished with an ordinary spectroscope. Herzberg reports similar findings. These differences from the results of other workers are readily explained by the differences in the experimental pressures employed. Studies have been made of the afterglow at different pressures with varying mixtures of nitrogen and oxygen and will be published in the course of time.

Does Methylene Blue penetrate Living Cells?

In Nature (vol. 121, No. 3053, p. 726) the following statement was made under "Research Items" (in connexion with the identification of dye found in the vacuole of cells of *Valonia*): "The methylene blue, moreover, penetrates as such, and it is not the lower homologue, trimethylthionine, that penetrates as Irwin thought. The latter is found in sap which has stood for some time after being expressed and arises from oxidation of methylene blue."

The matter is of far greater importance than would appear on casual reading, since methylene blue is widely used as a vital stain and as an indicator for the oxidation reduction potentials of cells. It therefore seems worth while to direct the attention of readers of Nature to the fact that the problem of methylene blue penetration is by no means so nearly settled as would be gathered from the above statement.

In my publication (Irwin, M., *Proc. Exp. Biol. and Med.*, **24**, 425; 1926–27. *J. Gen. Physiol.* **10**, 927; 1926–27), I have shown by spectrophotometric measurement (made in collaboration with W. C. Holmes, of the Bureau of Chemistry, Washington, D.C.) that it is chiefly trimethylthionin or azure B that is present in the sap extracted from cells placed in methylene blue solution at pH 9·5. These measurements were made immediately after extraction of the sap from the cells. This shows conclusively that the trimethylthionin was present in the sap and was not formed from demethylation of methylene blue after the sap had stood in air for some time, as is intimated in the sentences quoted above.

Moreover, it was shown that methylene blue was found in the vacuolar sap of cells (placed in methylene blue solution at pH 9·5) *only* (1) when the cells were injured, or (2) when the contamination of the sap by the stained cell wall occurred at the time of extraction of the sap.

The penetration at low pH values (namely, at pH 5·5) was too slow for analysis unless the cells were injured.

Furthermore, the experiments described in these papers were repeated by me at three different seasons, covering over a year, and using various samples of methylene blue, and identical results were obtained. The necessary optical measurements were made either by W. C. Holmes or by K. S. Gibson, of the Bureau of Standards, Washington, D.C. These additional results have not been published as they bring out no new facts.

Such results are not limited to *Valonia*, since experiments with a freshwater plant, *Nitella*, led to the same conclusions (Irwin, M., *Proc. Soc. Exper. Biol. and Med.*, **25**, 563; 1928).

It is still somewhat uncertain as to whether the trimethylthionin penetrated as such from the external methylene blue solution containing this dye as impurity (in too small concentration for detection by a spectrophotometer but detectable by extraction with chloroform) or whether it has formed from methylene blue after the latter has penetrated the cell. I am, however, from the evidence in hand, inclined to favour the former explanation.

All the results were obtained by examining the sap in the vacuole (that is, the central space in the cell which is surrounded by the protoplasm and filled with sap). The experiments do not show whether or not methylene blue penetrates the protoplasm. The latter question cannot be tested experimentally, since the protoplasmic layer is extremely thin.

There is, therefore, real danger that false theoretical conclusions may be drawn from data based on penetration of blue dye from methylene blue solution.

Research on the Control of Aeroplanes.

In his most interesting paper, "Research on the Control of Aeroplanes"—published as a supplement to Nature of May 12—Prof. Melvill Jones says, "they [the Wrights] must have experienced the stall or the approach to the stall." In point of fact, during their gliding experiments of 1900 and 1901, they were puzzled by the fact that on a turn the warped wing would invariably touch the ground first, or in other words, they found, as modern science has rediscovered, that increasing the angle of the lower wing accentuates instead of curing the tendency to stall. Their remedy was to fit a vertical surface at the rear of the machine, which before the end of the 1902 experimental season was converted into a movable rudder. The point here is that the Wrights originally fitted a rudder not as a directional organ, but as an aid to the wing-warp in maintaining lateral balance.

Actually they first definitely experienced the phenomenon of the 'stall' in their power-driven machine of 1904, when they found that the machine persisted in sliding down to the ground on one wing tip in spite of all attempts to right it with the combined rudder and wing-warping control. They eventually discovered that the only remedy was to put the nose of the machine down, and quite rightly attributed the trouble to loss of speed causing the controls to become inoperative.

If I may be forgiven criticising so sound an authority as Prof. Melvill Jones, I think he is wrong in lumping all the early experimenters with the Wrights in what I have always called in my own mind the 'acrobatic' as opposed to the 'stability' school. Surely the early French pioneers—such as the Voisins and Santos Dumont—quite definitely tried to produce a stable aeroplane, seeking to attain this end by such devices as 'curtains' between the wings and exaggerated dihedral angles. That their methods proved unsuccessful does not alter the fact that that was their *aim*. The greater success *aerodynamically* of the Wright machine gradually brought the French school to the view that stability must be sacrificed to control, but it has always seemed to me that originally they started from the other of the two extremes Prof. Melvill Jones so graphically describes. It was to me absorbingly interesting in the early days to watch the two 'schools' gradually converging. The French machines discarded their 'stability' devices, while the Wrights in time gave up the front elevator and fitted a wheeled undercarriage, until the Wright biplane of 1910 was in appearance scarcely distinguishable from, for example, the Farman of the same period.

W. Lockwood Marsh.

Sentinel House, Southampton Row,
London, W.C.1,
May 21.

In referring to the Wrights' use of a powerful rudder as a means of dealing with the stall, I had mainly in mind its use to control the lateral rolling of the aeroplane in the manner indicated in Figs. 6 and 7 of my article. I am much interested to hear from Lieut.-Col. Lockwood Marsh that the Wrights, as I had surmised, deliberately fitted it with this object in view.

My statement that on the whole the men who tried to fly were themselves interested in control, whilst the theorist and model constructor were more interested in stability, was intended to be read in a broad sense only, and in that sense I still think it is correct, bearing in mind such men as Lilienthal, Cody, and a host of others both before and after the Wrights. I had not, however, realised the extreme interest in stability of the French pioneers, and am grateful to Col. Lockwood Marsh for pointing it out.

B. Melvill Jones.

Base Exchange and the Formation of Petroleum.

I have read with great interest Dr. McKenzie Taylor's letter entitled "Base Exchange and the Formation of Coal" which appeared in Nature of May 19, and am particularly interested in his description of the experiments conducted by him concerning the bacterial decomposition of fats under a roof containing hydrolysing sodium clay. Fats, as a body, are lighter than water, and I am wondering whether Dr. McKenzie Taylor has conducted any experiments, or has any evidence, to show that in Nature solid fats could be a sedimentary deposit in water and accumulate as such together with sand. Some eighteen years ago I demonstrated that oils can be deposited in considerable quantity as an aqueous sediment together with mud or clay, but my experiments indicated that oils could not be similarly deposited by, or together with, sand. For a full description of the phenomenon and my experiments, and also how in Nature the oil would afterwards be squeezed out of the clay into a sand bed, reference may be made to my book, "The Geology of Oil, Oil-Shale, and Coal."

I gather from Dr. McKenzie Taylor's description that in his experiment the bacterial decomposition under alkaline anaerobic conditions of the fat which was distributed through a sand layer at the bottom of the beaker took place in fresh rather than in saline water. If so, this may possibly account for the yield of methane rather than of higher members of the paraffin series. Connate oilfield waters which occur, together with oil, sealed up in oil-sands, have a distinct resemblance to ordinary sea water. They differ from ordinary sea water in increased salinity and deficiency in sulphates and magnesia. Two years ago I deduced that natural petroleum oil owes its origin to the bacterial decomposition under anaerobic conditions, in some cases of vegetable oils, and in others of protoplasm, by sulphate-reducing bacteria in sea water, and that the differences between connate oilfield waters and normal sea water were just the differences which would be produced by the action of such bacteria. The actual discovery of sulphate-reducing bacteria in the connate oilfield waters of the Illinois, Sunset-Midway, and Coalinga oilfields of America, by Dr. Edson S. Bastin, affords a certain amount of support for my deductions. If, parallel with the experiments which he is conducting, Dr. McKenzie Taylor would conduct a second set of experiments to determine the effect of the bacterial decomposition in sea water under anaerobic conditions by *Microspira aestuarii* (van Delden) and its associates, of protoplasm on one hand, and of vegetable oils on the other, incorporated as sediments in clay, a comparison of the results obtained would be extremely valuable.

The Nierenstein Reaction.

During the past thirteen years, and in conjunction with several different collaborators, I have studied the reaction which takes place when diazomethane is added to various acyl chlorides, and I have shown that the change which takes place is always of the type represented by the equation,

$$R\,.\,CO\,.\,Cl + CH_2\,.\,N_2 = R\,.\,CO\,.\,CH_2\,.\,Cl + N_2.$$

The details of the method are described in my first paper (*Jour. Chem. Soc.*, **107**, 1491; 1915) on the subject, and it suffices to state here that the reaction was conducted by passing the diazomethane into the acyl chloride, the latter reactant being always in excess during the reaction. This is commonly known as the Nierenstein reaction.

Quite recently Arndt (*Ber.*, **61**, 1122; 1928) has confirmed my experimental results, and has also shown that if the method of conducting the process be reversed, and the acyl chloride added to the ethereal solution of diazomethane, so that the latter remains in excess, a change takes place which is represented by the equation,

$$R\,.\,CO\,.\,Cl + CH_2\,.\,N_2 = R\,.\,CO\,.\,CH\,.\,N_2 + HCl,$$

the main product being of the type, $R\,.\,CO\,.\,CH\,.\,N_2$, instead of the type, $R\,.\,CO\,.\,CH_2\,.\,Cl$.

In a paper published in the *Journal of the Chemical Society* a few days ago (p. 1310), Bradley and Robinson state that when diazomethane is treated with benzoyl chloride the main product is diazoacetophenone, and they therefore suggest that I and my collaborators, in this case Clibbens, have published statements which cannot be corroborated. I would point out that since they conducted the experiment in accordance with the second alternative method of Arndt, it is not surprising that they obtained the result which they might have anticipated had they been acquainted with Arndt's work, and not the result which would have been arrived at if they had followed the procedure of the Nierenstein reaction, as confirmed by Arndt.

I also take this opportunity of correcting a somewhat serious mis-statement which the same authors make in reference to my work. They express surprise that I should have stated that a certain substance containing two active Ph . Br . CO . groups should "crystallise unchanged from alcohol" (*J. Am. C. S.*, **47**, 1730; 1925), referring to this alleged statement as an "unconventionality." Reference to the paper will show that the substance is said to "crystallise in long needles from benzene," and that alcohol is not mentioned as a solvent from which the substance can be crystallised.

Infra-red Emission of Carbon Dioxide.

DURING the course of an investigation into certain infra-red emission spectra, we re-examined that of burning carbon monoxide. In the absorption spectrum of carbon dioxide it is necessary to presume the existence of three fundamental vibrations in the near infra-red; in this way the other bands observed in the so-called rotational-vibrational spectrum can be accounted for as a system of harmonics and combinations: nevertheless the observed values depart from those calculated by several units per cent.

If the emission spectrum is analysed, it is found that most of the bands have shifted towards the longer wave-lengths and so become exact multiples of a frequency, $\nu = 16 \times 10^{11}$, in the far infra-red. Our observations are recorded in the following table: the values for the absorption spectrum are taken from the work of Schaefer and Philipps (*Zeit. f. Physik*, **36**, 641, 1926).

No.	Emission.				Absorption.	
			$\nu \times 10^{-11}$.			$\nu \times 10^{-11}$.
	λ.	$n\nu_0$	Calc.	Obs.	λ.	Obs.
1.	1·70μ	$110\nu_0$	1760	1764	1·61μ	1864
2.	1·99	$94\nu_0$	1504	1508	2·02	1486
3.	2·40	$78\nu_0$	1248	1250	..	..
4.	2·79	$67\nu_0$	1072	1074	2·69	1115
	2·84	$66\nu_0$	1056	1056	2·72	1102
	2·87	$65\nu_0$	1040	1045	2·76	1086
5.	4·46	$42\nu_0$	672	673	4·25	706
6.	[15·6]	$12\nu_0$	192	..	14·87	202
7.	[187·4]	ν_0	16	..	..	..

No. 3 is new, not having been previously observed either in absorption or emission; No. 4 is a double doublet which can just be resolved with a rock-salt prism spectrometer; No. 5 is generally quoted as 4·40μ, but most careful calibration of the two spectrometers used, together with frequent repetition, confirms our result, the corresponding value for the bunsen flame at a lower temperature being 4·44μ.

Many interesting theoretical points present themselves, but it seems that here we are dealing with a pure rotational spectrum; it is suggestive that the Krüger gyroscopic molecule (founded on the earlier Bohr atom) executes a regular precession at low temperatures which changes to a true rotation at more elevated ones.

A corresponding simplicity underlies the water vapour emission spectrum which we have also investigated.

The Spectrum of Ionised Sodium.

IN a noteworthy article with the above title (*Phil. Mag.*, **5**, 150; 1928), Prof. F. H. Newman has given a new list of wave-lengths of the spark spectrum of sodium, which had previously been investigated by Foote, Meggers, and Mohler. The lines in question lie mainly in the near ultra-violet, between 2300 A. and 4800 A. No analysis of the Na II spectrum is attempted in the above-mentioned paper, but a number of pairs showing constant differences are given. I wish to show that using one of those differences (most of the others seem to be accidental) it is possible to arrange numerous strong lines as combinations of four s terms with ten p terms, corresponding to the transition $(3s^{1\,3}P - 3p^{1\,3}(S, P, D)$. The wave-length arrangement is the following:

	$(s_5)^3P_2$	$(s_4)^3P_1$	$(s_3)^3P_0$	$(s_2)^1P_1$
p_{10}	3533	3631	3711	...
p_9	3093			
p_8	3056	3130		3463
p_7	3008	3079	3136	3400
p_6	2918	2984	...	3286
p_5	2860	2924	2975	3212
p_4	2842	2905		3190
p_3		2881?		...
p_2	2810	2872	2921	3150
p_1		2586		2810

The frequency differences between the four lower levels $^3P_2$, $^3P_1$, $^3P_0$, $^1P_1$ are respectively: 765, 592, 2481 cm.$^{-1}$. The sum of the second and third of these is the difference 3073 cm.$^{-1}$ the occurrence of which was found by Prof. Newman. It is noteworthy that the difference $^3P_2 - {}^3P_0 = 1357$ cm.$^{-1}$, which may be interpreted as an L doublet yields, when inserted into the relativistic doublet law, exactly the same screening constant, 3·20, as the corresponding difference 780 of Ne I. For the comparison of the four differences of Na II with the corresponding ones of Ne I (417, 360, 1070), reference may be made to a paper by Mack, Laporte, and Lang (*Phys. Rev.*, June 1928). In every respect the above arrangement is similar to the first member of the principal series of Paschen's famous neon classification. As is easily seen, the next member of this system of series must lie deep in the Schumann region.

Parts of the diffuse series

$$3p^{1\,3}(S, P, D) - 3d^{1\,3}(P, D, F)$$

have also been found. All the strong and many of the weaker lines have thus been classified. The complete numerical material will be published soon.

A Nitrogen After-glow.

IN the course of evacuating glass vessels which were to be used for experiments on the maintenance and starting potentials in argon for continuous high frequency oscillations, we observed that a nitrogen after-glow appeared when a discharge was passed through a mixture of air and argon at low pressures. For pressures greater than two millimetres it is very difficult to pass a discharge through air using external electrodes and a small valve oscillator giving a wave-length of the order of 20 metres. But when the pressure is less than one millimetre a discharge takes place easily in air. A great many experiments have been made on the residual air contained in glass vessels, and in no single case of a discharge of this type have we noticed a nitrogen after-glow, whether or not the more volatile gases were frozen out with liquid air. Even in the preparation of pure nitrogen a glow was noticed in a discharge of this type only on one or two very rare occasions when there were impurities present in small quantities.

If, however, pure argon at about a millimetre pressure be admitted to a vessel containing air at a pressure of the order of 1/10 of a millimetre, a glow at once appears. We have not yet had the opportunity to investigate the relative proportions of the mixture over which this phenomenon may be produced, but they may be varied over a fairly wide range. Mixtures of neon and helium at about the same pressure do not show this effect. The after-glow is greenish-yellow in colour, and under the best conditions will persist for some seconds after the discharge has ceased to pass.

We have tried a Tesla discharge through the mixture, but such a discharge gave no sign of an after-glow. All the experiments with the usual methods of production seem to agree in showing that argon has no effect on the nitrogen after-glow and that the nitrogen after-glow is not produced when the proportion of oxygen and nitrogen is the same as that in the atmosphere. The mixture retains its properties over long periods; for example, we have a sealed-off glass tube in the laboratory which has been used to show this effect for a period of two months.

This method of production should be exceedingly useful in some types of research.

Thames Floods.

THERE is one possible cause of exceptionally high tides which is not always kept in mind. The effect of a system of low atmospheric pressure may be cumulative if the centre is moving in the same direction as the tidal wave and at the same speed. If the centre is at the correct distance in advance of the crest of the wave an exceptionally high tide may be experienced; and it may be inexplicable from consideration of wind and static barometric pressure alone.

I can give an example. A few years before the War, and about the month of June, a well-defined line squall passed up the English Channel. I happened to be in a 3-ton boat about 15 miles west of Portland Bill when it passed, and so I can definitely state that the wind effect was negligible. We had a barograph on board, and it indicated a sudden fall of 0·2 in. and a sudden rise of about 0·1 in. about 10 minutes later. That happened on a Saturday afternoon, and the Monday papers had reports from various parts of the south coast of a rise in the tide after the ebb had started, and of boats refloating after they had taken the ground.

Where the depths are about 20 or 30 fathoms, corresponding with tidal wave speeds of 36 or 45 knots, the *movement* of atmospheric depressions should always be taken into account.

The Pure Rotation Spectrum of Ammonia.

WITH the assistance of Mr. C. H. Cartwright, I have recently investigated the absorption of ammonia gas in the region of the far infra-red lying between 55μ and 130μ, and have observed an unexpectedly simple spectrum. Six lines were discovered which are approximately equally spaced in the frequency scale, and five of these were accurately measured. Within experimental error all of the lines may be represented, in terms of wave number, by means of the following equation,

$$1/\lambda_m = 19{\cdot}957m - 0{\cdot}00508m^3.$$

A thorough search failed to reveal other lines in the region investigated, and within the resolving power of the spectrometer those observed appeared to be singlets.

Presumably this spectrum is due to changes in the rotational energy of the ammonia molecule, as it rotates about one axis. According to the new theories it is not possible from the observed data alone to calculate the moment of inertia about this axis, for the molecule at rest. The estimate of $2{\cdot}77 \times 10^{-40}$ gm. cm.^{2}, however, is probably not greatly in error. The magnitude of the second term in the equation above shows that the molecule is relatively elastic and stretches considerably in higher rotational states.

A study of the absolute intensities of absorption was also made and will be published shortly.

The Sun's Outer Atmosphere.[1]

By Prof. E. A. MILNE, F.R.S.

AT a total solar eclipse, when the moon touches the sun's limb internally, a thin crescent of atmosphere is exposed. Its spectrum is a series of bright lines—general absorption at these levels has vanished. By measuring the lengths of the crescents from tip to tip, astronomers have estimated the heights to which the atoms of different elements exist. The following table gives samples of the observed heights:

It will be seen that the thickness in each case is of the order of thousands of kilometres. Roughly speaking, the sequence is: photospheric layer of the order of tens of kilometres, reversing layer of the order of hundreds of kilometres, chromosphere of the order of thousands of kilometres. We may complete the sequence by mentioning that the solar prominences are of the order of at least tens of thousands of kilometres and that the corona is of the order of hundreds of thousands of kilometres.

The mere size of this thickness shows that we are compelled to introduce a new force other than gravity and gas pressure. In ordinary gravitational equilibrium, under solar conditions, the pressure would decrease by a factor 0·07 in 10 km. In 10,000 km. it would decrease by a factor 10^{-1140}. At this pressure there would be no atoms at all at 10,000 km., and the pressure would have fallen to 10^{-18} atmospheres in 100 km. from the limb. When selective radiation pressure is introduced the pressure decreases much more slowly.

To see how this arises we must return to our arguments about selective radiation pressure near the boundary. We have still to explain what was wrong with our former assumptions. It will be remembered that we assumed 'local thermodynamic equilibrium.' This means that we assumed a definite temperature at each point. In strict thermodynamic equilibrium, as in an enclosure at a uniform temperature, the matter is traversed by radiation corresponding to its own temperature. At any point in a star the matter is traversed by radiation arising from places at a variety of temperatures, and strict thermodynamic equilibrium does not occur. But for many purposes the matter behaves as though it had a definite temperature. It can be shown, in fact, that when the density is sufficiently high, that is, when the atoms are sufficiently battered about by collisions with other atoms, the matter behaves according to the laws of Kirchhoff so far as the emission and absorption of radiation are concerned. The ratio of emission to absorption at any point is determined by Kirchhoff's universal function (Planck's function), which contains the temperature as a parameter. When we calculate the laws of transfer of radiation under these conditions, using Schwarzschild's equations, we find first the laws of selective radiation pressure mentioned earlier. We find also that energy is continually being transformed to longer and longer wave-lengths as it runs down the temperature gradient, the mechanism being inelastic and hyper-elastic collisions. Hyper-elastic collisions remove energy of shorter wave-lengths, and inelastic collisions introduce radiation of longer wave-lengths.

As, however, the density decreases, collisions become less important. Radiation, instead of being transformed in wave-length, tends to be handed on at the same wave-length. Ultimately, at sufficiently small densities, the whole of the radiation passes unchanged in wave-length. We call this state of affairs 'monochromatic radiative equilibrium.' Each portion of matter then emits as much radiation of the wave-length in question as it absorbs. Since there is no gain or loss of radiation of the given wave-length at any point, the net amount of λ-radiation crossing any one level—the difference between the inward and outward streams—is the same as that crossing any other level—for otherwise there would be either an accumulation or a loss of energy between the two levels. The net flux in a given wave-length is therefore constant. Hence if the absorption coefficient is constant, the selective radiation pressure will be constant.

We can now trace the origin of our previous contradiction. First, we erroneously assumed local thermodynamic equilibrium to hold right up to the boundary of the star. This led to the possibility of an uncompensated radiation pressure at the boundary. This, we saw, must cause the formation of an outer atmosphere, a chromosphere.

---

[1] Continued from p. 913.

Secondly, we ignored the inward stream of radiation arising from this outer atmosphere; we calculated the selective radiation pressure at the boundary of the layer in local thermodynamic equilibrium as though there were no inward stream there.

When we now take account of the inward stream from the outer atmosphere, we see that all contradictions are removed. The boundary of the region in local thermodynamic equilibrium is not the boundary of the star as a whole. Outside this there will exist in general, for each particular kind of atom, a region not in local thermodynamic equilibrium but in monochromatic radiative equilibrium. This acts as a cushion, gently pressing on the region beneath and keeping it in equilibrium, to a slight extent by its weight, but principally by its back radiation.

II. LOCAL THERMODYNAMIC EQUILIBRIUM (K_Y LARGE) PHOTOSPHERIC LAYERS.

FIG. 3.—The transition from local thermodynamic equilibrium to monochromatic radiative equilibrium, and its influence in the formation of the chromosphere. The slope of PQ and P'Q' is determined by the theory of radiative equilibrium. The length of PP' (residual intensity) is determined by the weight of the atom and the atomic absorption coefficient. These two data serve to fix the position of P'. The slope of Q_0R_0 is determined by the temperature distribution, which in turn is determined by the equilibrium of the integrated radiation of all frequencies. Different horizontal scales are used for I. and II. Actually there is no discontinuity between I. and II.; a discontinuity is introduced merely for illustration purposes, to show up the different factors at work. In the absence of the chromosphere, the residual flux AQ_0 would cause expulsion of atoms. The chromosphere grows from A to P', until its back radiation AQ' reduces the net flux to QQ' = PP' = residual intensity in centre of line.

In this region, the chromosphere, we can now see that the density is likely to fall off very slowly. A decrease of density upwards means a decrease of pressure, and hence a pressure gradient. This balances part of the weight. But we have seen that the creation of the outer atmosphere will go on until its weight is just sufficient to balance the otherwise uncompensated radiation pressure from the region beneath. In this equilibrium there is no part left for pressure gradients to play, and they will be practically non-existent. In other words, the density will be practically constant.

Actually this overstates the case. The density must, in fact, decrease slightly outwards. For it to be accurately constant, the radiation pressure would have to be accurately constant. We have seen that the net flux is accurately constant. But the radiation pressure is proportional to the net flux and the absorption coefficient, and the latter is not accurately constant. It must be smaller at lower levels, because owing to the increased density of radiation there (forward plus backward stream) more of the atoms at any instant will be excited and so not in a condition to absorb; thus the average absorption coefficient will be smaller. The consequence is that at least at the lower levels there must be some pressure gradient to take care of the uncompensated portions of gravity, and so there will also be a density gradient.

Theoretically, the density should fall off as the inverse square of the height measured from a certain datum level.

A further point is, that though we have demonstrated the possibility of the existence of an extended low-pressure outer atmosphere with small density gradient, we have not proved that this is the only type of outer atmosphere. There are a whole range of other possibilities. If, after expelling enough atoms to form an outer atmosphere, the lower regions exude for some reason more atoms, radiation pressure will further diminish. There will be too many atoms to be fully supported by radiation pressure, and the outer atmosphere will partially collapse on to the lower regions. It will then be strongly condensed towards its base. Nevertheless, an all but fully supported outer atmosphere is what is observed in the case of ionised calcium atoms on the sun. The spectral observations made by Col. Stratton and Mr. Davidson at the eclipse of 1926 (Sumatra) have been analysed by Mr. P. A. Taylor. He first extended the theory so as to allow for the curvature of the sun, and then compared the observed outward decrease of intensity of the flash spectrum with the calculated decrease. It appeared that all but about one ten-thousandth of the weight of the calcium chromosphere was supported by radiation pressure. Why this is so we cannot exactly say. One suggestion is that it appears possible that a strongly condensed 'partially supported' chromosphere would tend to re-introduce local thermodynamic equilibrium, in which case atoms would be once again expelled and a fresh chromosphere would be grown. This is a mere conjecture, and such calculations as I have been able to make do not confirm it. We must await further investigations.

Each species of atom occurring in the chromosphere should produce its own radiation gradient, independent of the others, and the complete chromosphere arises from the co-existence of the separate outer atmosphere for the separate species of atom.

We have arranged our argument as though the region of local thermodynamic equilibrium ends abruptly, and is superposed by a region in monochromatic radiative equilibrium. Actually, the two must shade into one another. The precise pressure at which the one set of conditions gives place to the other depends on the effective cross-section of the atom for collisions that are capable of exciting it, and if this cross-section is of the order of magnitude of the cross-section given by the dynamical theory of gases, then the transition pressure where an intermediate state holds is of the order of 10^{-3} atmospheres. If this is to be trusted, it would mean that all lines in the reversing layer are produced under conditions where, on the whole, the state is one of monochromatic radiative equilibrium rather than one of local thermodynamic equilibrium.

As a corollary it would follow that all lines except those due to very heavy atoms should appear in the chromosphere. Roughly speaking, this is what is observed.

The more nearly an outer atmosphere, in a particular kind of atom, is in monochromatic radiative equilibrium, the more nearly the ratio of the residual intensity in the line-centre at the limb to that at the centre of the disc should approach the value $\frac{2}{5}$. It will be a matter of interest to see to what extent this holds—investigations are now in progress at a number of different observatories. Schwarzschild pointed out long ago that on local thermodynamic equilibrium all absorption lines should vanish in the continuous background at the limb, and inferred that since they do not do so there must be a measure of monochromatic radiative equilibrium. Our general theory bears this out. For all atoms, local thermodynamic equilibrium must give place to monochromatic radiative equilibrium at low densities, and the more completely this holds the more completely should the limb-centre ratio approach $\frac{2}{5}$. Schwarzschild found that the ratio was in fact about $\frac{2}{5}$ for the *H* and *K* lines of calcium, for which lines the existence of a high level chromosphere makes it very probable that monochromatic radiative equilibrium holds strictly.

It is perhaps scarcely necessary to add that in the atmospheric structure we have sketched we have highly idealised the problem at a number of points. We have simply attempted to construct a model of the solar atmosphere useful for the points under discussion. It will not necessarily be useful for other points. Even as it stands it is not a complete model. For one thing, we have tacitly dealt only with electronic transitions as the origin of lines—we have ignored the effects of selective scattering as the cause of line-widening, as suggested by Stewart and brought into prominence by the recent work of Unsöld. Again, we have argued as though the boundary between monochromatic radiative equilibrium and local thermodynamic equilibrium coincided with the boundary between the low-pressure chromosphere and the higher-pressure reversing layer. Actually, we have found that monochromatic radiative equilibrium is coming into being at about 10^{-3} atmospheres, whilst, for example, the partial pressure of calcium at the base of the chromosphere can scarcely exceed 10^{-12} atmospheres. This involves no intrinsic self-inconsistency. It is merely that we have not dealt adequately with the few hundred kilometres in which this transition occurs. Somehow or other the sun knows how to arrange its layers in this region in accordance with the laws of physics, and in so doing it propounds an attractive puzzle for the mathematician and the solar physicist.

Centenary Conference of the Institution of Civil Engineers.

THE engineering conference held during the first week in June as part of the celebrations of the centenary of the incorporation of the Institution of Civil Engineers, proved a very successful function. Monday, June 4, was devoted to a reception of the many delegates representing kindred institutions and universities at home and abroad, and to the delivery of the James Forrest Lecture, the main part of which appears as a Supplement to this week's issue of NATURE. Such an occasion affords a very suitable opportunity for a general review of the developments which have taken place in this branch of applied science during the past hundred years. In his lecture Sir Alfred Ewing gave a masterly exposition of these developments, taking as his main thesis the prediction of Tredgold made in 1828 that "the scope and utility of civil engineering will be increased with every discovery in philosophy, and its resources with every invention in mechanical science," and emphasising at the same time the extent to which advances in engineering have been associated with many of the most noteworthy advances in physical science.

The mornings of June 5 and 6 were devoted to the presentation and discussion of a series of professional papers. The scope of the subjects chosen for discussion by the selection committee indicates in a striking manner the catholicity of the Institution, the majority of the papers dealing with matters which are commonly understood as coming within the purview of the mechanical or electrical engineer, and relatively few dealing with those branches of constructional and structural engineering with which the members of the Institution are commonly supposed to be most intimately concerned.

Since the papers were chosen with the view rather of considering recent developments in engineering, this is perhaps unavoidable, for there can be little doubt that modern developments in what may perhaps be termed the more dynamical branches of engineering have been much more marked than in those branches which deal with such constructions as railroads, docks and harbours, and bridges. It is somewhat surprising, however, in view of recent developments in this direction, that there should have been no paper dealing specifically with modern dams of the arch type. It is true that this type has been almost exclusively developed abroad, but in view of its interest and importance it would appear to be a subject well meriting discussion at such a conference.

It is worthy of note that no fewer than ten of the papers presented for discussion deal with one or other aspect of the generation of power from solid or liquid fuels. The possibilities embodied in the use of steam at high pressures, especially at high temperatures, are attracting much attention at the present time; and keen interest in this subject was evidenced in the discussion of papers dealing with such various aspects of the problem as the properties of the materials suitable for use in the construction of boilers for very high pressures; the design of such boilers, both for land and for marine use; and the design of steam turbines for utilising these pressures. The general trend of the papers and of the discussion would indicate that developments in this direction are likely to be far-reaching and important in the near future. At present, the difficulty of obtaining a steel which is at once fairly cheap and well adapted for use at high temperatures forms a serious handicap, but when this problem has been satisfactorily solved—and, in view of the attention now being devoted to it, the solution cannot be long delayed—the high-pressure installation is likely to become the rule rather than the exception both for land and marine work.

Discussions on the use of internal combustion engines, and of high-pressure steam for marine propulsion, show that the marine steam plant is very far from being dead, and its advocates see every reason to believe that the use of high pressures on shipboard may do much to bring the balance of advantages once more on to the side of steam propulsion. A paper on the latest types of steam and internal combustion locomotives shows that the battle between the steam and the internal combustion engine is being waged with some intensity here also.

Some interesting facts were brought out in a paper on light high-speed internal combustion engines, and in the resultant discussion. Thus it is probably not generally realised that the output of such engines to-day, measured in horse-power, is more than ten times that of all existing power stations, ships, and railways. Largely owing to its application to aerial flight, this branch of engineering has engaged the attention of some of the most skilful and scientific British designers during the past fifteen years; and the progress during that time has probably been more marked than in any other branch of motive power engineering. The highest thermal efficiency yet recorded by any heat engine, namely, 39·5 per cent on the brake horse-power, was obtained on the Napier aero-engine which won the Schneider Cup trophy in 1927, while almost, if not quite, the highest thermal efficiency ever recorded on a Diesel engine was obtained by the Royal Aircraft Establishment on a small high-speed Diesel engine of 8 inches bore running at 1000 rev. per minute.

The design of such an engine sufficiently light to be used in an aeroplane is still some way from solution, but in view of the progress already attained in this direction, it would appear extremely probable that the Diesel engine will at no remote date form the power unit for moderate speed heavy aeroplanes intended for long-distance flights.

The general interest shown in the work of the Electricity Commission is reflected by papers on prospective developments in the generation of electricity; on the electric transmission of power as applied to large areas; and on domestic lighting and heating and its influence on the load factor of supply. This forms a very interesting and suggestive trilogy of papers.

Two papers on water power were discussed, one dealing with recent progress in hydro-electric installations of conventional type and one with tidal power. In the former paper the remarkable rate of development of water power is emphasised. The total world development now amounts to about 35 million horse-power, practically all of which has taken place in the last thirty years, and this is increasing at the rate of about 1·5 million horse-power per annum. The capacity of the hydro-electric plants now operating in Great Britain, however, does not exceed 100,000 horse-power, which is almost negligibly small compared, for example, with the 12 million horse-power of the United States. At the same time, it is encouraging to know that Great Britain takes a share in the design and manufacture of hydro-electric plants altogether out of proportion to its own meagre water-power supplies.

In view of the investigation of the possibilities of a tidal scheme on the Severn; of the published particulars of a proposed tidal development on the Wash; and of the tidal scheme on the French coast at Aberv'rach, the discussion on tidal power was timely and of interest. Such a development probably involves more diverse problems than are to be found in any other single engineering development. There can be little doubt that these problems are on the way to solution, and that sooner or later large-scale tidal development will provide a very large source of energy supply. One can, indeed, visualise the time when water-power development from tides will be relatively as important in Great Britain as is water-power development from rivers in such a country as the United States.

Papers on recent developments in concrete for engineering structures, and on developments in the use of materials in railway engineering, indicate the extent to which the use of concrete, especially in conjunction with steel reinforcement, is extending. Even in the most conservative of engineering circles, interest is now being shown in the possibilities of reinforced concrete, and its use is rapidly extending. The introduction of reliable, rapid

Supplement to NATURE

No. 3059 JUNE 16, 1928

A Century of Inventions.[1]

By Sir JAMES ALFRED EWING, K.C.B., F.R.S.

THE Council of the Institution of Civil Engineers, when inviting me to deliver the James Forrest lecture as an item in the celebration of our centenary, suggested a very comprehensive text, namely, a prediction which Thomas Tredgold added to the definition of civil engineering which he drew up for the petition for a Royal Charter presented in 1828. It ran thus :—

“ The scope and utility of Civil Engineering will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical science.”

Seldom, surely, has a prophecy been so justified in the event. The history of engineering during the century which has passed since these words were written is in its main features the story of their fulfilment. Every advance in scientific theory has increased the engineer's mastery of the material world. Discoveries, which at first may have seemed wholly unserviceable to him, have in fact furnished new points of departure, leading in ways that were often unforeseen to enlargements of his many-sided art.

It may be doubted whether even Tredgold, with all his vision, saw the outer side of the picture ; whether he realised the beneficent reaction by which science was itself to profit. But we, at any rate, see it now. We see how developments in science are fostered and even initiated by industrial requirements, by engineering enterprise ; how inventions that were made for the purpose of serving a public need have widened the outlook of science and given it new tools for research. Nowadays theory and practice march together in such close association that it is often difficult to distinguish them as separate figures in the procession. In chemistry, in metallurgy, in thermodynamics, in electricity, who would venture to apportion the credit for progress, as between the man who pursues abstract truth and him who strives after technical application ? Looking back, we may assert that there has from the first been some mutual obligation, not indeed so constantly operative as it is to-day or so clearly admitted, but often very influential. From modest beginnings physical science and engineering have advanced, side by side, and in the advance their intimacy has developed ; they have discovered the benefit of relationship and the relationship has itself become closer. A century ago they were both sturdy infants, playing, one may say, in more or less separate nurseries, sometimes meeting and perhaps sometimes quarrelling a little. Now, adult and masterful, they are partners in one firm, still conscious—as partners may be—of differences in temperament and taste and viewpoint, but very conscious also of the strength that comes from co-operation.

To-day we can take no more than an aviator's survey—what used to be called a bird's-eye view. For this purpose I may claim the doubtful advantage of having seen more than half a century pass since I began to teach engineering. I recall as a boy finding inspiration in an account of the doctrine of the conservation of energy then published as a new gospel—a doctrine which flooded with light much that had been very dark in earlier attempts to co-ordinate mechanical ideas. My recollections go back to a period before the coming of the oil engine, of the dynamo, the electric motor, and the transformer, when the only practical application of the electric current was in telegraphy, when the arc lamp was a scientific curiosity and the telephone had still to be born. It is something to have witnessed the whole pageant of electrical engineering display itself before one's own eyes, from tiny beginnings to its present greatness ; to have seen the dream realised of a distribution of power from central stations ; to have watched each stage in the development of the steam turbine and its use on land and sea ; to have observed the internal combustion engine arrive as a modest ally to steam, and gradually turn into a serious rival, after effecting a social revolution by making transport by road easy and transport by air possible. These things are familiar to everyone ; but it is perhaps to the old, who saw their first coming, who knew a simpler, homelier world before they came, that they make their strongest appeal. To me, who began engineering experience with the telegraphy of the early 'seventies, it is much to have been a spectator of the wizardry which has so transformed the art of communication that the spoken word literally goes forth to the end of the world.

---

[1] From the Thirty-fourth James Forrest Lecture, delivered before the Institution of Civil Engineers on June 4, on the occasion of the celebration of the centenary of its incorporation.

In this review, however, we have to go back farther than the reach of even the longest individual memory. Try to realise what engineering meant in 1828, what was its relation to the science of the day, and what in fact was, in that day, the state of science. The engineers of that period were mainly concerned with roads, bridges, and canals; the era of railways was about to begin. The steam engine, which first served as a device for pumping water out of mines, had been adapted by Watt and his followers to the driving of machinery in factories, and had thereby become a potent agent in the industrial revolution which followed the Napoleonic wars. It had been applied experimentally to drive carriages on roads, and had established its position, especially in America, as the motive power of paddle-boats for river traffic. To a small extent steam was being adopted as an auxiliary in sailing ships, and reformers were urging that the Navy should give it a trial—alleging what seems to us the curious reason that a steamship would cost less to build than a sailing ship. We have not found the *Hood* cheaper than the *Victory*.

Watt's prejudice against the use of high-pressure steam for a long time dominated English practice. Nevertheless, Jacob Perkins, rightly described by a contemporary as "an experimenter of no common cast," ventured even before 1828 on pressures such as would still be considered very high. He exhibited a piece of steam artillery which, under a pressure of sixty-five atmospheres, projected nearly one thousand musket balls per minute. But Perkins was one of those unfortunate inventors who are born before their time. What is relevant for us to notice is, that in those days the theory of steam was even more rudimentary than the practice; the early development of the steam engine proceeded without the guidance which it would have had if the properties of steam had been known. Carnot had already written his wonderful essay on the motive power of heat. But it had fallen flat. Its meaning was not appreciated; and at the time of which I speak the very alphabet of thermodynamics had still to be framed.

Remember that these early steam engineers had no idea that what they were doing was to convert heat into mechanical work. Many years were to pass before the notion of energy, as a thing neither produced nor destroyed, was to become an established part of natural philosophy; before Joule determined the mechanical equivalent of heat, and the first principles of the subject were formulated by Kelvin and Rankine and Clausius. But it may fairly be claimed that the way was prepared for these conceptions by the work of the engineers, by the invention and frequent use of the indicator, by Watt's numerical definition of the term 'horse-power,' and by the sporting interest of the Cornish mine managers in the 'duty' of their engines, a figure which expressed the relation of what we now call the work done to the coal consumed.

When one looks into the technical literature of that period one is sorry for the early student of engineering. Physicists and engineers alike were groping their way, confusedly, towards mechanical ideas which were as strange then as they are familiar now. The mathematical theory of elasticity is described by its historian Todhunter as having had its birth in 1821, when Navier first gave the equations for the equilibrium of elastic solids. Navier had brilliant colleagues among the other mathematicians of France. But between them and the stolid practicians of Westminster there was a wider difference than one of language or political sentiment. Their ways were not as our ways. Tredgold, in a preface to his "Essay on the Strength of Cast Iron," which discusses the stresses in beams, goes so far as to repudiate the use of fluxions as unsound. He appears to have regarded a differential coefficient as a device for "forcing the assent rather than convincing the judgment." This prejudice against the calculus remained for long a serious handicap to the British student of engineering.

Not less than mechanics and heat, the science of electricity was still in its infancy. Chimerical ideas found vent in engineering papers about the possibility of driving ships by the consumption of a little zinc in a galvanic battery. One sanguine inventor estimated the cost of propelling a ship in this way at 3*s.* 4*d.* a day. Ohm's Law had been formulated in 1825, but in the absence of units and instruments of measurement its significance could not be understood. It was not until the requirements of the telegraph had to be met that engineers and physicists together attacked the problem of framing a logical system of electrical units, determined their magnitude, set up standards, and established practical means of comparing electrical quantities with them. The work was begun in the early 'sixties, mainly at the instigation of William Thomson, afterwards Lord Kelvin. It was done under the auspices of a committee of the British Association, of which the secretaries were Clerk Maxwell the physicist, and Fleeming Jenkin the engineer. What it accomplished was an incalculable boon to the investigator in pure science no less than to the technician.

Not in electricity only, but also in mechanics, in heat, in all the properties and actions of matter where engineers and physicists find common ground, it is through the alliance between practice and science that the art of measurement has been evolved. It was to meet the needs of engineers that Whitworth brought precision into mechanism by laboriously creating for the first time a true straight-edge, a true plane surface, a satisfactory screw. This was no less a service to science: it made practicable the scales and standards and gauges that are now familiar alike in the laboratory and the workshop.

It was to meet the rapidly growing needs of steam engineering that Regnault undertook his researches into the properties of steam, which led to the publication, in 1847, of tables and data which for long remained a classic of the engineer. Now, thanks to Callendar, Mollier, and other workers, we enjoy a fuller and more accurate knowledge of these properties than Regnault could achieve, hampered as he was by the uncertainties of early thermometry. The science of thermometry became definite only after Kelvin introduced the absolute scale of temperature—a brilliant philosophical conception which runs through all physical and chemical science like a thread of gold in a woven fabric. It guides the engineer to the ultimate standard of thermodynamic efficiency; and it was from meditating on the action of heat-engines that the inspiration came.

It was to meet the requirements of the naval architect that William Froude attacked the problem of ship resistance, devised the method of the experimental tank, and showed how measurements on the drag of small models might, through application of what is now called the principle of dynamical similarity, furnish data from which to determine the power required at any speed to drive the largest ships. In more recent days the same principles, applied by aid of experimental wind channels to study the forces which air currents exert on model objects, have been a powerful factor in the development of aeronautics—an art the beginnings of which many of us have witnessed and the progress of which, sensationally rapid, compels attention from day to day.

A new art, such as flying, becomes inevitably and at once a branch of applied science; it advances like a fire-engine in a crowded thoroughfare; it escapes the long period of empiricism through which the older arts had to pass while they were laboriously making their way into the light.

It is to aid engineering no less than pure science that we now supplement private enterprise by the official organisation of research. In this it must be admitted that we followed somewhat slowly the example set by continental neighbours. The National Physical Laboratory was promoted by the joint efforts of physicists and engineers. It was, from the first, fortunate in having for its head a man in the fullest sympathy with both schools of thought, who for many years, and with the happiest results, applied his faculty for leadership to build up an establishment the work of which is accepted as authoritative and the influence of which on the scientific development of engineering has been, and continues to be, profound. Sir Richard Glazebrook has himself dealt with "The Interdependence of Abstract Science and Engineering" in a James Forrest Lecture delivered five years ago. No man could speak with a closer personal understanding and experience of the subject. In his hands the value of the Laboratory was so fully demonstrated that after a time, from being semi-official, it was made official—becoming a truly national laboratory, administered by a new Government office, the Department of Scientific and Industrial Research.

That Department, established in 1916, remains with us as a beneficent legacy of the War. It is a notable item on the credit side of an account that is mainly one of debit. The War turned men's thoughts, as never before, to mechanical problems. From being questions of mere luxury or convenience, such problems became, almost suddenly, questions of national life or death. Physicists and mathematicians whose interests had been wholly abstract were brought, as it were, from the clouds to earth. They faced facts—often, one should add, to excellent purpose. With the community generally, applied science took on a new significance; until then it had meant little to them; they now saw it as a man struggling in the water sees a plank within his reach. Research, and the adaptations of research, from being treated with general indifference, were hailed as a way to public salvation—salvation not only from the immediate menace of the struggle itself, but (after that was past) salvation from the abiding danger of international competition and the burden to industry through waste and debt. The national intelligence was stirred; blind eyes were opened. They have remained open, and the Department does much to keep them open.

The Department works largely through committees where experts in industry co-operate with men of scientific habit. It also subsidises young research workers. For a young worker to attempt research is often educative, and he may discover a real aptitude. But we must not forget that researchers, of the best sort, are like poets; they are born, not made. You may produce in this field competent hewers of wood and drawers of water, men who will usefully assist or follow a real leader. But the wind bloweth where it listeth; no man who says, "Go to, I will research" can count on inspiration, and not even the draught in an air-channel will make dry bones live. On the other hand, when the right man is found, there is no limit to his potential achievement. He may give the world a new idea; he may create a new industry; he may make for himself a name; he may make, generally for others, a fortune.

From time to time in the history of engineering we find a new idea born, resembling what biologists call a 'sport,' which gives an unexpected turn to the process of inventive evolution. No one can confidently extrapolate the curve of engineering progress; its equation is liable to capricious change. Besides those occasional fresh departures we find, especially in modern times, that the scientific method is continuously at work, acting always as an auxiliary to experience in improving what is already familiar. Thus the influence of science is felt in two ways; in occasional spectacular events which open up channels where the stream did not flow before, and also in constant guidance of established currents, giving them greater volume and a more favourable course.

Take an illustration or two from the history of metallurgy. In 1828 the only forms of iron available for construction on a large scale were pig-iron, the product of the blast furnace, and puddled iron, the same product decarbonised in the reverberatory furnace. When railways began there was doubt whether rails should be cast or wrought. Wrought iron had Stephenson's support and won the day. But it was not easy for the output of puddled metal to keep pace with the rapidly increasing demand which arose for rails, for boiler plates, and presently also for ship plates when iron came into use as the material for building hulls. It became urgent to find some other way of obtaining iron in the malleable state. In 1856, Bessemer attacked the problem as an outsider who broke away from the traditions of the trade. His method was a 'sport,' but no accident; it was an outcome of scientific thought. His first success was quickly followed by failures which only stimulated him to investigate their cause and cure. The difficulties were overcome, and mild steel began slowly to take its place as the most valuable of all constructive materials known to the engineer.

A few years later the alternative process of the open hearth was developed by Siemens, not less novel, and not less an offspring of scientifically trained intelligence. Regenerative heating—an idea which had already found engineering expression in the Stirling air-engine—secured the high temperature necessary for the molten bath. Less simple and less rapid than the process of Bessemer, it had the advantage of easier control; it could be made static. Each method has its own field of usefulness; together they supply the world with nearly a hundred million tons of steel a year.

In more recent times electricity, which is the handmaid of every branch of engineering, has given the steel-maker additional types of furnace with large application in the blending and refining of special steels. Steel has become a word of many meanings. We have learnt, and are still learning, the amazing variety of characteristics which can be produced in a metal by adding regulated quantities of other substances. The study of alloys, both ferrous and non-ferrous, is an immense field of research in which the resources of chemistry and physics are placed at the service of the engineer. By their aid he learns how to obtain a product that will fit a special purpose. It is, in each case, a question not simply of composition but of heat treatment, for the atoms are like a community of alien races, subject to collective excitement and liable in their stormy moments to assume new groupings which largely and permanently affect the properties of the piece.

By means of such study the engineer is now provided with cutting steels which have revolutionised workshop practice; stainless steels the use of which goes far beyond the requirements of the cutler; mechanically strong and wear-resisting steels in a profuse variety; magnetically hard steels which are retentive of magnetism to a degree not approached before. It would seem you have only to specify a new requirement, and the metallurgist finds an alloy that will meet it. You want a metal which will not change its dimensions with temperature, and he discovers invar. You want a steel which will refuse to take up any magnetism at all, and he discovers manganese steel. You want a metal immensely susceptible to weak magnetic fields, with which to 'load' a telegraph cable, and he discovers permalloy. You want a metal which will combine the lightness of aluminium with something of the strength and ductility of mild steel, and he discovers duralumin and the Y alloy.

It is a scientific process of high-temperature electrolysis that has made aluminium a commercial product. The designers of aircraft and of motor cars appreciate its value, in the alloyed state, and one may conjecture that in many fields of engineering construction we are on the threshold of an aluminium age. A material, not too costly, which has nearly the strength of mild steel, with little more than one-third its weight, ought to have an unlimited future. It has even been suggested that for the new age we should look to the alloys of another and still lighter metal, magnesium. Research in these directions proceeds apace.

A century ago the development of the steam engine had not emerged from the empirical stage. A change came soon after 1850, when men began to think of energy as protean and imperishable. The mechanical theory of heat was established, and in 1859, Rankine published his "Manual of the Steam Engine." Kelvin rediscovered Carnot, and the Carnot cycle came to be recognised as an ideal criterion of performance which no engine could conceivably surpass. Engineers strove to bring their engines nearer to that standard by compound expansion, by superheating, and by other means of reducing avoidable waste. They also strove to widen the interval between the temperatures at which the working substance took in and rejected heat, for the 'heat drop' between these limits determines how much of the supply of heat is ideally capable of conversion into work. Boiler pressures went up and up: they are rising still. A committee of this Institution helped to spread a sound gospel by recommending the Rankine cycle as a basis of comparison with the results of tests, a cycle which differs from that of Carnot only by assuming that no reversible process is followed in the return of the condensed water to the boiler. But it is interesting to notice that modern steam plants of the most efficient type have introduced a reversible process through the device of 'bleeding,' which enables the condensate to be heated step by step on its way back to the boiler, in a manner so nearly reversible as to make the whole cycle approximate to the ideal of Carnot.

All this exemplifies the continuous steady pressure of scientific ideas in improving the procedure of the practical engineer. In a different category I would place the invention, by Parsons, of the steam turbine. That too was an application of scientific ideas, but it is an example of what I have called a 'sport.' It broke away from established lines, and we may say that in the world of engineering the genius of Parsons opened up a new kingdom. He gave us a power producer, wholly novel in action and design, capable of immensely augmented efficiency, with a concentration and magnitude of effect never even imagined before.

Another 'sport' was the internal combustion engine. Time would fail me to trace its development from primitive forms; to tell of the steps, big and little, but all essentially scientific, which brought into operation the cycles of Otto and Clerk and Diesel; of the multitude of engines which have turned the man in the street into an engineer, crowding the highways, dotting the seas, and achieving in some sense a conquest of the air.

Reverse a heat-engine and you have a heat-pump, which means that by expending power from outside you can make a body colder than its surroundings and keep it colder. From this simple piece of thermodynamics has sprung a branch of engineering with great and growing economic importance. Refrigeration makes the whole world our orchard, our sheep farm, and our cattle ranch. Perhaps in no other field do so many scientific problems arise for solution as in the transport and storage of foodstuffs under such conditions of cold as will, without substantial damage, preserve them from bacterial attack.

The science of refrigeration, too, offers a conspicuous example of how an industrial process, strikingly novel, may take its origin from an apparently insignificant physical fact, and then repay the debt to pure science by promoting the progress of research. Long ago, Kelvin and Joule, in experiments on the properties of gases, discovered that when air escapes under pressure through a throttling orifice it undergoes a small drop in temperature—about one-fourth of a degree for each atmosphere. Years afterwards, Linde and others, by applying a regenerative interchanger to transfer the cold from the escaping air to the stream that was approaching the orifice so as to obtain a cumulative effect, used this as a practical means of liquefying air, and of separating its oxygen and nitrogen, with the result that each of the two may be commercially utilised. This is now the foundation of more than one considerable industry; moreover, it has given to physicists a new tool of research, enabling them to bring temperatures down to an extreme never before reached in any terrestrial laboratory.

In the region of applied electricity, perhaps more than in any other part of engineering, examples multiply themselves of the exchange of benefits between practice and science. One may, of course, say, with perfect truth, that all the applications of electricity are in their origin fruits of scientific research. If we trace, for example, the history of the dynamo, we go back through Hopkinson's formulation of the principle of the magnetic circuit to an experiment of Faraday, which, in 1831, first showed that the movement of a conductor across a magnetic field generates electromotive force. The very language in which one describes this fundamental discovery is language we owe to Faraday himself. From that experiment what a progeny has sprung! May it not be fairly claimed that all the practical devices of electrical engineers, the dynamo, the motor, the transformer, the storage battery, the arc lamp, the vacuum bulb, the electrolysis bath, the electric furnace, the telephone, and many more have advanced the purely philosophic study of electricity? With their help the physicists have now discovered that in positive and negative electrification—in the protons and electrons, which together compose the atom—we have the primitive brick-bats of which the whole material universe is built. Perhaps some day the philosophers, who have analysed matter into these brick-bats, teaching us how many of each kind are in the atom of any element, and the engineers, who are always searching for sources of power, may put their heads together and discover a means of tapping, in some sufficiently controllable manner, the huge stores of internal energy which the atoms are known to conceal. That would, indeed, be a new departure, but I dare not predict that it will ever happen. Prophecy, as George Eliot said, is of all forms of human error the most gratuitous.

When Kelvin, in 1853, discovered as a piece of mathematical reasoning that under certain conditions as to resistance, self-induction, and capacity, a discharge of electricity would be oscillatory, he little knew what he was letting the world in for. From that seed has grown a great tree. The branches, one may say, are visible over many housetops. Through Clerk Maxwell, Hertz, Lodge, Marconi, Fleming, de Forest, and many others, discovery and invention have proceeded, hand in hand, to accomplish what seems to me the most wonderful of all the wonders of applied science. The telephone of Graham Bell, the microphone of Hughes, the phonograph of Edison were arresting marvels the first coming of which I vividly recall. But wireless broadcasting still more impresses the imagination. It gives other marvels an added value, and works an even greater social change.

Towards the end of last century, when physical science seemed to some of its votaries to have settled into a groove, suddenly there was an astounding outburst of discovery. The X-rays, radioactivity, the electron—these followed one another in bewildering succession; discoveries wholly unexpected and pregnant with uses to mankind. Each in turn was a revelation to the philosopher; it gave a fresh direction to his concepts of Nature, and it enriched him with novel methods of research. Each of these discoveries also offered an untrodden avenue of practical application. Let me for a few minutes speak of what engineers have done to harness the free electron.

About 1895, Sir J. J. Thomson, examining the discharge which proceeds from the cathode or negative pole of a Crookes' vacuum tube, established the fact that it consists of a stream of separate particles—corpuscles he called them—of negative electricity, independent and all absolutely alike. These corpuscles are now called electrons; normally, in the absence of electrical disturbance, they make up, as it were, the crinoline or fender of a material atom; but when streaming from the cathode they have escaped from domestic ties. Each electron is a definite quantity of disembodied electricity—an irreducible unit—delightfully free to respond to any electric force, for its inertia is barely the eighteen-hundredth part of that of the lightest atom of ordinary matter. Free electrons are known to be given out by highly heated substances, such as the glowing filament in the vacuum bulb of an electric lamp.

This fact was turned to account by Fleming in an invention which one may, with no exaggeration, call epoch-making. He was in search of a sensitive detector of wireless signals, a detector more sensitive than the types Marconi originally employed. When a telegraphic signal sent by wireless strikes the receiving aerial it sets up a group of electrical oscillations, where crests and hollows alternate in very rapid succession—many thousands of times per second. To get them to make a signal which will be heard on a telephone or shown by a galvanometer, you must rectify the group, cutting out the hollows, one may say, and leaving only the crests. Fleming, in 1905, had the happy inspiration to employ the electrons which are given off by the hot filament in a vacuum bulb as agents in the work of rectification. For this purpose he fitted the bulb with a second conductor, now called the plate or anode, to which the stream of electrons from the hot filament may pass. He connected the bulb with the receiving aerial in such a manner that oscillations due to the wireless signal endeavoured to bridge the gap between filament and plate. When this is done, the crests—as we may call those parts of the oscillating current which flow *with* the stream of electrons—pass easily; but the hollows, which are the parts that try to flow the opposite way, are stopped. Thus the device acts as a rectifier of the received oscillations, keeping the crests but cutting out the hollows, and for that reason the inventor very appropriately called it a valve—a thing that allows passage only one way.

The Fleming thermionic valve soon came into use as a sensitive detector of wireless signals. Two years or so later its capabilities were much extended by the American electrician Lee de Forest, who introduced a third conductor in the form of a grid through which the stream of electrons passed on their way from the filament to the plate. With this addition, the device, now called a triode valve, could be applied as a powerful relay or amplifier, receiving any electrical oscillations and passing them on, greatly magnified. It is arranged that the incoming oscillations shall cause small variations in the potential of the grid; these produce large and sensibly proportional changes in the electron stream which passes to the plate. The triode valve is the essential instrument of modern wireless; it serves not only to rectify and magnify the received signals, but also, at the sending end, to create the oscillations which are radiated into space. Thus, from the great station at Rugby, a group of mammoth triode valves converts hundreds of horse-power into high-frequency electrical oscillations which carry signals to America.

Even this is not the end of the wonderful story, for the triode valve also acts as what is called a modulator, impressing upon the high-frequency waves which constitute wireless radiation the fluctuations of amplitude which enable them to serve as carriers of speech or of music, so that they may thereby convey the relatively slow vibrations of quite another sort which make up sound. Further, in telephoning over wires, the triode valve forms an admirably effective relay, acting, at a succession of points along the line, to restore the energy of the transmitted sound without injury to its quality. Moreover, by using suitable 'filtered' bands of carrier currents, a number of entirely independent conversations can take place simultaneously over the same wire, while it serves also as channel for a multiple group of telegraphic messages. All these wonders are made possible by the triode valve. Its technical applications appear to have no bounds. It is also an instrument of research; in the hands of physiologists and others it measures the slightest and most fugitive of electrical effects.

I have cited enough examples to illustrate the broad truth of Tredgold's dictum that the scope and utility of civil engineering are increased by every discovery in natural philosophy. But so sweeping a statement can scarcely fail to have some exceptions, and exceptions are in fact suggested by the present curious state of physical science. At the moment the very basis of physics is in a state of flux. Its exponents are struggling to assimilate two momentous new ideas—the principle of relativity and the quantum theory. The relation of these ideas to the accustomed body of older physics is obscure. They present dilemmas which are not yet solved. Their exact form and place in the logical scheme of scientific thought has still to be determined. One may say that, while the superstructure remains intact, the philosophical foundation on which it stands is strangely disturbed. Physicists are, as it were, confronted with a difficult but not impossible task; they have to transfer bodily their elaborate and beautifully coherent building, as a going concern, from one foundation to another, and the new foundation is not quite ready. They are hard at work laying it, laying it indeed so deep that the passer-by cannot see what is going on. When the operation is completed it will be a great achievement. But I do not think it will make much difference to the engineer, for his concern is with the superstructure itself. That will doubtless settle down quite comfortably when the necessary adjustments are made. It will function as well as before, and continue to admit of extensions which the engineers will in due time turn to practical account.

The century we now review is but a petty unit in the multitude of centuries that make up the recorded and unrecorded history of man. By comparison it is a mere fragment of time, yet how big when judged by the changes it has wrought! If we test progress by the conquest of inanimate Nature, then the century now closing finds no parallel in the past. It may be likened to the efflorescence of a plant which for long has been quietly growing to maturity and suddenly bursts into flower. We have witnessed as it were the change from bud to blossom. What is to follow? What is left for the future engineer to do? When you celebrate the second centenary of this Institution, of what will your lecturer have to tell? Can the recent astounding pace of discovery and invention be maintained? Or does a time approach when engineers will sit down like so many Alexanders to lament a too-completely conquered world of mechanical things, just as a time comes to geographers when there are no more regions to explore? Transport, especially by air, may be made less perilous and more convenient. Communication may be extended to include vision; that is half done already, and I confess to no enthusiasm for the other half. Power will certainly be more generally distributed.

Can we expect, however, that the engineers of the coming century will bring about developments in the application of natural resources comparable to those of the past hundred years? I am, as I said, no prophet, but I doubt it. To me it seems more likely that there will be something of a lull in the revolutionary fervour of the engineer. Social changes—drastic social changes—may be looked for, but not, I think, so directly consequent on his activities as in the century now ending. Mechanical devices will, of course, be increasingly used, but probably they will become standardised and taken for granted, like the watches we carry. We cannot be surprised if we find interest in them slacken. Improvements will be made, but they will attract little notice, for the things they affect will already be commonplaces of life. It may very well happen that the mental energy of mankind, now flowing so strongly in this channel of ours, will seek and find outlets in other directions. While as engineers we may regret such an issue, we cannot but admit that it may prove beneficial to the human race, since beyond question there is grave need for progress of quite a different kind.

For the fact remains that all our efforts to apply the sources of power in Nature to the use and convenience of man, successful as they are in creating for him new capacities, new comforts, new habits, leave him at bottom much what he was before. I used, as a young teacher, to think that the splendid march of discovery and invention, with its penetration of the secrets of Nature, its consciousness of power, its absorbing mental interest, its unlimited possibilities of benefit, was in fact accomplishing some betterment of the character of man. I thought that the assiduous study of engineering could not fail to soften his primitive instincts; that it must develop a sense of law and order and righteousness. But the War came, and I realised the moral failure of applied mechanics. It was a shock to find that a nation's eminence in this department of intellectual effort did nothing to prevent a reversion to savagery, conscienceless, unbridled, made only the more brutal by its vastly enhanced ability to hurt. I saw that the wealth of products and ideas with which the engineer had enriched mankind might be prostituted to ignoble use. It served to equip the nations with engines of destruction incomparably more potent and ruthless than any known before. We had put into the hand of civilisation a weapon far deadlier than the weapons of barbarism, and there was nothing to stay her hand.

Civilisation, in fact, turned the weapon upon herself. The arts of the engineer had indeed been effectively learnt, but they had not changed man's soul. In our diligent cultivation of these arts we engineers have perhaps forgotten that progress in them has far outstripped the ethical progress of the race. We have given the child a sharp-edged tool before he has the sense to handle it wisely. We have given him the power to do irreparable mischief when he scarcely knows the difference between right and wrong. Does it not follow that the duty of leadership is to educate his judgment and his conscience? Collective moral sense, collective political responsibility, the divine maxim to do to others as we would that they should do to us—these are lessons in respect of which all the nations, even the most progressive, have still much to learn.

There are people who talk glibly of the next great war. I wonder if they know how near, in the last war, the world came to destruction through misapplying the endowment which it owes to the engineer. Do they realise that with added experience and further malignant ingenuity, the weapons of a future war will be more than ever deadly, more than ever indiscriminate, and the peril to civilisation will be indefinitely increased?

Surely it is for the engineer as much as any man to pray for a spiritual awakening, to strive after such a growth of sanity as will prevent the gross misuse of his good gifts. For it is the engineer who, in the course of his labours to promote the comfort and convenience of man, has put into man's unchecked and careless hand a monstrous potentiality of ruin.

Printed in Great Britain by R. & R. Clark, Limited, *Edinburgh.*

hardening brands of cement has been of considerable assistance in this connexion, owing to the reduction in the length of time necessary before a new work can be put into service. The introduction in large numbers of heavy express locomotives has necessitated bringing up the track on fast lines to a very high standard, and much attention is being paid to experiments in the United States on a track consisting of a continuous raft of reinforced concrete on which the rails are directly bedded.

Papers on railway design and maintenance as affected by the application of electricity; on modern road and bridge construction; and on the engineering aspects of the problem of road traffic, focus attention on some of the problems with which recent development in transportation has provided the engineer.

In view of the interest and importance of the various papers, it is unfortunate that the time allowed for discussion was so inadequate.

An interesting series of visits to the National Physical Laboratory, the University of Cambridge, and various engineering works, was arranged as part of the programme, and was attended by a large number of members and delegates.

Obituary.

Prof. C. G. J. Petersen.

THE Danes have long been prominent in marine fisheries investigations, and the names of Carl Georg Johan Petersen, Johs. Schmidt, Th. Mortensen, and Commander Drechsel are familiar in this respect. The latter passed away last year, and now the busy life of Dr. C. G. J. Petersen is ended. A native of Denmark, his earlier years of study were at Aarkus, on the east coast of Jutland, and by and by, after graduation, following his natural bent, he entered as a junior helper in the Zoological Museum, Copenhagen, in 1881, acted as assistant curator, 1883–89, meanwhile aiding in the reorganisation of the Danish fisheries investigations. So far back as 1882–83 he had been on board the fishery inspection-vessel *Hauch* with Prof. Japetus Steenstrup and Commander C. F. Drechsel, and afterwards with Prof. Chr. Lütken; his researches, along with those of Cleve, Posselt, Meinert, Levinsen, and Traustedt, being published in 1893 in a 4to vol. with an atlas in Fol. under the title "Det videnskabelige Udbytte af Kanonbaaden Hauch's Togter." In continuation of the work on the fisheries carried on by H. Kroyer, Chr. Lütken, and G. Winther, he was by and by (1888) officially appointed by the Government under the Department of Agriculture. Seeing that his investigations could not be fully carried out on board the inspection-vessel, he, by the aid of Commander Drechsel and Prof. Lütken, got an old transport vessel transformed into a laboratory, which thus had the advantage of easy transference to the scattered fjords and islets of the Danish shores. A small open motor boat and a dinghy were also attached to the station.

Thus settled in a congenial post, Petersen entered into the fisheries work with enthusiasm, producing year by year for nigh forty years a series of important researches on the food-fishes and fisheries of Denmark, occasionally illustrating his memoirs by excellent plates, charts, and tables. The thorough manner in which he dealt with the subject in hand was characteristic. In no memoir was this better shown than in his investigation of the plaice of the Lim Fjord, and his advice for the transplanting of the young to Thisted, Bredning, and Vilsund. Much interest was taken in Great Britain, indeed, at the carrying out of the scheme. The re-stocking of the Lim Fjord fisheries in 1908 had the result of bringing 200,000 Kr. annually in excess of the average figures for the years previous to that date. Of late years two million of young plaice have annually been transplanted to these waters at a cost of 20,000 Kr.

Not only were the food-fishes of Danish waters carefully investigated, but also the distribution of their eggs and young, the nature of the food of both young and adult, and the character of the sea bottom were minutely investigated. Thus a quantitative study of the inhabitants of the sea bottom, with lists and plates showing their distribution, formed one or more of Petersen's various papers, one of his earliest, indeed, dealing with the Mollusca and Echinoderms of the areas frequented by the food-fishes. In his study of the animal communities of the level sea bottom—sand, mud, clay—he distinguished seven as follows: I. the *Macroma baltica* community, including *Mya*, *Cardium*, and *Arenicola*. II. The *Venus* communities, with *Venus*, *Tellina*, *Mactra*, *Abra*, *Psammobia*, *Cyprina*, with *Ethucardium* and *Spatangus purpureus*. III. The *Brissopsis* community, including *Brissopsis*, *Amphiura*, *Calocaris*, *Nucula*, and *Eumenia*. IV. Communities from deeper water than *Brissopsis*, such as *Pecten vitreus* and *Abra longicollis*. V. included *Macoma calcarea* and *Astarte borealis*. VI. The communities of the Lusitanian region, including *Tapes decussatus*. VII. Bottom fauna of the Atlantic. These he illustrated by coloured charts—each community having a special tint. His investigations of the pelagic fauna and flora of the several areas were equally methodical, the oceanic and neritic diatoms and *Peridineæ* receiving careful attention. He held that the organic matter of the sea bottom was due to plant growth and was not derived from the plankton. Both the pelagic and demersal eggs of fishes were studied, and the development of such as the gobies to the adult stage followed—with accompanying figures.

Not only did Petersen work out the life histories of the marine fishes of the Danish waters, the possibility of their increase, the means of protecting them from their enemies, but he also studied the life history of the eel, a fish so important to his countrymen, inspecting the numerous traps which are set singly or in rows, and carrying out experiments with artificial light during its migration. Further, he prepared two reports on the oysters and oyster fisheries of the Lim Fjord, giving a historical summary, an account of the banks, the food, age, spawning, and methods of capture. These oyster fisheries yielded in the decade 1900–1909 an average annual revenue of 70,000 Kr. to the State. Since the introduction of the new rental tariff they have furnished 140,000 Kr. in rental alone, and by the new methods of working this will be still further increased. Amongst other schemes he considered the question of utilising the common starfishes as manure. Nothing, indeed, relating to the Danish fisheries escaped him, and his training and abilities as a practical naturalist enabled him to improve various nets, such as otter-seines, as well as invent an apparatus, 'grab' as it was called, or bottom sampler, to lift samples of the sea bottom with its inhabitants for investigation. In connexion with the organic matter on the sea bottom, he found *Zostera* richer in pentosan compounds than plankton organisms, and that bivalves were capable of digesting it. In 1914 he urged the establishment of a permanent biological station on land on which young men could be trained for the work of the fisheries—with the prospect of regular employment.

Taken all in all, it is seldom that so able and so experienced a naturalist has given his life-long services to his country, or left so noteworthy a record behind him. Petersen often attended the meetings of the British Association, where he was equally welcome as popular. He was no less esteemed abroad than at home, as testified by his honorary degrees of LL.D. from the University of St. Andrews and D.Sc. from the University of Leeds, whilst for seven years he was at the head of the International Council for the Exploration of the Sea. He was inclined to recommend the policy of increasing the size of the fishes—especially flat fishes—rather than increasing their numbers by artificial hatching as in Norway and America.

W. C. M'Intosh.

Prof. A. H. Leahy.

Arthur Herbert Leahy, who died at Littlehampton, Sussex, on May 16, just before he had completed his seventy-first year, will be mourned by many generations of Sheffield students. For thirty years he was one of the best-known members, first of Firth College, then of University College, and finally of the University of Sheffield.

Leahy was born at Corfu in 1857, and was the eldest son of Colonel Arthur Leahy, R.E., of Flesk, Killarney. He was educated at Uppingham School, Trinity College, Dublin, and Pembroke College, Cambridge, and was placed ninth wrangler in 1881. In 1886 he was made a fellow and mathematical lecturer at Pembroke, and in 1892 became professor of mathematics at Firth College, Sheffield.

While at Pembroke, Leahy contributed to the study of spherical and tesseral harmonics and helped to introduce into England some of the Continental work in this branch of applied mathematics. At all times he was keenly interested in what may be called the mathematical side of theoretical physics, but his teaching and administrative duties took up his time, and his mathematical interests were satisfied by following developments from afar. An aspect of the breadth of his tastes appears from his work on old Celtic literature and his classical learning. Leahy's interest in astronomy led Pembroke College to give to the University of Sheffield a valuable telescope and transit instrument, housed now in the Observatory in Weston Park adjoining the University. Many were the nights spent there by him, and many the visitors whom he was delighted to welcome there.

Leahy's main achievements were in the building up of what is now the University of Sheffield, in setting the foundations of the Mathematical Department, and in teaching many of those who are now carrying on the torch. The University remembers him with grateful appreciation of his services.

The issue of the *Physikalische Zeitschrift* for Feb. 15 contains an obituary notice of Prof. Ferdinand Kurlbaum, by Dr. F. Henning, a former colleague at the Reichsanstalt. F. Kurlbaum was born at Burg, near Magdeburg, on Oct. 4, 1857. On the death of his mother, his father, a district judge, placed him in charge of an aunt until he was six, when his father married again.

As he grew up Kurlbaum hated school, and was twenty-three years of age before he passed the university entrance examination and became a student at Heidelberg, and later at Berlin. In 1887 he got his doctor's degree with a research on the wave-lengths of certain lines in the solar spectrum, done under the guidance of Kayser, who was then one of Helmholtz's assistants. On Kayser's promotion to Hanover, Kurlbaum became his assistant and remained with him until 1891, when he was appointed assistant at the Reichsanstalt in Lummer's department. In 1901 he became head of the Electrical Machinery Department, and in 1904 left the Reichsanstalt to become professor at the Charlottenburg Technical School, with Rubens as a colleague. Military occupations had a great attraction for him, and during the War he did a large amount of testing mirrors and guns. He died on July 29, 1927. His work on black body radiation and on the radiation thermometer is well known.

We regret to announce the following deaths:

Mr. Charles S. Boyer, of Philadelphia, known for his studies of Diatomaceæ, aged seventy-one years.

Dr. John S. Dexter, since 1923 professor of zoology in the University of Porto Rico, on April 19, aged forty-two years.

Prof. Léon Guignard, professor of general botany in the Faculty of Pharmacy of Paris, and president in 1919 of the Paris Academy of Sciences, aged seventy-five years.

Prof. Harris H. Wilder, professor of zoology in Smith College, Northampton, Massachusetts, known for his work on the anatomy of amphibia and also for his anthropological studies, on Feb. 27, aged sixty-three years.

News and Views.

In this issue we are publishing as a supplement an abridgment of the remarkable James Forrest Lecture on "A Century of Inventions" delivered by Sir Alfred Ewing on Monday, June 4, before the Institution of Civil Engineers. This is the thirty-fourth lecture of the series, and the subject suggested by the council for the lecture was a remark of Tredgold's to the effect that "the scope and utility of civil engineering will be increased with every discovery in philosophy, and its resources with every invention in mechanical or chemical science." This sentence was contained in the same document wherein Tredgold defined civil engineering as the art of directing the great sources of power in Nature for the use and convenience of man. Tredgold himself died a few months after he penned these lines, worn out by incessant study, but his phrases, so often quoted, will remain as long as civil engineering is practised. Sir Alfred Ewing's lecture was listened to with rapt attention by a large gathering of distinguished engineers and men of science, some of whom had themselves witnessed the vast extension of scientific discovery and engineering so eloquently referred to by Sir Alfred. Of absorbing interest throughout, the lecture ended upon a somewhat unusual note and many readers will probably find in its closing paragraphs its most pregnant passages. In proposing a vote of thanks, Sir Richard Glazebrook referred to the work of Sir Alfred Ewing at the Universities of Tokyo, Dundee, and Cambridge, as Director of Naval Education and also as Principal of the University of Edinburgh—and recalled the pioneering work he has carried out in magnetism and other subjects. Sir Alfred, it may be added, was born in Dundee on Mar. 27, 1855, and in the early 'seventies was first a student under Fleeming Jenkin and afterwards a member of his permanent staff, where he obtained experience in cable engineering.

In connexion with the celebration of the centenary of its incorporation, the Institution of Civil Engineers has issued a brief history of the Institution of some sixty pages. In the course of the short chapters are given some of the most interesting facts regarding the foundation of the Institution, its constitution, its growth in membership, its various homes, its prizes and endowments, and its several activities. Founded in a Fleet Street coffee-house, the Institution had its first permanent home in Buckingham Street, Adelphi; in 1834 a house was taken in Cannon Row, Westminster, from whence the Institution removed four years later to Great George Street, where it has had three homes. The present buildings, completed in 1913, represent a capital investment of more than £350,000. Photographs are reproduced of the fine vestibule, staircase, great hall, theatre, and library. The library contains more than 54,000 volumes, among which are forty editions of Vitruvius in various languages, and 896 volumes of tracts which to some future historian of engineering "may well prove to be a mine of curious information." The *Minutes of Proceedings* published up to the present run to 224 volumes, and on these and the *Abstracts*, etc., more than £400,000 has been expended. A list of presidents and secretaries of the Institution is given, while the interest of the record is increased by a series of marginal illustrations of great engineering works, from the bridges of Rennie and Telford down to the present time.

A banquet was given to Mr. A. V. Roe by his aeronautical friends on June 8 to commemorate the twentieth anniversary of his entry into aeronautics. Mr. Roe was a trained engineer and tried athlete, and in this way was specially equipped for the building and testing of his early experimental triplane. His admirers need not bother about the current controversy over his 'hops' in 1908, entirely credible in themselves, but scarcely ranking with flights officially controlled by competent observers. Roe's reputation is independent of such accidents of fortune, and is firmly based on the manner in which he evolved, from his early triplane, a series of designs culminating in the standard biplane, well known as peculiarly free from 'vices.' Looking through the old records, one is struck by the way in which the first freakish-looking triplane is transformed into an entirely modern design. It was a step-by-step process, but now appears almost an organic growth, save for the sudden change from triplane to biplane, since approved by the progress of aerodynamical science.

It is almost impossible now to project one's mind back into these early days of aeronautics, when a fog of ignorance concealed the most fundamental facts and requirements. The physical principles of flight had then been revealed only to Lanchester's prophetic eye. The circulation theory of lift was scoffed at in the highest places, for one could see that no air 'circulated' round the wing, and the trailing vortices were invisible to the eye of the pitot-tube. The principles of stability were still wrapped up in Bryan's mathematical statement. Structural stresses were based on the roughest information as to pressure distribution. But one can follow from page to page the steady evolution from a thing of stick and string and cloth, into an engineering design. It is Mr. Roe's distinction that he was one of the earliest British starters, and that he stayed through the race in which so many fell by the way. If an established position as a successful designer and constructor is not a relevant reward, he may add the esteem of his contemporaries in the old flying days of unforgettable memories.

Capt. G. H. Wilkins and Lieut. C. B. Eielson, who recently flew across the Arctic Ocean from Alaska to Spitsbergen, arrived in London last week and were entertained at luncheon by the British Government on June 7. Capt. Wilkins gave some indication of his plans for Antarctic explorations. His aim is not to reach the South Pole, but to explore the unknown region lying south of the Pacific between the Ross Sea and Graham Land. This flight will be about 3000 miles over entirely unknown parts of the ice-sheet of Antarctica. One object which Capt. Wilkins has in mind is the selection of sites for meteorological observatories, but there is little likelihood that any descents will be possible in the course of the flight. He proposes to leave the Ross Sea in January, taking off from a whaling ship on the open water which is often found off the Ross Barrier at that season. He hopes to be brought home by a whaler from the Graham Land area. The machine will be a Lockheed Vega seaplane. The *Times*, which gives an outline of Capt. Wilkins' plans, also announces that Commander R. E. Byrd will make his base on the Ross Barrier next southern summer, and explore by aeroplane to the south and east, hoping to reveal the course of the great mountain ranges which are known to border the Ross Sea.

IN addition to the expeditions of Capt. G. H. Wilkins and Com. R. E. Byrd, a third expedition to the Antarctic is announced for next season. According to the *Times*, Com. D. G. Jeffrey, R.N. (retired), will lead an American-financed expedition in September to Graham Land, where a base will be established on the west coast, in the area explored by Dr. J. Charcot. From there it is proposed to explore eastward to Coats Land with the view of filling in the missing western coast-line of the Weddell Sea and determining the course of the Antarctic Andes of Graham Land. A vessel of the deep-sea minesweeper type will be used, and two aeroplanes will be taken, the larger with a cruising radius of 6000 miles. The South Pole is not the objective of the expedition, but there may be a flight in that direction. Com. Jeffrey hopes to include among his staff certain men who served with him on Sir E. H. Shackleton's expedition in the *Endurance* in 1914–17. Only six months' stay in the Antarctic is anticipated, which is rather a short time for the completion of the programme.

ON May 31, the aeroplane *Southern Cross* started from Oakland, California, to cross the Pacific Ocean in three laps, ending in Australia. On June 9 the aeroplane landed at Brisbane, having accomplished safely a journey of 7340 miles. The *Southern Cross* carried a crew of four: Capt. Charles Kingsford-Smith and Mr. Charles Ulm, pilots, both of whom are Australians, and Lieut. Harry W. Lyon, navigator, and Mr. James Warner, wireless operator, both of whom are Americans. The first lap of the journey, California to Hawaii, a distance of 2400 miles, was covered in a little more than twenty-four hours. The second lap, Hawaii to Suva, Fiji, nearly 3200 miles, took about thirty-four hours; this flight is the longest over water that has yet been made. The last stage of the journey, Suva to Brisbane, was about 1500 miles, and took about twenty hours; during this time the weather was often unfavourable. It is a great achievement to have flown and navigated an aeroplane over the Pacific Ocean for the first time, and all the members of the crew are to be congratulated on the successful conclusion to their months of careful preparation.

WIRELESS messages from the airship *Italia* were received by the base-ship, *Città di Milano*, at King's Bay, Spitsbergen, on June 9, after two weeks' silence. The crew of eighteen were all safe on the ice in approximately lat. 80° 30′ N., long. 28° E., a position about fifteen miles from the nearest land in the island of North-East Land of the Spitsbergen group. The airship is reported to have been completely wrecked. Three men were sledging westward to find help, and the others were drifting with the ice. The drift will carry the Italians to North-East Land, but may take them to the inhospitable east coast which is faced with an ice-cliff. They have provisions for a month, and should be able to shoot some seals. The steamer *Braganza*, in trying to reach the shipwrecked men, was stopped by heavy ice near Cape North, about a hundred miles to the west. The difficulty of navigating along the north coast of Spitsbergen this month may delay rescue, but Norwegian airmen will no doubt locate the wreck and bring food to the men, even if they cannot carry them to safety. There are several good dog teams in Spitsbergen, and these are being used to take help. They should succeed, unless the drifting ice in Hinlohen Strait proves impassable. A Russian ice-breaker, which has been asked for by the Norwegian government, could probably get through the ice to North-East Land in four or five days.

WE understand that it has now been intimated that Great Britain will not be represented officially at the International Congress of Americanists which is to be held at New York in September next. As these matters are conducted on behalf of His Majesty's Government through the Foreign Office, it is to be presumed that that Department has now decided that the Congress is not of sufficient importance to warrant the attendance of an official representative. If this should be correct, it is, to say the least, unfortunate. At the last congress in Sweden, when Great Britain was officially present in the special circumstances of a member of the British Royal House being Royal Consort, all the principal governments in the world, including even China, were officially represented. Americanist studies, it is true, are not numerously represented in Great Britain, but British students of American archæology, few as they are, are universally recognised as being in the first rank. It would be interesting to know if the action of the Foreign Office in refusing an invitation to the only congress devoted to Americanist studies, and otherwise recognised by the whole world as of first-rate importance, was taken under advice, and, if so, what body was consulted.

AT the close of the International Congress of Geography at Cambridge, the delegates and others will pay a visit to the Borough of Newbury Museum on July 27. Members will stay in the town overnight and will be received at the Museum on the following morning. The visit takes place at a moment of importance in the history of the Museum. It has been decided to enlarge the premises as a memorial to the late Mr. Walter Money, the historian of Newbury, whose death at the age of ninety years took place last year. The Museum, in addition to the preservation of objects of local interest, aims at being educational on broad lines, and much use has been made by students of the archæological collections which, under the curatorship of Mr. H. J. E. Peake, have been arranged on the 'space for time' method. With the enlargement of the Museum, these collections will be extended to 3000 B.C. instead of 2400 B.C. as at present, with a prelude dealing with the Palæolithic age. For the enlargement a sum of £1200 is required immediately, for which an appeal has been made by the Mayor and Museums Committee. Subscriptions may be sent to the Mayor, Municipal Buildings, Newbury.

IN his Friday evening discourse, delivered on June 8 at the Royal Institution, on "The Waves of an Electron," Prof. G. P. Thomson stated that it now seems that the original view of the primitive elements of electricity and matter called electrons, which regarded them as small spheres, is inadequate to explain all the facts, and that an electron has associated with it a group of waves. This idea, originally due to L. de Broglie, has been tested experimentally by Davisson and Germer in the United States, and by Reid and Prof. G. P. Thomson himself in Great Britain. When electrons are scattered by atoms, it is found that if the atoms have a regular arrangement, as in a crystal, the scattered electrons are concentrated in definite directions and form a pattern, sometimes of considerable complexity. This is what would be expected if the electrons are guided and controlled by waves. In the case of scattering in metals the crystal structure of which is known, the pattern to be expected can be calculated and compared with the experiments. Prof. Thomson showed that there is complete agreement for all the metals which he has tested. In order to allow the electrons to get through the metals, very thin films of the latter are necessary, those used being less than a millionth of an inch thick. At this thickness metals are quite transparent to ordinary light. While the experiments prove the existence of the waves, their exact relation to the mass and electric charge of the electron remains mysterious.

THE Slaughter of Animals (Scotland) Bill, which is to be read in the House of Commons for the third time on June 22, provides for the training and licensing of slaughtermen in Scotland and for the use of humane-killers in that country on all animals except pigs, and those killed by the Jewish method or on farms. It is expected that the Meat Traders' Federation, which is opposed to any change in the existing methods of slaughtering, will seek to obtain the exclusion of sheep from the operation of the bill, on the plea that loss of time would be occasioned by the use of the instrument when these animals are being slaughtered at high speed. It has been calculated that time is worth about three-farthings per man per minute under the normal conditions of working in Edinburgh. The humane-killer is simpler to handle than, for example, a Lewis gun, which can be positioned, mounted, and loaded by recruits in 9 seconds, so the time lost per sheep should be considerably less than a minute of one man's time. An average dressed carcase of mutton weighs about 60 lb., and about 18 lb. of home-killed mutton was consumed per head of the population in 1922, so that the loss of time due to humane killing would be worth about a farthing per annum per head of the population.

IN 1926 the Ministry of Agriculture issued an Order prohibiting the use in Great Britain of arsenical dips for the second of the two statutory 'dippings' for sheep scab where a dip of that character had been used for the first dipping. This Order was made because of complaints that serious losses had been sustained by farmers where, as is essential for sheep scab, the second dipping had been carried out within 14 days of the first dipping. Since that Order was made the Ministry has received representations from farmers in Wales and other parts of Great Britain urging that they should be allowed their former discretion in the choice of an approved dip, so that they might use an arsenical dip for both dippings where desired, and the National Farmers' Union of England and Wales, in support of these representations, has informed the Ministry that a guarantee against loss has been obtained from the manufacturers of the bulk of the arsenical dip used in Great Britain. The Ministry is therefore satisfied that it can now properly remove its prohibition on the use of an arsenical dip for both dippings. There are some 306 approved sheep dips, of which 222 are non-arsenical; an owner has therefore a wide range of choice, and there is no compulsion upon him to use an arsenical dip if he does not wish to do so.

FELSTED School is to be congratulated on the success and enthusiasm of its scientific society. Surely few such societies can boast a half-century of useful work, for in 1877, when the Felsted School Scientific Society was founded, nature study and science courses were still in embryo, and of England's present total of 428 museums only 84 were in existence. The thirtieth *Report* of the Society indicates continued liveliness. A generous donor has presented an observatory, a 4¼-inch equatorial telescope, a 3¼-inch transit instrument, and an altazimuth, and an astronomical section has been created. Two new dark rooms for photography have been formed, and that good work is being done is shown by the excellent natural history pictures which illustrate the report, and by the descriptions of the use of bird-watching 'hides.' The majority of the papers read before the sections were by the boys themselves, and that is as it should be.

THE Zoological Society of Scotland had the misfortune to open its zoological park in Edinburgh just before the War, and as a consequence its survival value was put to a severe test. The *Annual Report* for the year ending March 31, 1928, shows that the test has been safely passed and that the Society is now assured of complete success. The surplus of revenue over expenditure for the year was £3445, as against £735 last year, and this sum has been used in paying off the debt upon a Reptile House and Tropical Bird House, while a sum of more than £10,000 has been raised for the development of the Park and the bringing in of the new ground to the crest of Corstorphine Hill. The Scottish Zoological Park is outstanding on account of the natural beauty of its site, and the extensions foreshadowed in the report promise to add greatly to its amenity, since a track for a service of small motor conveyances is being laid to the top of the hill, which overlooks the Firth of Forth, and fine masses and ledges of weathered rock afford ideal places for the construction of natural enclosures. The Carnegie Aquarium, erected at a cost of more than £20,000, and designed on the most modern lines, was opened in July, and has proved to be a great attraction. Amongst the most interesting of the births in the Park was a Californian sea-lion and a king penguin, the fourth of its kind to have been successfully reared. During the year 346,452 individuals visited the Park. The report contains a number of photographs, which show the attractiveness of the enclosures and their inmates.

PRESIDENT THOMAS S. BAKER, of the Carnegie Institute of Technology, who recently visited Europe in connexion with the forthcoming second International Conference on Bituminous Coal to be held at Pittsburgh on Nov. 19–24 (concerning which a preliminary announcement appeared in NATURE on Mar. 3), has already received tentative acceptances from some seventy engineers and other prominent scientific men from twelve countries, to attend or present papers to the conference. The list contains such well-known names as Dr. F. Bergius, Prof. W. A. Bone, Dr. G. Egloff, Prof. F. Hofmann, Dr. A. D. Little, Prof. A. Mailhe, Sir Alfred Mond, Prof. S. W. Parr, and Prof. H. S. Taylor. Scientific workers of all countries who may wish to take part in the congress are requested to notify the secretary, Prof. S. B. Ely, Carnegie Institute of Technology, Schenley Park, Pittsburgh, U.S.A., as soon as possible, and foreign delegates desiring to avail themselves of the opportunity to visit industrial plants in the United States of America are invited to make known their wishes. As has already been announced, the programme will include the discussion of low temperature distillation, high temperature distillation, coal tar products, power, smokeless fuel, complete gasification of coal, hydrogenation, pulverised fuel and its new applications, fixation of nitrogen, coal beneficiation, and cognate matters. The purpose of the congress is similar to that of the first congress held in 1926, namely, to present the results of recent studies of coal that have to do with improved methods of utilisation and combustion.

THE *Annual Report and Proceedings of the South-Western Naturalists' Union*—a record up to Dec. 31 last—shows a membership of 70 members, 16 societies, and one institution. Considering the large area covered, this seems small, as very good work has already been done by individual members of the Union since its foundation on Nov. 25, 1922, and the annual conferences offer exceptional opportunities for the meeting together of all concerned. The president for both 1927 and 1928 is Dr. G. P. Bidder; the vice-presidents for 1928 are Prof. C. Lloyd Morgan and Dr. E. J. Allen. Dr. Bidder's presidential address at the fifth annual conference held at Exeter last year on "Some Sponges of the South-West Coast" is contained in the present report. In this interesting survey he describes the common sponges of Britain and suggests a classification based on that given at the Leeds meeting last year of the British Association. His presidential address for this year, delivered at the sixth annual conference, held at Bristol on May 25–28, dealt with "The Relationship to each other of the Various Groups of Animals." The *Proceedings* also contain short sectional reports, a lecture by Mr. C. W. Bracken on "Insect Casuals and Migrants," and concludes with three short papers on Lundy Island. This Union is as yet in its infancy. It was founded in order to bring local naturalists together, that real team work might be done in all branches. A scheme for organising the work was planned, and sections established with recorders and referees chosen from the leading authorities on the various subjects. There is an annual conference, lectures are given and excursions arranged. A glance at the names of the officers for both past and present years, and also of the lecturers, should be a guarantee of efficiency, and it is to be hoped that the Union will enlarge its membership and produce still more good work in the future.

THE second conversazione this year of the Royal Society will be held in the rooms of the Society on Wednesday, June 20, at 8.30 P.M.

THE following have been nominated by the Council of the Institution of Electrical Engineers for the vacancies which will occur in various offices on Sept. 30 next: *President*, Lieut.-Col. K. Edgcumbe; *Vice-Presidents*, Mr. P. V. Hunter and Dr. A. H. Railing; *Honorary Treasurer*, Lieut.-Col. F. A. Cortez Leigh.

THE Right Hon. Sir Alfred Mond, president of the British Science Guild, will take the chair at the annual general meeting of the Guild, to be held in the hall of the Royal Society of Arts, John Street, Adelphi, W.C.2, on Thursday, June 21, at 5 P.M. The annual report of the Guild for the year 1927–28 will be presented at this meeting, which will be open to the public.

PROF. A. W. PORTER, who has been associated with the Physics Department at University College, London, since 1892, is retiring from the chair of physics at the end of this term. Prof. Porter is one of the founder members of University College Mathematical and Physical Society, of which he has several times been president, and the past and present members of the Society are entertaining him at dinner in the College on Monday, June 25, at 7.30 P.M.

MANY readers of NATURE are familiar with the pioneer work carried out by the late Mr. W. H. Dines in investigations of the upper air and other aspects of meteorological science. As a memorial to Mr. Dines, the Royal Meteorological Society has taken steps to establish a fund to be employed to assist and encourage the advancement of meteorological knowledge, especially along the lines which he did so much to create and foster. Contributions to this Dines Memorial Fund are invited by the Society and should be sent to the assistant secretary, 49 Cromwell Road, South Kensington, S.W.7. We hope that the appeal will meet with a generous response, so that the fund raised may provide a worthy memorial of a great meteorologist.

AT the annual meeting of the British Association to be held in Glasgow on Sept. 5-12, Sir William Bragg, who succeeds Sir Arthur Keith as president, will deliver an address on the subject of "Craftsmanship and Science" at the inaugural general meeting in St. Andrew's Hall. Dame Helen Gwynne-Vaughan, professor of botany at Birkbeck College, London, has accepted the office of president of Section K (Botany) of the Association, and will address the section on the subject of "Sex and Nutrition in the Fungi." Prof. R. H. Yapp was originally elected president of the section, but resigned when he found he was unable to attend the meeting.

THE spring issue of *The Fight against Disease*, the quarterly journal of the Research Defence Society, contains a portrait of its late treasurer, Sir David Ferrier, and an address delivered by Lady Briscoe on "Animal Experimentation and Knowledge," which gives a useful summary of the value of experiments upon animals in advancing our knowledge, prevention, and cure of disease. The annual general meeting of the Society will be held at 11 Chandos Street, W.1, on June 19, at 3 P.M., when Sir Bernard Spilsbury will deliver the Stephen Paget memorial lecture.

THE annual summer meeting of the London Students' Section of the Institution of Electrical Engineers will be held in Holland and western Germany. The party will leave London on Saturday evening, July 28, for Rotterdam, where two days will be spent. Visits have been arranged to works at Rotterdam, Eindhoven, and Utrecht, and a pleasure trip to The Hague. In Germany visits have been arranged to works of engineering interest at Essen, Dusseldorf, and Cologne. The party will return from Cologne on the evening of Aug. 6.

THE council of the Royal Society of Edinburgh has awarded the Keith Prize for the period 1925–27 to be divided equally between Prof. T. J. Jehu and Mr. R. M. Craig for the joint series of papers which have recently appeared in the publications of the Society on the geology of the Outer Hebrides, and the Neill Prize (1925–27) to Prof. Arthur Robinson, professor of anatomy in the University of Edinburgh, for his contributions to comparative anatomy and embryology. The Bruce Prize for the period 1926–28 has been awarded by the joint committee consisting of representatives from the Royal Physical Society, the Royal Scottish Geographical Society, and the Royal Society of Edinburgh, to Prof. Dr. H. U. Sverdrup, of the Geophysical Institute, Bergen, for his contributions to the knowledge of the meteorology, magnetism, and tides of the Arctic, as an outcome of his travels with the Norwegian Expedition in the *Maud* from 1918 to 1925.

THE Council of the Royal Statistical Society is this year again awarding the Frances Wood Memorial Prize, value £30, for the best investigation, on statistical lines, of any problem affecting the economic or social conditions of the wage-earning classes. Competitors must generally be undergraduates, or graduates of not more than three years' standing, of a university of Great Britain or Ireland, and less than thirty years of age on Oct. 31 next. Theses submitted or intended to be submitted as university exercises, and also published papers, are admissible. Essays must be sent to the honorary secretaries of the Royal Statistical Society, 9 Adelphi Terrace, W.C.2, not later than Oct. 31 next.

THE Booth Steamship Co., Ltd., has arranged a summer cruise to the South American continent of unusual interest. The Booth liner *Hildebrand*, starting from Liverpool, touches the Portuguese Riviera and Madeira, and then crosses the Atlantic to the mouth of the Amazon, up which the liner goes about 1000 miles. The cruise lasts six weeks, during which 11,800 miles are covered. It is stated that the trip costs little more than an equal period of time in a good European hotel.

A GENERAL discussion on "Homogeneous Catalysis" will be held by the Faraday Society in the physical chemistry laboratory of the University of Cambridge, on Friday and Saturday, Sept. 28 and 29, under the chairmanship of Prof. C. H. Desch. The subject will be discussed under the following principal headings: (1) Uncatalysed homogeneous reactions and negative catalysis; (2) intermediate addition-compounds in homogeneous catalysis; (3) neutral salt and activity effects in homogeneous catalysis; (4) ionisation as a factor in homogeneous catalysis. A number of foreign guests have been invited by the Society to take part in this discussion. Members and visitors will be accommodated at Pembroke College during the period of the visit. Particulars can be obtained from the secretary of the Faraday Society, 13 South Square, Gray's Inn, W.C.2.

THE Report of the Bristol Museum and Art Gallery Committee for 1926–27 mentions that about 800 examples of living wild plants were exhibited during the year, and continues: "It is a matter for regret that so greatly has wild plant life been destroyed by building and other agencies in the neighbourhood of the City in the post-War years, that the area of collecting has had to be increased over a wider two-mile belt around the City." The report bears witness to much good work in all branches of museum activity except perhaps research; this may be because the labours of the staff are bent towards preparing for a move into the extension now being built.

A NEW part (No. 811) of "Sotheran's Price Current of Literature" has just been issued, and is as interesting and valuable as previous issues. The catalogue is always a mine of bibliographic wealth and should be of great help to collectors of rare editions and to librarians. The present part contains particulars of upwards of 3000 works of science classified under the headings of general and collected works, mathematics, astronomy, physics, meteorology and physical geography, geology, mineralogy and crystallography, chemistry, and rare and valuable books. Copies can be obtained from H. Sotheran and Co., 140 Strand, W.C.2.

Applications are invited for the following appointments, on or before the dates mentioned :—A demonstrator of chemistry at St. Bartholomew's Medical College—The Dean, St. Bartholomew's Hospital Medical College, E.C.1 (June 19). An assistant in the Intelligence Section of the Mineral Resources Department of the Imperial Institute—The Secretary, Imperial Institute, South Kensington, S.W.7 (June 20). An assistant lecturer in mathematics at King's College, London—The Secretary, King's College, Strand, W.C.2 (June 22). An assistant pathological chemist at St. Mary's Hospital, Paddington—The Secretary, St. Mary's Hospital, Paddington, W.2 (June 25). An agricultural economist and a lecturer in agricultural engineering at the Edinburgh and East of Scotland College of Agriculture—Mr. Thomas Blackburn, 13 George Square, Edinburgh (June 25). A woman assistant lecturer in botany in the Department of Education of the University of Birmingham—The Secretary, The University, Birmingham (June 26). A lecturer in electrical and mechanical engineering at the Forest of Dean Mining School, Cinderford—The Secretary, County Education Office, Shire Hall, Gloucester (June 27). A lecturer and demonstrator in the pharmacy department of the Birmingham Central Technical College—The Principal, Central Technical College, Suffolk Street, Birmingham (June 30). An assistant lecturer in the Mathematics Department of the Belfast Municipal College of Technology—The Principal, Municipal College of Technology, Belfast (June 30). A demonstrator of biology at Guy's Hospital Medical School—The Dean, Guy's Hospital Medical School, London Bridge, S.E.1 (July 3.) An assistant lecturer in agricultural chemistry at the University of Leeds—The Registrar, The University, Leeds (July 7). A psychiatrist and medical director, a psychologist and an assistant psychologist under The Child Guidance Council—The Secretary, Child Guidance Council, 24 Buckingham Palace Road, S.W.1. An advisory bacteriologist at the Midland Agricultural and Dairy College—T. Milburn, Sutton Bonington, Loughborough. An assistant mistress at the County School for Girls, Beckenham, with qualifications in either botany or chemistry—The Head Mistress, County School for Girls, Beckenham. A science teacher at the Technical School, Lurgan—The Principal, Technical School, Lurgan, Co. Armagh.

Our Astronomical Column.

Nova Pictoris.—Dr. H. Spencer Jones, H.M. Astronomer at the Cape, gave some interesting information about this object at the meeting of the Royal Astronomical Society on June 8. It appears as an oval nebulosity the major axis of which, lying approximately east and west, is about 1¼″ in length; within this there are four nuclei. The relative positions of the nuclei may be indicated by drawing an equilateral triangle with its base upwards; the nuclei are, (1) at the centre of gravity (this is the brightest), (2) at the lower angular point (this is the faintest), and (3) and (4) slightly below the two upper angular points. The three brighter ones could generally be seen, the faintest one only when definition was very good. The sketch that was shown indicated that these nuclei appeared somewhat nebulous.

Dr. Spencer Jones agrees with the Greenwich astronomers in thinking that the large nebulous rings (some 3′ in diameter) surrounding the star are not objective, but are optical phenomena due to the star's light having a different mean wave-length from the average star. Hence no weight can be given to values of the star's parallax deduced from them.

It is fortunate that owing to its position near the pole of the ecliptic, it is possible to observe the star at some time of the night throughout the year. Its behaviour has been in many respects unique among the novæ, and its further development is likely to give valuable information.

Planetary Photography.—Prof. W. H. Wright chose this as his subject for the George Darwin lecture which he delivered at the meeting of the Royal Astronomical Society on June 8. Numerous photographs were shown of Venus, Mars, Jupiter, and Saturn in light of various wave-lengths from infra-red to ultra-violet. The photographs of Mars were the only ones that showed far more surface detail in the long than in the short wave-lengths. The well-known outlines of the so-called seas appeared with very strong contrast in the infra-red photographs, but were practically invisible in the ultra-violet ones, showing that the Martian atmosphere, like our own, exerts considerable absorptive action on the shorter waves, so that the photographs in these show atmospheric detail, but nothing on the surface. On the other hand, the photographs of Venus in short wave-lengths show fairly distinct markings, which were found to vary from day to day, thus giving hope that they may teach something about the planet's rotation; while the infra-red photographs were completely featureless. It may be that these do not penetrate to the actual surface, but only reach a lower cloud layer.

The Jupiter photographs, while not identical in the different colours, do not differ so widely as those of Mars. Very great interest was excited by some remarkable cinematograph films of Jupiter. These were exposed at intervals of minutes, but run through the lantern so quickly that the planet was seen in rapid rotation, its entire surface being rendered visible. The films included the transit of a satellite and its shadow across the disc. The satellite could be traced for part of its course and then became invisible. The film, like those taken during the eclipse of last June, shows the possibility of astronomical applications of the cinema, not merely for popular exhibitions, but for serious scientific work.

Discovery of Minor Planets.—*Astr. Nach.*, No. 5559, contains the annual article from the Berlin Rechen Institut on the discovery of minor planets during the year. There were 112 planets found in the twelve months ended June 30, 1927; only 103 were really new, the others being identified with planets that had been missing for some years. Unfortunately 58 of the new planets were only observed once; thus nothing could be deduced about their orbits. Sixteen planets were observed sufficiently to deduce trustworthy orbits; to these were assigned the numbers 1058 to 1072, also the number 933; it was found that the planet previously numbered 933 was really 715, Transvaalia. The highest inclination of the new planets is 17° (planet 1070), the highest angle of eccentricity is also 17° (planet 1065). Five planets lately discovered have been named Bodea, Zachia, Piazzia, Gaussia, Olbersia, commemorating the names of astronomers concerned in the search for the first minor planets.

Research Items.

GYPSY MARRIAGE.—Mr. T. W. Thompson, in a continuation of his study of gypsy marriage in England, in pt. 4 of vol. 6, Ser. 3, of the *Journal of the Gypsy Lore Society*, deals principally with the question of permanence and divorce. A number of temporary unions are recorded. These lasted for varying periods from a few days or weeks to six months, a year, or even two years. In effect, these seem to have been trial marriages; though the Heron family seems to have been peculiar in this respect and deliberately to have taken their wives on trial, which as a premeditated act can be paralleled in a few cases only in other families. It is suggested, however, that this postponement of the marriage rite may have been a survival of the practice among German gypsies whereby marriages were not ratified by the Hauptmann until they had been in force for two years, during which period the bridegroom had to serve his father-in-law. There is no evidence that service in return for a bride ever existed in England. Marital fidelity after a settled marriage seems to have been more or less the rule, at any rate among the women. Some, however, had a regular succession of lovers or husbands. Among the men the patrilineal Herons claimed to have the right to occasional intimacy with gypsy women, though allowing their wives no liberties. Unfaithful wives were punished by stripping naked, when they were sometimes tied up and whipped or chased round a field; mutilation, such as nose slitting or cutting off an ear, was sometimes practised. Among English gypsies divorce was purely informal; but the Scottish gypsies parted with a good deal of ceremony. A century ago the woman received a token made of cast iron with a mark on it resembling the character T, and she was never permitted to marry again. If she did she was liable to the extreme penalty; she was tied to a stake with an iron chain and beaten to death.

QUATERNARY HUMAN SKELETONS FROM THE VALLÉE DU ROC, CHARENTE.—In the *Bull. et Mém. de la Soc. d'Anthropologie de Paris*, T. 8, Sér. 7, fasc. 1-3, Dr. Henri Martin describes three skeletons from a rock shelter in the Vallée du Roc. The remains were found buried under blocks of fallen stone, by the weight of which they had been much damaged. They belonged to three individuals, possibly the members of one family, a man of about fifty years of age, a woman of about forty, and a boy, probably of about eighteen, in view of the fact that the first wisdom tooth had not yet fully erupted. The remains had evidently been buried and the fall of rock was posthumous. The point of greatest interest in the skeletal remains lay in certain resemblances to Chancelade man as described by Testut. This was manifested in the cephalic index of the man, 72·8, as compared with Chancelade, 72·02, as well as in the scaphocephalic character of the skull of both male and female. Yet notwithstanding the keel-like ridge, both skulls were comparatively low. The supraciliary ridges were well marked. The cephalic index of the woman was 76. The skulls bear no resemblance to neolithic skulls, but are comparable rather with those of Brunn, Cro-magnon (female), and Laugerie Basse, but, as stated, particularly of Chancelade. The cranial capacity is approximately 1350 cm. (female) and 1525 cm. (male). The teeth are large and well formed, the third molar being smaller than the second, which is contrary to the state found in Neanderthal man. The wearing of the teeth shows a lateral bite. There are signs of caries in the man. The remains were found immediately above a Solutrean layer among signs of numerous hearths, and it is suggested that they belong to late Solutrean or the beginning of the Magdalenian period.

CAPROKOL.—We have received from the British Drug Houses, Ltd., London, N.1, a small booklet on Caprokol therapy. Caprokol (or hexyl resorcinol) is used both as a urinary antiseptic by internal administration and also as a general antiseptic by external application, including the cleaning of mucous surfaces. Its use as a general antiseptic has recently been referred to in our columns. Caprokol was introduced as a urinary antiseptic about three years ago, and considerable clinical evidence has now accumulated as to its value in various infections of the urinary tract. In doses of 1-2 gm. daily it clears up cystitis, pyelitis, or urethritis caused by staphylococci, streptococci, gonococci, or *B. coli*. In cases of infection with the latter organism it is advisable to give local treatment also in the early stages. To ensure complete and permanent sterility of the urine, prolonged treatment is sometimes necessary: an immediate effect, however, of the administration of the drug is the cessation of pain and relief from the frequency of micturition which so often accompanies urinary tract infections. The drug's antiseptic action is enhanced by its power of lowering the surface tension of the urine: fluids or alkalis which raise the surface tension should not be given at the same time as Caprokol. The evidence suggests that this compound has a definite use in practical therapeutics.

ATTITUDE OF EMPLOYEES TO INDUSTRIAL PSYCHOLOGY.—In the *Journal of the National Institute of Industrial Psychology* (vol. 4, No. 2) there is an interesting discussion on the attitude of employees to investigations of a psychological nature. It is obvious that no investigation can succeed without the co-operation and goodwill of the workers concerned, and it is equally obvious that workers are quite likely to view with suspicion strangers who come and observe them at work, who suggest alterations in long-established habits, and seem to take up a new attitude to problems. Mr. A. Stephenson points out that the present attitude of the workers towards investigations depends very largely on their attitude to the investigator and on local traditions and temperament, unless political convictions are so strong as to exclude all other considerations. In some industries where there is fear of dismissal it is sometimes very difficult to get rid of the impression that any worker who is being observed must necessarily be inefficient. Older workers are sometimes intolerant of innovations, and tend to consider that twenty years' experience must be worth more than any instruction. Where changes in the firm's policy are imminent and of a kind distrusted by the worker, then an investigator may be regarded as a spy: Mr. Stephenson said that such difficulties can usually be resolved by holding a conference and explaining clearly the objects of industrial psychology. On the whole though, workers prove to be interested in, or at least tolerant of, such investigations, and when one considers their novelty one is surprised at the willing help afforded in so many cases.

MARMOT PLAGUE IN UNITED STATES.—There has been a remarkable increase in recent years in the numbers and extent of the range of the eastern woodchuck (*Marmota monax*), a native of the States east of the Great Plains and north of northern Arkansas, Alabama, and North Carolina. Where these rodents confine their activities to their accustomed haunts on rocky hillsides, thickets, or forest land, no harm results, but their extension of range has led them to transgress on cultivated land, and corn and forage crops, young fruit trees, and poultry have suffered. It is even recorded that disastrous flooding of crops and erosion of soil has followed upon their burrowing in levee and ditch banks. The U.S. Department of Agriculture (*Leaflet 21*) states that the surest practicable method of controlling the pest is gassing the woodchucks in their burrows, and recommends the use of carbon disulphide, calcium cyanide, or exhaust gases from a motor car. No individual effort, however, can afford any but a temporary success, and co-operation over a large area is essential for effective control. The leaflet states that the factors contributing to this recent general increase are not fully known, but curiously enough it says nothing about protecting and encouraging the wild creatures, birds and beasts, which are the natural controllers of such ground rodents.

The Insects of Samoa.—Two further fascicles of "Insects of Samoa," a work in course of publication by the British Museum (Natural History), have recently come to hand. Part 4, Fasc. 2, deals with a number of families of Coleoptera, and Part 5, Fasc. 1, with aculeate Hymenoptera. The several accounts are written by specialists well known as authorities in the groups concerned, and should prove specially valuable in connexion with distribution, modification due to isolation and other problems of island life. Certain of the species described or listed are peculiar to the Samoan group: others, such as the beetles *Gnathocerus* and *Tribolium*, are cosmopolitan, while some other insects appear to be limited to certain of the Pacific Islands or extend into the continental tropics. The longicorn beetles are of exceptional interest, since each of the Samoan islands seems to possess endemic species, and four genera are unknown outside the archipelago.

Spermatogenesis in Spiders.—Dr. E. Warren contributes to the *Annals of the Natal Museum* (vol. 6, Part 1, March 1928) an important paper on the comparative histology of the testis of South African spiders, in which special attention has been directed to the nuclear divisions. The nuclei of the young genital cords of the embryo are capable of dividing by amitosis, and in the testis the germinal nuclei at the margin can divide without mitosis, and the spermatogonia can also divide amitotically to form primary spermatocytes, though in some spiders occasional mitoses were present. In some spiders the primary spermatocytes divide without mitosis to form secondary spermatocytes and spermatids, and chromatin structures indistinguishable from spermatozoa are formed in cells which have originated either without mitosis at all or without the full complement of mitotic divisions characteristic of typical spermatogenesis. In many species there are two kinds of sperms originating in different lobules of the testis. The presence of typical spermatogenesis in many spiders indicates that the various atypical methods which have been observed are to be regarded as simplifications of the typical process rather than as something fundamentally new or as a survival of primitive methods. The occurrence of amitosis is too general to be explained as an abnormality resulting from the temporary absence of the correct stimulus for the normal development of the spermatozoa. "The truly remarkable diversity which is seen in the chromatin behaviour of the genital cells of allied spiders is not in accord with the view that heredity depends on a system of material genes lodged in specific chromosomes and bodily passed on as a complete system from one generation to another." In most spiders the spermatozoa in the vesiculæ seminales become enclosed in capsules, and in some species the chromatin of the encapsuled spermatozoon may divide into pieces or may even be transformed into a resting nucleus.

A New Family of Turbellaria.—N. Nasonov describes in the *Bulletin de l'Académie des Sciences*, Leningrad (1927, No. 9-11, pp. 865-874), a new family Multipeniatidæ of the Turbellaria Allœocœla. The animals were discovered in the mouth of the River Maiche, which flows into Ussuri Bay, Sea of Japan. The representatives of the new family, two species of the same genus (*Multipeniata batalansæ* and *M. kho*), differ greatly from members of other families of Allœocœla, especially in the remarkable structure of the male genital apparatus, since they possess several copulatory organs in different stages of development. A fully developed copulatory organ is a closed system isolated from testes and from glands; when it fulfils its function, it is replaced by the next one when this reaches its full development, and so on.

Non-Marine Mollusca of Buru.—The non-marine molluscan fauna of the island of Buru has never been thoroughly investigated, and only scattered notes exist. Mr. Toxopeus has, however, visited a limited portion of the island for something less than a year, and the result of his collection of mollusca is now reported on by Dr. T. van Benthem Jutting (*Treubia*, vol. 7, suppl.). Omitting varieties and unidentified forms, the number of species amounts to 50, only 6 being described as new, while 18 are reported for the first time. There are two excellent plates and a number of rather rough, but effective, text illustrations, including distribution maps of the genera *Isidora*, *Physastra* and *Ameria*. A list of species formerly reported from the island but not found by Mr. Toxopeus is given, with references to the places of their description.

Iron Ores of South Africa.—While on the staff of the Geological Survey of South Africa, Dr. P. A. Wagner contributed liberally to geological literature of the type that is of far more than local interest, and since his resignation he has prepared for publication still another memoir of outstanding importance, dealing on this occasion with "The Iron Deposits of the Union of South Africa" (*G. S. S. Africa, Mem. 26*, 1928). The types of ores considered include magmatic segregations; contact metasomatic deposits; lode and vein deposits; banded ironstones of the characteristic pre-Cambrian type; bedded ores of various ages; replacement and metamorphosed deposits, including those of the Lake Superior type; and laterites and other surface ironstones. Each chapter contains a wealth of observational data and critical comment—stratigraphical, petrological, chemical, and economic. South Africa possesses the most extensive titaniferous ores in the world, but apart from these her known reserves are exceeded only by those of India, the United States, Brazil, and France. As there are also associated resources on an ample scale of coking coal, limestone, dolomite, manganese, and fluor spar, the production of iron and steel should in the future prove to be a factor of prime importance in the economic development of the Union.

Geological History of Tasmania.—A stimulating account of this critical region of Gondwanaland, by A. N. Lewis, has recently appeared in the *Proc. Roy. Soc. Tasmania* for 1926 (pp. 1-24; 1927), with special reference to the relation of the existing topography to the Triassic dolerite intrusions and the major block-faulting. Mr. Lewis considers that after the intrusions the old land surface was reduced to a peneplain, and that the present surface features have been moulded on variously uplifted blocks of country, the faulting and elevation responsible for these being of Tertiary age, probably late Miocene or early Pliocene, about which time there were at least two phases of volcanic activity. A discussion of the paper by P. B. Nye and others, with a reply from Mr. Lewis, appears in the same *Proceedings* for 1927 (pp. 67-77; 1928). Mr. Nye contends that the present physiography dates from the time of the dolerite intrusions, while Mr. Lewis retorts that if this had been so Tasmania would long ago have been reduced to a most mature peneplain. He thinks it inconceivable that 200 million years of denudation could still have left conspicuous dolerite-capped hills if the latter had been finally elevated at the time of intrusion. Apart from this controversy, the paper and discussion are valuable as a contribution to our growing knowledge of the great dolerite intrusions of the Mesozoic era.

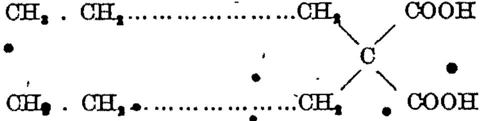
FIELD CURRENTS FROM POINTS.—A paper in the May number of the *Physical Review*, by Prof. Millikan and Messrs. Eyring and Mackeown, on the extraction of electrons from cold, negatively charged points by strong electric fields, is of particular interest in view of recent theoretical investigations of the problem on the basis of the new mechanics. The data which are presented show conclusively that a detectable current is first obtained for a definite strength of the field at the surface of the metal, irrespective of the applied potential and the disposition of the electrodes. The critical field is about the same for a tungsten point as for a tungsten wire, but it is greater for platinum than for tungsten. The importance of the field as variable rather than the potential was shown very clearly with a steel point and plane discharging system. The electric fields used are enormously high, thirty-five million volts per centimetre being attained in one instance.

INTERNATIONAL WEIGHTS AND MEASURES.—The *Proceedings of the International Bureau of Weights and Measures* for the year 1927 show that the question of the gas thermometer scale is to be considered, and that Prof. Keesom and Mr. Tuyn, of Leyden, have been asked to draw up a report on the subject. The various copies of the standard metre have been examined as to their expansion with increase of temperature, but there is a slight difference between the results obtained by the two methods used which has not yet been explained. The standards made at the same time have the same expansion, and the new quartz standards agree very closely with each other. The fine lines which mark the length of the standard are shown in the *Proceedings*, magnified 500 diameters, and it is noticeable how much finer the lines on the newer standards are than on the old. Several of the quartz standard kilograms having decreased in weight by 0·1 milligram in three years after being heated, observations have been made on a platinum kilogram submitted to a current of air at 100° C. for thirteen months, but no change in its weight could be detected. The proposal to make the British yard and the United States yard identical was withdrawn.

LONGITUDINAL STABILITY IN AEROPLANES.—An interesting new presentation of aeroplane stability analysis, in practical form, is contained in a publication of the Aeronautical Research Committee by S. B. Gates, on "A Survey of Longitudinal Stability below the Stall, with an Abstract for Designers' Use" (*R. and M.*, No. 1118. London: H.M. Stationery Office, 1928. 1*s*. 3*d*.). The paper develops in terms of new units, in which the resistance derivatives are expressed as non-dimensional quantities, a more compact analysis of longitudinal stability below stalling than has hitherto been attempted, and throws it into a form to bring it immediately within the scope of designers. The description is in terms of the two quantities, in practice at the disposal of the designer, position of centre of gravity and size of tail. With these co-ordinates the region of longitudinal stability is defined on a series of plane diagrams, and in typical cases curves have been filled in from which the damping and period of the phugoid motion may be estimated.

THE STRUCTURE OF A DETERMINANT.—In his lecture on the Rouse Ball Foundation at Cambridge in 1927, Major P. A. MacMahon gave an account of some recent developments in the theory and structure of determinants. A worker in this field is fortunate in having, in the four volumes of Muir's "History of the Theory of Determinants," a classified summary of the progress of the subject from 1693 until 1900. No important discovery has escaped the notice of Muir, who has spared no pains in mastering the great variety of notations employed at different times. During the last few years, two important advances have been made in the theory of the structure of a determinant. In the first place, various connexions have been established with symmetric functions appertaining to such algebras as that of hyper-determinants. Again, a certain algebraical expression, brought into prominence by Muir and named by him a 'permanent,' has been found to be a corner-stone in the algebraic theory. Both advances, which proceed hand-in-hand, are linked in a remarkable way with MacMahon's own work on the partitions of numbers. As yet the connexion with symmetric functions, arising from the new outlook, is but in its infancy. The study of the symmetric function of the umbral algebras, of which determinants are particular cases, is only just broached. Major MacMahon's very stimulating lecture is printed *in extenso* in *Jour. London Math. Soc.*, vol. 2.

THE STRUCTURE OF LONG CHAIN COMPOUNDS.—The *Proceedings of the Royal Society of Edinburgh*, vol. 48, Part I., contains an account of a further X-ray investigation by E. Henderson of a number of normal saturated dicarboxylic acids. Between the odd and even members of this series there is a definite alternation in physical properties, and this difference is also apparent in the crystal structures. The work has been extended to mono- and di-alkyl malonic acids with interesting results. The structure attributed to dioctadecyl malonic acid indicates that in acids of this type the two long hydrocarbon chains lie approximately parallel to one another, thus:



CH₃ . CH₂......................CH₂
COOH
C
CH₃ . CH₂......................CH₂
COOH

It has previously been observed that long chain compounds terminating in an incompletely saturated group form bimolecular layers in the crystal, the molecules of one layer being oppositely orientated to those in the other. Results now obtained with fatty acid amides confirm the view that the formation of these bimolecular layers is due to the presence of the incompletely saturated group in the molecule. In the malonic acids these bimolecular layers are not observed, and it appears, therefore, that the two carboxyl groups mutually satisfy their residual affinity.

Ancient Greek Physical Types.

AT a meeting of the Royal Anthropological Institute on Tuesday, May 22, the president, Prof. J. L. Myres, read a paper on ancient Greek physical types. He said that though the number of ancient skeletons from Greek sites is still small, evidence already published, especially by Duckworth and Hawes, is sufficient to show that at the beginning of the Bronze Age the population of Crete and the Cycladic Islands was already a mixed one. Both the chief ingredients, 'Mediterranean' and 'Armenoid,' can be traced in separate occupation of certain islands, and where there is mixture of breeds, the proportions of these ingredients vary, both locally and from period to period. Single skulls of neolithic period, from Lycia, Crete, and Leucas, are alike broad-headed. It is, however, only in the early part of the Bronze Age that evidence becomes more copious. In Crete, the proportion of Armenoids begins at about 10 per cent; falls somewhat in the Middle Minoan Age, as though this continental type were being absorbed in the insular; then rises to 46 per cent in the Late Minoan Age, indicating fresh intruders from adjacent mainlands. It is not at present possible, however, to distinguish arrivals from Greece and from Asia Minor.

So early as the 'third city' on the site of Troy (about 2000–1900 B.C.), there is direct evidence of the presence of a northern type, confirming inferences from the distribution of tumulus-burials south of the Lower Danube at a period when tumulus-burying people were spreading from east of the Dnieper into Central Europe. Probably these people were blond, like their descendants farther north; but direct evidence for colour only becomes available at all quite late in the Bronze Age. Blondness, however, is not confined to pure 'northern' strains, but is shared by many mixed breeds in Central and Eastern Europe, which are more or less broad-headed; and there was probably a larger element of relatively fair, and especially of ruddy or auburn-haired people in classical Greece than could be inferred from the prevalent head-forms.

To supplement the scanty records of human remains, ancient representations of bald men are of value; and also the representations of satyrs, giants, centaurs, and low-class individuals, as evidence for the persistence of a 'backwood' type with snub-nose, wrinkled forehead, heavy brow-ridges, and low forehead. This is quite distinct from the markedly Armenoid appearance of Thersites in the "Iliad." That it was a real type and widespread, is shown by the portraits of Socrates, and Egyptian representations of Asiatic captives in the thirteenth century. Other valuable features are the distinct types of beard, Mediterranean and Armenoid, in Greek portraiture and vase-paintings; and the varying proportions of the whole body, indicating co-existence of a slight-built and a thick-set type.

Literary evidence for colour of hair and eyes is supplemented, though scantily, by archæological. The blond and ruddy complexions already mentioned are not to be ascribed solely to the 'coming of the Dorians' in the twelfth century, for they are recognisable rarely so far back as the fourteenth, and characterised the greater heroes of the Trojan War period, in the thirteenth and twelfth. In general, it is inferred that the 'Greek type,' like the Greek people generally, was in process of determination whenever the Ægean was temporarily secluded from invasions; then local conditions, which are peculiar and austere, operated to eliminate the less acclimatisable breeds. The well-marked varieties which are now to be observed in the more remote districts, and especially in some of the islands, show that this process has been going on since the great period of open intercourse in later classical times. The results of this are displayed in Græco-Egyptian mummy-portraits, and in Byzantine mosaics and frescoes.

Durham Castle.

THE conclusions reported by Prof. Arthur Holmes in his paper on "The Foundations of Durham Castle and the Geology of the Wear Gorge," published in the *Durham University Journal* for March 1928, should do something to reassure those who have feared for the architectural glories of that ancient palace and fortress building, and make it clear that its repair, though likely to be both difficult and costly, is not impracticable.

Prof. Holmes has refuted the current local hypothesis that percolating waters, short-circuiting across the neck of the river bend, have removed material from under the cracked and broken walls. He accepts the historian's assurance that coal working has never been permitted where subsidence consequent thereon could have affected the castle buildings. He and his colleague, Dr. Hopkins, have made a large-scale geological map and have shown that the deeply incised meander which almost surrounds both Durham Cathedral and Durham Castle is post-Glacial in age and is cut through unweathered Coal Measure sandstones and shales. The 'Cathedral sandstone' on which the Cathedral is firmly founded is recognised as the 'Low Main Post' of the local miners.

Towards the castle the strong rock-beds dip down, and the castle buildings stand partly upon the rubbly top of the Cathedral sandstone, but mainly upon drift-sands and boulder clay which forms part of the filling of the deep pre-Glacial valley long famous as the 'Teme Wash.' The main course of that great drift-filled trough passes some few hundreds of yards to the eastward of Durham Castle; but, under the town and market place, a sand-filled tributary valley comes in and joins it from the west. The drift beneath the castle walls rests against a spur of Cathedral sandstone between the two channels. The Castle was in fact "founded on what is little better than loose rubbish," but the rock, some twenty or more feet below ground level, is strong enough to afford a stable and trustworthy foundation. As and when funds permit, it is proposed to continue the underpinning of the damaged walls and to construct beneath the neighbouring shaken parts of the buildings a reinforced concrete raft which will bear directly on the solid rock.

Appearances may well be deceptive, but to a visitor from another coalfield the character of the cracking and the distribution of the damage done recall occurrences in buildings beneath which old colliery workings are in process of slow collapse. Prof. Holmes points out that at the Durham Castle courtyard boring, the place of the valuable Hutton coal seam is only some 40 to 60 feet below Wear River level, and if one dare suspect the completeness of the historical record in a coalfield where the art and practice of coal working was so early begun, one would suggest that before a great expenditure is incurred upon the work of reconstruction, the presence or absence of ancient coal workings, and the condition of the measures above them, ought to be tested further by modern methods of exploratory boring.

W. G. F.

Association of Teachers in Technical Institutions.

Conference at Bradford.

The recent conference of the Association of Teachers in Technical Institutions gave ample evidence that the period of peace as regards such matters as salary and superannuation is being used for the discussion of the larger questions to which teachers should have opportunity of addressing themselves. The presidential address of Mr. W. W. Sirman (Handsworth Technical College) contained no reference to salaries other than a comment that industry is still the highest bidder for the services of what he called the 'ideal teacher,' namely, "one possessing experience in research, experience in industry, and ability to teach," and no reference to superannuation other than a reminder that the minimum number of hours required to qualify for superannuation leaves but little time for keeping abreast of industrial changes and improvements. His address was mainly concerned with points arising out of the recent reports of the Emmott Committee on technical education and of the Board of Education's Consultative Committee (cf. Nature, Jan. 14, 1928, and Feb. 5, 1927). He made a special plea for the development of day technical classes, and underlined important sections of the Emmott Report dealing with grouped courses, equipment, and the personnel of governing bodies of colleges.

The Emmott Committee's report was also the subject before an open meeting, when the discussion was opened by Mr. A. E. Evans and Mr. Wickham Murray, who used the history and principal features of the report as a background for the Association's educational policy. Mr. T. Boyce (Director of Education, Bradford) emphasised the necessity of linking technical education—which he said is not yet thoroughly envisaged as an intrinsic part of our system—to other forms of education, and he asked that the Hadow Report, in spite of certain criticisms levelled at it by Mr. Evans, should be accepted as a great move forward to those very ideals for which the A.T.T.I. has so long worked. Finally, a resolution urging the establishment of a central committee to co-ordinate the local inquiries suggested by the President of the Board of Education in his reply to the Emmott Committee, received the approval of the meeting.

This attention to the wider developments and implications of technical education was also reflected in other resolutions passed by the Conference. While, at conferences held under the shadow of salary and similar negotiations, much time has been taken by resolutions affecting purely domestic policy, the Bradford resolutions were concerned with several vital points at which educational endeavour may influence the life of the community. Three resolutions dealing with the social significance of biological science, particularly so far as its application can provide a foundation upon which to build a sense of racial responsibility, were passed unanimously.

An important feature of the Conference was a visit to the Research Station of the British Research Association for the Woollen and Worsted Industries at Torridon, Leeds. Addressing the Conference dinner, this Association's Director of Research, Dr. S. G. Barker, made reference to an important development in the linking of education and industry so far as research is concerned. Hitherto the science graduate who left the university to enter industry had some difficulty in obtaining the Ph.D. degree, since regulations necessitated further university residence. But such an interruption of his industrial life was not always possible, and strong representations had therefore been made from the industrial research side for permission for Ph.D. work to be carried out completely in industry. It was therefore gratifying to note that two universities have already granted such permission.

An exhibition of books and apparatus was held in the College of Arts and Crafts, but all the Conference meetings were held in Bradford Technical College, which is deservedly known for the scope and standard of its work. Diploma courses are available in textiles, chemistry, dyeing, engineering, physics, and biology, and are specially suitable to students wishing to attempt the honours degree examinations of the University of London. An important link between education and industry also exists in the award of the College associateship to diploma students who have had one year's industrial practice and submit an approved thesis embodying the results of original work.

University and Educational Intelligence.

Cambridge.—Dr. T. C. Fitzpatrick, president of Queens' College, has been elected as vice-chancellor for the year 1928–29.

In connexion with the International Geographical Congress in July, honorary degrees of Sc.D. are to be awarded to General Vacchelli, Surveyor-General of Italy, the president of the Congress, to Prof. E. de Martonne, of the Sorbonne, and to Sir Charles Close, president of the Royal Geographical Society.

The John Winbolt Prize in engineering has been awarded to A. Callender, Pembroke College, for a dissertation on "A Method of Determination of Impact Allowances for Railway Bridges."

Prof. Baker, St. John's College, Mr. R. H. Fowler, Trinity College, and Mr. F. P. White, St. John's College, have been appointed delegates from the University to the International Congress of Mathematicians at Bologna in September next.

Applications for the John Lucas Walker studentship in pathology, value £300 annually and tenable for three years, should be sent, accompanied by copies of papers containing published work, testimonials, and references, before June 30, to Prof. H. R. Dean, Pathological Laboratory, Medical School, Cambridge.

London.—The following doctorates have been conferred: *D.Sc. in Physics* on Mr. E. G. Richardson (University College), for a thesis entitled "Measurements of Sound Waves and other Periodic Aerial Motions"; Miss Kathleen Lonsdale (University and Bedford Colleges), for a thesis entitled "An X-ray Study of some simple Derivatives of Ethane"; *D.Sc. in Geography* on Mr. J. N. Carruthers, for a thesis entitled "The Flow of Water through the Straits of Dover," and other papers; *D.Sc. in Geology* on Mr. W. G. St. John Shannon, for a thesis entitled "The Petrography and Correlation of the Sedimentary Rocks of the Torquay Promontory," and other papers.

Mr. R. A. Wardle, lecturer in economic zoology in the University of Manchester, has been appointed to the chair of zoology in the University of Manitoba, Canada.

Dr. Ethel M. Poulton has been elected by the corporation of Yale University to the Seessel fellowship for advanced research in biology. Dr. Poulton is at present lecturer in botany in the Education Department of the University of Birmingham.

Calendar of Customs and Festivals.

June 17.

St. Moling Luachra, Bishop of Teach Moling, now St. Mullins, Co. Carlow (late seventh century, *d. circ.* 696), a descendant of the Leinster royal line. The interest of the legends and cult of the saint lies in their very evident connexion with earlier pagan belief. The saint settled at Rosbrock—'Badger Wood,' an ancient name for Tegh Moling—a place also associated with Finn MacCumhaill. St. Moling is said to have built here the first mill in all Ireland, and in a time of scarcity to have initiated the use of rye for food among the inhabitants. He spent many years in irrigation work with his own hands, and acted daily as a ferryman over the River Barrow.

St. Mullins, situated on the banks of the Barrow near the confluence of one of its tributaries, later became a place of considerable strategical importance. It was the site of a round tower and was a point of defence of the English Pale. The story of the saint's activities as ferryman, his association with milling, the cultivation of rye, and irrigation work, the name 'Badger Wood,' probably a sacred grove, and the existence of a dun or tumulus near by, point to this locality having been a stage on an early line of communication which became an important centre of pagan belief and culture.

The famous artificer Goban Saer is said to have constructed an oratory of oak for the saint, and several stories are connected with the building work of St. Moling. He is also associated in legend with both trees and stones. He lived for seven years in the hollow trunk of a tree, and one of the miracles which took place at his intercession was the transport of a huge oak felled by his workman to the banks of the Barrow to enable it to be cut up. The nature of the story points to this having been a sacred tree. He also shared in the allocation of the wood of the great yew of Lethglen felled by St. Molaise. When his great irrigation channel was completed, after many years of work, all those present waded through it against the current, and the saint undertook to intercede for all who did likewise in after days. This continued to be the practice of all the many pilgrims of both sexes who resorted there in after times, thereby obtaining remission of their sins and relief in illness. It continued to be the practice to walk barefoot through the traditional channel when it had become overgrown with thorns. On one occasion St. Moling cast the dead body of a young man into this channel, whereupon he came to life and swam about, though unable to swim before.

Pilgrims to St. Mullins venerated the saint by saying two prayers each of the nine times they circled on their knees in the largest of the buildings around a great stone on which the saint was said to have celebrated mass, placing a pebble on the stone for each round. They then deposited a leaf in the window of the inner shrine under which the altar had once stood and kissed the stone beneath before they resumed their shoes. The churchyard was much used for interments, and it was the custom to follow the practice, of pagan origin, of bearing the corpse around the churchyard before interment. Both legends and practice point to a survival of a pagan cult.

St. Moling was the patron saint of Leinster, and in particular of the royal Kavanagh clan, who were always buried in his churchyard. He is said to have negotiated the abrogation in favour of Leinster of the Borumha tribute to the High King of Ireland, which was afterwards reimposed in the eleventh century by Brian, known, in consequence, as Boru.

June 23.

St. John's Eve—Midsummer Eve.—The summer solstice was the most important of the festivals of the year among the Aryan peoples. The most significant survival of its observance is the wide-spread custom of the midsummer bonfire or need fire. In Celtic Britain the importance of the fire festivals of May 1 and Hallow-e'en point to a different calendrical system; but, either by transference or by superposition, the midsummer observances in the British Isles duplicate the May fire festival.

Under the Christian Church, the popular observances at midsummer have been connected with St. John the Baptist, but there can be no question as to their derivation from earlier pagan custom. Certain rites of Adonis, for example, of which Frazer thinks a survival is to be found in customs connected with St. John which are found in Sardinia and Sicily, were observed in June. There was at Rome a midsummer saturnalia celebrated by slaves and plebeians. It was specially connected with the fire-born Servius Tullius, and was in part a water and flower festival. It is also significant that the Mohammedan Berbers of Algeria and Morocco still observe traditional midsummer customs analogous to those found elsewhere, although this date does not appear in the Moslem calendar.

The turn of the year, when the sun has attained its zenith, is for a primitive people a critical period. Frazer, indeed, has suggested that the midsummer observances may have been intended to strengthen the sun as his power begins to wane. The part played by water in many of them may be taken as an index of the anxiety of the people for the prosperity of the harvest now at hand. The apparent combination of spring and midsummer in the fact that in Sweden St. John's Eve is the day for the observance of the maypole festival, in association with the practice of jumping through fires, may be due to climatic conditions; but in some parts of Russia the death and resurrection of Kupalo, which takes place on this date, is also associated with both fire and water. A straw figure dressed in woman's clothes with necklace and floral crown, and a tree felled for the purpose named Marena (winter or death), are the central figures of the festival, the straw figure being carried by couples as they jump through the fires. On the next day the figure is stripped and thrown into a stream. Frazer quotes a number of similar customs from various localities in Russia which take place between the feast of St. John and the end of the month.

It is significant of the critical character of this period that it should be regarded as a time for divination. By a familiar process of inversion, the measures originally taken to avert a contingent evil or secure a benefit become a forecast of the event. This is especially to be seen in the widespread customs associated with St. John's Eve, which foretell the character of the future partner in marriage, for example, by means of a looking-glass, in which the form of the future husband will appear looking over the inquirer's shoulder, as in Scotland and in Greece, or by placing it under the pillow, as in the Balkans, when it will affect the maiden's dreams. In Russia, the Balkans, Greece, and many parts of Europe, the white of egg, or melted wax, thrown into water, are believed to be equally efficacious, by the symbolism of the forms they produce in solidifying. In England the 'dumb cake,' made, baked, and broken by two and placed under their pillows by a third, brought the desired vision to the three diviners. In Wales spinsters made a garland of nine different kinds of flowers. Walking backwards they tried to throw the garland on a tree. The number of times it fell to the ground foretold the years they would remain unmarried.

Societies and Academies.

LONDON.

Royal Society, June 7.—**O. W. Richardson**: The emission of secondary electrons and the excitation of soft X-rays. These two groups of phenomena are closely interrelated. In order to harmonise the agreement between the soft X-ray and secondary electron discontinuities with the low soft X-ray and high secondary electron generation efficiencies, it is necessary to postulate an abnormally high absorption of the soft X-rays in the medium in which they originate. The possibility of a similar misfit in connexion with thermionic emission and chemical action is considered. In each case the radiation appears to behave as if it were absorbed about a million times faster near its point of origin than it would if it were separated out into a beam and its absorption coefficient measured elsewhere.

R. H. Fowler and L. Nordheim: Electron emission in intense electric fields. The emission of electrons from a cold metal under a strong applied field is calculated exactly, using the new mechanics, Sommerfeld's theory of metals and the simplest form of boundary field, which is sufficiently representative for the problem in hand at all ordinary temperatures.

O. W. Richardson and F. C. Chalklin: The excitation of soft X-rays (2). Earlier measurements on the critical potentials of iron have been extended. There is now a substantial agreement between different observers as to the complex phenomena displayed by this element. Rollefson's series is probably real; similar series are suggested for cobalt and nickel and also combination series. The tungsten 'spectrum' has been re-examined by deposition of tungsten on a carbon target. In this way it has been possible to show that the former 'spectrum' was a mixture, the probable contaminant being nickel.

G. Timms: The nodal cubic surfaces and the surface from which they are derived by projection. Cayley's classical treatment of the twenty-three types of cubic surface proceeds by the separate consideration of the several cases; it has been proved, but in a highly abstract manner, that every surface should be obtainable as the projection of a non-singular surface in higher space: the subject of this paper is the actual generation of all the various types of cubic surface by the projection of non-singular surfaces, namely, the non-ruled surfaces of order *n* in space of *n* dimensions.

J. M. Robertson: An X-ray investigation of the structure of some naphthalene derivatives. The X-ray investigation of naphthalene tetrachloride and 1.2.3.4.5.8.-hexachlornaphthalene.1.2.3.4.tetrahydride shows that in both cases the lattice is body-centred, and the space group probably C_s^4, involving polarity in the crystals. The reflection molecule and the groups of halogen atoms lie on a virtually different type of lattice and interleave the nearly flat carbon rings, the long axis of the molecule being approximately the *c*-axis of the crystal.

C. V. Raman and C. M. Sogani: A critical absorption photometer for the study of the Compton effect. The great difference in transmission through a filter on the two sides of the *K*-absorption edge forms the basis of a very simple and convenient method of studying the characteristics of the Compton effect. The materials of the target for the X-ray tube and for the filter in the path of the scattered X-rays are so chosen that the unmodified scattered ray lies on the short-wave side of the limit, while the modified ray scattered through a sufficiently large angle is on the long wave-length side of the limit. The increased transparency for the scattered radiation at such angles is readily shown by a photographic plate behind the filter, a steel wedge placed side by side with the filter forming the standard of comparison.

C. G. Darwin: The wave equation of the electron. In two papers Dirac has recently reconstructed the quantum mechanics of the electron, accommodating in a natural manner the properties associated with the 'spinning electron.' He works throughout with the calculus of *q*-numbers. The present work starts from his equation, but develops the same properties by the use of ordinary differential equations. There are four simultaneous partial differential equations of the first order, which are invariant for Lorentz transformations. A comparison with previous theories shows that Schrodinger's equation is a first, and the equations of the present author a second, approximation to the exact equations. In the case of hydrogen the solution leads exactly to Sommerfeld's original values for the levels.

S. Chapman: The molecular displacements in diffusing gas-mixtures. The displacement–distribution function found by Einstein for Brownian grains is applicable to a uniform gas mixture, but the constant *D* in his formula in general differs from the coefficient of diffusion for the mixture. The form of the function is found for a gas-mixture which is non-uniform in temperature and concentration, in the case where the concentration of one constituent is small.

J. R. Wilton: A series of Bessel functions connected with the lattice-points of an *n*-dimensional ellipsoid. It is known that the number of lattice-points in a many-dimensional ellipsoid is expressible by a series of Bessel functions. The paper is concerned with the degree of approximation given by a partial sum of this series, and with similar problems of a more general character.

E. H. Linfoot: On the law of large numbers. The paper discusses the following problem: Given an infinite sequence of trials, the probability of a success at the *i*th trial being p_i and the p_i being subject only to the most lenient possible condition, how can we estimate the probable deviation of the number *m* of successes actually obtained in the first *n* trials from the 'normal' number?

A. T. Price and S. Chapman: On line-integrals of the diurnal magnetic variations. Line-integrals of the field of the diurnal magnetic variation are calculated, taken round the boundary of an area of 400,000 square kilometres in northern Europe. The data used are the mean hourly inequalities of the two components of the horizontal magnetic force for the 20 international quiet days of the summer of 1924, derived from six observatories. The line-integrals do not vanish exactly, but their values are interpreted as due, not to earth–air currents, but to slight uncertainties in the data, owing to the observatories being too far apart round the boundary curve. If the non-zero line integrals were interpreted as indicating earth–air currents, the current–densities would be of the order 10^{-3} amp./km.^{2}, which is about one-tenth the order of the mean current densities inferred from line-integrals of the whole magnetic field; but the observed order of magnitude of the vertical electric currents in the atmosphere is 10^{-6} amp./km.^{2}.

W. G. Bickley: The influence of vortices upon the resistance experienced by solids moving through a liquid. Two cases of two-dimensional streaming past a cylinder, with vortices present, are worked out in detail. Where there are two symmetrically disposed vortices, the resultant is a force in the line of motion. With one vortex and circulation, the force is inclined to the direction of motion. The lift–drag curves show a resemblance to those found experimentally for the Flettner rotor.

H. S. Edwards: The effect of temperature on the viscosity of neon. The new method previously described for the accurate determination of the variation of the viscosity of air with temperature is modified to deal with a gas of which only a limited quantity is available. Neon was purified by a simple method of fractional distillation over charcoal surrounded by liquid air and measurements taken over the range − 78·4° to 444·5° C.

W. G. Bickley: The distribution of stress round a circular hole in a plate. The paper considers the distribution of generalised plane stress in a uniform, infinite, elastic plate due to an arbitrary distribution of traction round the boundary of a circular hole. The stresses are expressible in terms of two pairs of conjugate functions, and these in turn are expressible as definite integrals involving the boundary tractions. A physical interpretation of these integrals in terms of 'stress sources' is obtained. The results are in fair accord with experimental determinations.

J. D. Cockcroft: On phenomena occurring in the condensation of atomic streams on surfaces. The conditions under which atomic streams of cadmium and silver condense on different surfaces have been investigated. As shown originally by Wood, condensation into a homogeneous deposit does not occur unless the surface temperature is below a certain critical value; this value is a function of stream density, which varies by a factor of 10^4 as the surface temperature varies over a range from − 80° to − 150° C. When no precautions are taken to outgas the surface, the surface adsorption forces are identical for different metallic surfaces and glass. When the effect of gas is eliminated, the surface forces are increased. The experiments confirm Frenkel's theory of formation of surface films.

C. D. Ellis and **G. H. Aston**: The dependence of the photographic action of β-rays on their velocity. Measurements have been made of the relative photographic activity of β-rays in the range of speeds $H\rho$ 2000—$H\rho$ 8000 by direct comparison of photographs of the continuous spectrum of radium *B* and *C* with Gurney's electrical measurements. The results show, for example, that electrons of speed $H\rho$ 5000 have only one-half the photographic effect of electrons of speed $H\rho$ 2000.

P. Kapitza: The study of the specific resistance of bismuth crystals, its change in strong magnetic fields, and some allied problems. Part 1. Growth of crystal rods with definite orientation of crystal planes, and specific resistance of the crystals. In order to obtain crystal rods with perfect cleavage plane orientated in any desired direction relative to the axis of the rod, no strain must be set up during crystallisation. During the growth of the crystals, cracks and imperfections are developed in the lattice, which account for the variation of specific resistance observed in previous researches; in the case of a perfect crystal the specific resistance along the trigonal axis is $1 \cdot 38 \times 10^{-4} \pm 1$ per cent, and perpendicular to the axis $1 \cdot 07 \times 10^{-4} \pm 1$ per cent at 16°. The cracks are produced during cooling at a temperature very close to that at which bismuth solidifies. A perfect bismuth crystal has no well-defined cleavage plane at room temperature, and is very flexible. There seem to be two crystalline bismuth modifications; one at present unknown but probably cubic, and transferred to the ordinary rhombohedral modification at a temperature slightly below melting-point, accompanied by a change of shape, which accounts for the occurrence of the crack.

Part 2. Methods for observation of change of resistance in strong fields. The study of the change of resistance of a conductor in a magnetic field which exists for 1/100 second is made possible by the fact that larger current densities are permissible in the conductor, during this short interval, without heating the conductor. The measurements can be made with an oscillograph. A special switch is used, the make-and-break of which can be adjusted relatively to the current wave through the coil producing the magnetic field, with an accuracy of about 0·0002 sec.

Part 3. Change of resistance of bismuth and time-lag in magnetic fields. A method is described of eliminating time-lag in measuring the change of resistance in a magnetic field. Experimental results at 290°, 196°, and 91° abs. are given for change of resistance when the current is perpendicular to field, for different orientations of crystal axis relative to the field. Impurities and imperfections in the crystal lattice greatly influence the change of resistance, especially with low temperatures and strong fields. In weak fields the change of resistance of a perfect crystal follows a square law, and in strong fields a linear law; the linear law is practically independent of orientation of the crystal relative to field. In the case of current parallel to lines of force of field, a 'saturation effect' was found; the change of resistance is very small and strongly affected by imperfection of crystal lattice.

Geological Society, May 23.—**P. G. H. Boswell** (lecture): Geological features of the New Mersey Tunnel. The tunnel will be the greatest subaqueous tunnel in existence. The subaqueous portion of the tunnel (44 feet in diameter) and the two Birkenhead approach-tunnels lie in the Middle Bunter Sandstone ('Pebble-Beds'), which dips eastwards at about 3° to 5°. A fault-system, apparently of small aggregate throw, was met with at about 1828 to 1870 feet from the Liverpool shaft. The hade was eastwards, whereas in the case of the sub-river fault in the Mersey Railway Tunnel it was westwards. On the Liverpool side, the presence of the 'Castle Street Fault,' which throws down the Upper (Soft) Bunter Sandstone on the east, was confirmed. At the Old Haymarket entrance another north-north-west and south-south-east fault throws eastwards, and brings Lower Keuper Sandstone into contact with Upper Bunter. It has been possible to construct exceptionally accurate profiles of the system of buried channels. They appear to be of subglacial origin, and do not deepen seawards; they are filled with gravel and sand, overlaid by boulder-clay. In place of the single channel found in the Mersey Railway excavations, two (or more) feeding-channels occur farther north. Interesting, and at present unexplained, features have been observed in the levels of underground water. As would be expected, the fresh water table rides on the back of the salt water table in the neighbourhood of the Mersey estuary.

PARIS.

Academy of Sciences, May 14.—**A. Mesnager**: A rectangular specimen, submitted to normal pressures on its bases.—**Pierre Termier** and **Eugène Maury**: New geological observations in eastern Corsica; the tectonic unities.—**Ch. Gravier** and **J. L. Dantan**: Some results obtained in the course of night fishing (with a light) in the Bay of Algiers.—**P. Helbronner**: The altimetry of Corsica. Outline of some results of measurements of heights above sea level of some points in Corsica.—**E. Mathias**: A curious photograph of lightning obtained in the region of the Lake of the Four Cantons. This photograph supports the theory of lightning put forward by the author in 1924.—**W. A. Tartakowsky**: An expression for the number of representations of a number by a positive quadratic form with more than three variables.—**Paul Alexandroff**: The homeomorphy of closed ensembles.—**Bertrand Gambier**: Ruled algebraic surfaces: singularities and classification.—**A. Th. Masloff**: The deformation of surfaces with conservation of a conical conjugated system.—**Rodolphe Raclis**: Theorems of existence for the integral equation of Fredholm of the first species, the nucleus of which possesses lines of discontinuity.—**Alex. Froda**: A new classification of the discontinuities of a uniform function of real variables.—**Corps**: The experiments of M. Esclangon and their application to the study of the movements of the ether in the neighbourhood of material masses.—**C. Gaudefroy**: Observations on the fringes obtained in convergent light.—**J. Gilles**: The structure of the spectrum of the second order of sulphur.—**Paul Mondain Monval** and **Paul Schneider**: The refractive index and specific mass of liquid sulphur and of viscous sulphur. Curves are given showing the variations of refractive indices, densities and specific refraction as a function of the temperature. These afford evidence of an internal transformation at 160° C.—**J. Trividic**: The absorption of iodine by carbon from solutions in mixed organic solvents. In all the experiments the Freundlich equation covered the observed facts.—**R. Locquin** and **V. Cerchez**: Ethyl amino-malonate. This has been prepared with a 90 per cent yield by reducing ethyl isonitrosomalonate $(CO_2Et)_2.C=N(OH)$ with aluminium amalgam and water. One atom of hydrogen in this ester is still replaceable by sodium, which reacts with alkyl halides in the usual way.—**Charles Jacob**: The metamorphism of limestones and the structure of the North Pyrenees slope.—**Marcel Roubault**: The tectonic of the neighbourhood of Arbas (Haute-Garonne).—**A. Pereira Forjaz**: Spectrochemistry of the Portuguese mineral waters: the water of Gerez. Germanium, cæsium, silver, and lead have been detected in this water.—**Roger Guy Werner**: Study of the family Gyrophoraceæ.—**A. Sartory, R. Sartory**, and **J. Meyer**: Contribution to the study of the morphological and biological characters of *Mucor spinosus* (*Zygorhynchus spinosus*) cultivated on media resembling the habitat from which it has been isolated.—**Pierre Dangeard**: The conditions of release of free iodine in Laminaria. Details of experiments on *Laminaria flexicaulis*. With the exception of young specimens less than 10 cm. long, all the *Laminaria* in their natural state give off iodine vapour. The rate of evolution of the iodine is increased if the plant is cut or treated with acid or alcohol.—**Gard**: Rotting of the cultivated walnut, *Juglans regia*, and calcium carbonate. The distribution and intensity of diseased walnuts due to *Armillariella mellea* varies greatly from one region to another. After eliminating numerous possible factors, a distinct connexion was proved between the proportion of chalk in the soil and the disease, absence of disease corresponding with high proportions of chalk. The principal cause of the disease is considered to be the progressive decalcification of the soil by the intensive use of chemical manures.—**Georges Nichita**: Follicular atresia in *Girardinus Guppyi*.—**J. J. Rouzaud** and **L. C. Soula**: The influence of pinching the subhepatic veins on glycæmia and cholesterinæmia.—**A. Policard**: The proportion of calcium of the various regions of the ossification cartilage of the long bones.—**Edouard Chatton** and **André Lwoff**: The structure, evolution, and affinities of the ciliated Opalmopsidæ of the Cephalopods.—**Labbé, Nepveux**, and **Hiernaux**: The influence of insulin on the disturbance of nitrogen metabolism in diabetes.

Diary of Societies.

SATURDAY, JUNE 16

ROYAL SOCIETY OF MEDICINE (Therapeutics Section) (at Pharmacological Laboratory, Oxford), at 3.—Annual General Meeting and Laboratory Meeting.

MINING INSTITUTE OF SCOTLAND (at Dunfermline).

MONDAY, JUNE 18.

ROYAL GEOGRAPHICAL SOCIETY (at Æolian Hall), at 3.—Anniversary General Meeting.—Presidential Address, Presentation of Medals and Awards, etc.

ROYAL INSTITUTE OF BRITISH ARCHITECTS, at 8.30.—Presentation of Royal Gold Medal.

TUESDAY, JUNE 19

RESEARCH DEFENCE SOCIETY (Annual General Meeting) (at 11 Chandos Street, W.1), at 3.—Sir Bernard Spilsbury: The Work and Responsibilities of a Pathologist (Stephen Paget Memorial Lecture).

ROYAL STATISTICAL SOCIETY (at Royal Society of Arts), at 5.15.—John Hilton: Some Further Enquiries by Sample.

ROYAL SOCIETY OF MEDICINE, at 5.30.—General Meeting.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.30.—Rev. Neville Jones and Col. W. E. Hardy: Stone Implements of South Africa.

WEDNESDAY, JUNE 20.

ROYAL METEOROLOGICAL SOCIETY, at 5.—J. Edmund Clark, I. D. Margary, R. Marshall, and C. J. P. Cave: Report on the Phenological Observations in the British Isles, December 1926 to November 1927.—C. K. M. Douglas: On the Relation between Temperature Changes and Wind Structure in the Upper Atmosphere.—R. M. Poulter: Simple Formulæ for Computing Relative Humidity.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE (at the Café Royal, Regent Street), at 7.30 for 8.—Dinner to celebrate the Society's 21st Anniversary.

FOLK-LORE SOCIETY (at University College), at 8.—Madame Fia Fastré: Exhibition of Toys from Mexico, France and Japan.

NEWCOMEN SOCIETY FOR THE STUDY OF THE HISTORY OF ENGINEERING AND TECHNOLOGY (Summer Meeting at Stourbridge) (continued on June 21, 22, 23).

THURSDAY, JUNE 21.

ROYAL SOCIETY, at 4.30.—Sir Robert Robertson: Studies in the Infra-Red Region of the Spectrum. Part I. Description of Prism Apparatus. Part II. Calibration of Prism Spectrometer; General Procedure and Preparation of Pure Ammonia, Phosphine, and Arsine Gases. Part III. Infra-Red Spectra of Ammonia, Phosphine, and Arsine. Part IV. Consideration of Bands of Ammonia, Phosphine, and Arsine. With Exhibition of Apparatus.—C. V. Boys: Solid Dipleidoscope Prisms.—Prof. G. I. Taylor: The Forces on a Body placed in a Curved or Converging Stream of Fluid.—S. S. Cook: Erosion by Water-Hammer.—*To be read in title only*:—J. Hollingworth: The Polarisation of Radio Waves.—A. C. Menzies: The Spark-Spectrum of Copper.—W. H. Taylor and W. W. Jackson: The Structure of Cyanite.—F. H. Constable: A New Interference Method of Measuring the Surface Area of Film Catalysts. Part I. Theory. Part II. Nickel.—S. J. Davies and C. N. White: An Experimental Study of the Flow of Water in Pipes of Rectangular Section.—L. P. Davies: The Photoelectric Properties of some Metals in the Soft X-Ray Region.—C. F. Powell: Condensation Phenomena at Different Temperatures.—J. M. Walter and S. Barratt: The Existence of Volatile Intermetallic Compounds: The Band Spectra of the Alkali Metals and of their Alloys with each other.—G. Temple: The Theory of Rayleigh's Principle as applied to Continuous Systems.—E. S. Semmens: The Selective Photo-chemical Action of Polarised Light. Part II.—W. R. Brode and Dr. R. A. Morton: The Absorption Spectra of Solutions of Cobalt Chloride, Cobalt Bromide, and Cobalt Iodide in Concentrated Hydrochloric, Hydrobromic, and Hydriodic Acids.—Prof. T. M. Lowry and G. G. Owen: The Mechanism of Chemical Change. I. Promotion and Arrest of the Mutarotation of Tetra-Acetylglucose in Ethyl Acetate.—C. H. Gibson and C. N. Hinshelwood: The Homogeneous Reaction between Hydrogen and Oxygen.—R. Schlapp: The Stark Effect of the Fine Structure of Hydrogen.—H. Glauert: The Characteristics of a Karman Vortex Street in a Channel of Finite Breadth.—D. M. Newitt: Gaseous Combustion at High Pressures. X.—K. R. Rao and A. L. Narayan: On Series in the Spark Spectra of Germanium.—N. K. Adam: The Structure of Thin Films. Part XI.—E. Newbery: A Revision of the Theory of Transfer Resistance.—E. Newbery: Metal Overvoltage Measurements with the Cathode Ray Oscillograph.—Lord Rayleigh: Observations on the Band Spectrum of Mercury.—G. B. Bandopadhyaya: Photoelectric Effect of Soft X-Rays.—A. Caress and Dr. E. K. Rideal: On the Chemical Reactions of Carbon Monoxide and Hydrogen after Collision with Electrons.—F. P. Bowden and Dr. E. K. Rideal: The Electromotive Behaviour of Thin Films. Part I. Hydrogen. Part II. The Areas of Catalytically Active Surfaces.—W. Payman: The Detonation Wave in Gaseous Mixtures and the Pre-Detonation Period.—Prof. G. P. Thomson: Experiments on the Diffraction of Cathode Rays. II.—R. Ironside: The Diffraction of Cathode Rays by Thin Films of Copper, Silver, and Tin.—A. Reid: The Diffraction of Cathode Rays by Thin Celluloid Films.—Prof. W. E. Curtis and W. Jevons: The Zeeman Effect in the Band Spectrum of Helium.—B. F. J. Schonland: The Scattering of Cathode Rays.—Prof. H. M. Macdonald: Note on Total Reflexion of Electric Waves at the Interface between two Media.—Prof. G. I. Taylor: The Energy of a Body moving in an Infinite Fluid, with an Application to Airships.

CHEMICAL SOCIETY, at 5.30.—H. M. Dawson and W. Lowson: Acid and Salt Effects in Catalysed Reactions. Part XV. The Catalytic Activity of Hydrochloric Acid in the Hydrolysis of Ethyl Acetate.—A. A. Goldberg and R. P. Linstead: The Chemistry of the Three Carbon System. Part XVIII. Quantitative Investigations on the $\alpha\beta$-$\beta\gamma$ Change in Unsaturated Acids; Observations on the Reduction of Sorbic Acid and a New Synthesis of Pyroterebic Acid.—G. M. Bennett and W. G. Philip: The Influence of Structure on the Solubilities of Ethers. Part I. Aliphatic Ethers.—G. M. Bennett and W. G. Philip: The Influence of Structure on the Solubilities of Ethers. Part II. Some Cyclic Ethers.—R. G. W. Norrish and J. G. A. Griffiths: The Photochemical Decomposition of Glyoxal Vapour.

BRITISH PSYCHOLOGICAL SOCIETY (Industrial Section) (at the Royal Anthropological Institute, 52 Upper Bedford Place), at 6.—Elton Mayo: The Practical Outcome of Psycho-Pathology.

ROYAL SOCIETY OF TROPICAL MEDICINE AND HYGIENE, at 8.15.—Annual General Meeting.—Prof. E. Brumpt: The Differential Diagnosis of the Intestinal Amœbæ of Man.

NEWCOMEN SOCIETY (at Stourbridge) (continued on June 22 and 23).

FRIDAY, JUNE 22.

PHYSICAL SOCIETY (at Imperial College of Science), at 5.

ROYAL SOCIETY OF MEDICINE (Epidemiology Section) (Annual General Meeting), at 8.—Dr. J. A. Glover: Some Observations on Nasopharyngeal Infections in Public Schools.

ASSOCIATION OF ECONOMIC BIOLOGISTS (at Long Ashton, nr. Bristol).

SATURDAY, JUNE 23

NORTH OF ENGLAND INSTITUTE OF MINING AND MECHANICAL ENGINEERS (at Newcastle-upon-Tyne), at 2.30.

FRIDAY, JUNE 22, AND *SATURDAY*, JUNE 23.

ANATOMICAL SOCIETY OF GREAT BRITAIN AND IRELAND (Summer Meeting) (in the Department of Anatomy, University of Manchester).—J. M. Yoffey: Essentials of Hæmopoiesis as seen in Fishes.—D. Stewart and S. L. Wilson: Regional Anæsthesia and the Innervation of the Teeth.—G. Jefferson and H. M. Morris: Movements of the Spine with Reference to the Localisation (Incidence) of Spinal Injury.—A. J. E. Cave: (*a*) Case of Symmetrical Thinness of the Parietal Bones; (*b*) Two Cases of Congenitally Enlarged Parietal Foramina; (*c*) Nerve Markings on the First Rib.—G. Elliot Smith: The Optic Connexions in the Brain—the Need for a Revision of the Traditional Description.—G. L. Streeter: The Lewis-Gregory Film showing the Living Rabbit Egg and the Phenomena of Cleavage and Formation of the Segmentation Cavity.—J. Beattie: The Sympathetic Nervous Control of the Heart.—J. Beattie and R. B. Malcolm: The Cerebro-spinal Circulation in Man.—W. E. LeGros Clark: The Optic Thalamus of Tupaia.—T. Wingate Todd: A Study of the Normal Mobility of the Alimentary Tract.—R. D. Lockhart: (*a*) Variations Coincident with Congenital Absence of the Zygoma (Zygomatic Arch), (*b*) The Anterior Commissure of the Brain.—E. Fawcett: A Few Remarks on the Vertebræ.—H. A. Harris: (*a*) The Closure of the Cranial Sutures in Relation to the Evolution of the Cortex Cerebri; (*b*) A Preliminary Note on the Relation of Ossification in the Hind Limb and Skull to the Index of Cerebral Value of Anthony and Coupin.—Tudor Jones: Note on the Evidence concerning the Minute Structure of Striped Muscle.—C. J. Patten: The Syrinx, and Mechanism of Voice Production.—A Discussion on Anatomical Terminology will be opened by T. B. Johnston.

SATURDAY, JUNE 30.

The Significance of Imperial Chemical Industries.

FOUR years ago a Labour Government, pledged to the ideal of international co-operation, in a fit of political expediency exercised the veto of the State to frustrate the attempt of the majority of the board of directors of the British Dyestuffs Corporation, Ltd., and the Interessen Gemeinschaft to reach a working agreement for the better production and distribution of their products. The succeeding Government, although not prepared openly to be a party to co-operation between powerful chemical groups in Great Britain and Germany, sold its holding in the British Dyestuffs Corporation (albeit at a great depreciation), and thus left the directors free to do as they pleased.

In the meantime, however, the various German chemical groups had amalgamated into the most formidable chemical combine in the world. The new combine has made possible the pooling of resources upon research problems of importance; there are no longer trade secrets to be withheld from any unit of the industry: the State and the universities have given the combine all assistance within their power to afford. Its financial resources are enormous. Obviously its competitive strength in relation to that of Great Britain has been considerably enhanced, and equally obviously it would be difficult for such a combine to make an agreement based upon complete mutuality with any specialised chemical group in Great Britain.

Evidently Sir Alfred Mond, now Baron Melchett of Landford, had these considerations in mind when he conceived the plan of a corresponding combination in Great Britain. If there is eventually to be an international chemical combine to include Great Britain, Germany, and the United States, the sooner the chemical industry of Great Britain attains to the dignity of a unit the more potent will be our influence in any greater combine. The energy with which Sir Alfred has initiated his project is illustrated by the report of Imperial Chemical Industries, Ltd., covering the year 1927, the first year of its existence. The merger now directly controls the British Dyestuffs Corporation, Ltd., Brunner Mond and Co., Ltd., Nobel Industries, Ltd., the United Alkali Co., Ltd., as well as thirty-five other lesser manufacturing and trading concerns, indirectly controls thirty other companies, and has interests in certain American undertakings. The original scope of the undertaking has thus been considerably widened, and the process of consolidation and expansion is steadily going on. Its trading connexions extend to virtually every corner of the world map.

The authorised capital of the combine is £65,000,000, its assets nearly £70,000,000. The gross profit for the year was £4,567,225, excluding a capital profit of £1,000,000 arising from the realisation of certain investments of the member-businesses which has been placed to the reserve accounts. In the first year of its existence the merger is in a position to pay a dividend of 8 per cent on its ordinary capital, 7 per cent on its preference shares, and to bring its deferred capital into the dividend list, in spite of the fact that in 1927 Great Britain was only just emerging from the disastrous industrial struggle of 1926. The financial results obtained indicate that the member-businesses have made good use of the advantages offered by the pooling of resources, and in view of the absence of criticism in the country as a whole, it can be assumed that these advantages consist of greater efficiency in production and distribution of multitudinous products, and that the consumer has gained and not been exploited unfairly because of the decrease of competition. Fertilisers, for example, are being sold at four-fifths of the pre-War prices, a fact of tremendous importance to the farming community.

The production of the maximum amount of goods at the least price, at a profit calculated to inspire confidence in the investing public and consistent with proper conditions of life for the work-people of the merger, are, however, merely means to an end, judging from the public utterances of its chairman. He appreciates the wider implications of creative industry, that its proper function is to consider world problems as a whole, to serve mankind as a whole, and in order to do this all relevant factors must be taken into consideration and fully examined. He realises that there is likely to be short shrift for monopolies the activities of which are actuated by the same lack of principle as the average small business. For the modern monopoly is acquiring more and more the character of a public corporation, serving a public uncircumscribed by political boundaries, its activities directed more and more by creative minds fully aware of the responsibilities attaching to their task, with a higher ideal than mere profit-making; attracted to the great enterprise, in fact, by the tremendous scope it offers for scientific methodology, and the adventurous application on a grand scale of the discoveries of science.

Probably Mr. H. G. Wells regards the men whom Sir Alfred Mond has gathered round him as among the "more vigorous intelligences in the business directorates of to-day" who "are beginning to realise the uncompleted implications of their enterprise," and as such the most promising instruments in the "open conspiracy" for the "awaking of mankind from a nightmare of the struggle for existence and the inevitability of war," men who refuse to regard the environment as a static entity, whose struggle is directed towards a modification of their environment. Conspicuous on the façade of the austerely beautiful and noble building rapidly approaching completion on Millbank, which is to serve as the headquarters of Imperial Chemical Industries, Ltd., are some sculptured peacocks. These, says the architect, Sir Frank Baines, should not be regarded as symbolic of mere pride of achievement, but of the incorruptibility of the commercial ideals which it is hoped will actuate the infant enterprise.

It would savour too much of blind optimism to assert that this generation of English people realises fully the appalling reactions of science, applied in a spirit of brutal materialism, upon the life of nations, or that the attitude of mind towards science has completely changed. Science is still largely judged by the material benefits it confers on those who have the prescience to utilise its discoveries, or the material comfort it brings to the multitudes, not very much by the habit of thought it engenders. Its social implications are still unappreciated even by the large majority of scientific workers themselves. When science has relieved man of material cares—and at the present rate of progress of scientific discovery that is not an impossible achievement—it will still be confronted with the task of showing man how to live. "It is," as Prof. Whitehead has said, "among the merits of science that it equips the future for its duties." It can be truly said that it has equipped Imperial Chemical Industries for its future duties. This gigantic industry is based on science, and modern science with its progressive dynamic outlook forces its disciples along hitherto untrod paths in search of greater knowledge and towards greater power.

Nevertheless, we discern an unmistakable tendency in the new combine to leave the main direction of the enterprise to what may be called the financial as distinct from the scientific interest. Only a small minority of the members of the Board inspire us with the confidence that they have had the requisite training in, and possess the requisite knowledge of, science, to be able to appreciate the implications of a discovery. It may be urged that this contingency is met by leaving the direction of certain of the subsidiary companies to leading scientific workers, and by the creation of the advisory research council, through which agency academic and industrial men of science will co-operate to keep the central board abreast of scientific progress. But is this enough ? It has to be borne in mind that the Mond and Nobel companies, which acted as the nucleus for the combine, were founded and controlled by the great men of science after whom they are named. They did not receive their first stimulus from financiers ; finance followed their brains, which is the habit of finance the world over. The operations of banks and financial trusts since the War have not inspired the masses of the peoples of Europe and the United States with a great deal of confidence in anything but their capacity to exact a steady toll on industry, whether industry is flourishing or depressed. Booms in trade have been over-financed, but at the first signs of depression, credits have been either withdrawn altogether or made available on such terms that industry and trade have still further declined. It would be interesting to know if Sir Alfred Mond and his colleagues consider that the possibilities of any situation which may arise in the chemical industry are satisfactorily met by the formation of the new Finance Company of Great Britain and America, on the board of which he and Sir Harry M'Gowan are to provide a liaison with Imperial Chemical Industries, Ltd.

From the growth of internationalism in industry and finance, Mr. Wells visualises " an effective world-control . . . of the production and main movements of staple commodities and the drift and expansion of population. . . . These things assured, the abilities and energies of a greatly increased proportion of human beings could be diverted to the happy activities of scientific research and creative work with an ever-increasing release and enlargement of human possibility." We are prepared to believe that Sir Alfred Mond is inspired by an idealism akin to this, that he realises that economic direction of world affairs must be based on the scientific study of all those factors fashioning the environment of man, that industry at its truest and best must be the prelude to man's highest expression. The men he has chosen to deal directly with these matters and to control certain factories and processes enjoy his confidence and inspire us with the same feeling. But there is no guarantee that the same relations will exist between his successors and them or their successors. He has not started a tradition through which the supreme direction of production will be vested in men with a scientific outlook and creative minds.

In addressing the delegates of the Imperial Agricultural Research Conference in October last, Sir Alfred referred to the difficulty experienced in wresting " from short-sighted treasuries the necessary funds for carrying out . . . experimental work, which in its ultimate effect must vastly increase wealth and happiness and economic prosperity, though to those of little imagination it appears to be a wasteful means of immediate expenditure." Is he certain that there is no danger of a similar short-sightedness afflicting members of a board on which the financial elements predominate ? This is an age of bold experimentation. Can it be suggested that the substitution of some of the financial elements by scientific workers of proved aptitude for direction and control and one or two creative artists might be amazingly successful in carrying the merger forward in pursuit of an ideal for industry, an ideal which would act as a beacon for every other industry ? A. G. Church.

The West African Negro.

The Peoples of Southern Nigeria : a Sketch of their History, Ethnology, and Languages, with an Abstract of the 1921 Census. By P. Amaury Talbot. Published for the Crown Agents for the Colonies. Vol. 1 : *Historical Notes.* Pp. xii + 365. Vol. 2 : *Ethnology.* Pp. xx + 423 + 67 plates. Vol. 3 : *Ethnology.* Pp. x + 425-976 + 66 plates. Vol. 4 : *Linguistics and Statistics.* Pp. v + 234. (London : Oxford University Press, 1926.) 4 vols., 70s. net.

THE Government of Nigeria is to be congratulated on its wise policy in relation to anthropology. Not only is the study of this subject encouraged in its officials, but also official anthropologists have been appointed both in the northern and southern provinces, and a census has been published for each. Instead of these latter being mere lists of names and numbers, they are in both instances (the other instance being Mr. Meek's " The Northern Tribes of Nigeria ") mines of information which will be valuable alike to administrators and to all other workers and travellers in these vast and little-known districts.

The four volumes before us attest the great industry and the sympathetic observation of the author. Mr. Talbot's chief interest is in religious matters, and the greater part of vols. 2 and 3, comprising together almost 1000 pages, is concerned with religion. This proportion is in no way excessive, for religion plays an immense part in the life of all primitive peoples, especially Africans. There can be no understanding of native life in any branch—government, law, social organisation, agriculture, or any of the arts and crafts—without some knowledge of the religious ideas of the people. The beliefs of the southern Nigerians are too numerous to classify here. Mr. Talbot, who describes gods, kings, and ancestors, has rather unfortunately retained the term 'juju,' a word used by so many authors with such different meanings, that in common parlance it conveys no more than something vaguely magical or supernatural; in these volumes it is used to signify a minor deity who may sometimes be extremely powerful, but whose worship is usually more localised than that of the major deities. *Per contra*, we may be thankful to Mr. Talbot for avoiding 'fetish,' another word which has done much to confuse our knowledge of West African religion.

While the older writers were horrified by the cruelty of West African worship, and could see no motive behind it but blood-lust, Mr. Talbot has much to say of the goodness of the gods and the 'juju,' who act as guardians of society, to whom the oppressed can appeal, and whom the guilty, however rich and powerful, will fear. He does not, however, deny the reality and the extent of these sacrifices, but points out that most of the victims were captives or criminals. In the same way the secret societies, though powers greatly to be feared, also act as police, punishing crime and executing criminals. In respect of the death penalty and human sacrifice, the influence of religious beliefs must be considered, for to the West African life after death is no shadowy possibility, but a reality of which he is convinced. Certainly, life in the spirit world is not so pleasant as life on earth, but reincarnation is part of the general plan, and among most tribes is believed to occur fairly speedily, the only exceptions being persons so evil that the survivors take special measures to prevent their rebirth.

When we consider that these African holocausts were believed to be necessary to the gods in order to ensure the fertility both of man and of the earth itself, and that the price paid by the victims was merely death and rebirth, the motive can no more be attributed purely to blood-lust than that of the Inquisitors who burnt bodies to save souls. Nor can these people be accused of being specially revengeful, for compensation for murder is accepted; among many tribes of the Ibo a woman is handed over, and sometimes after she has borne a child she is allowed to return to her own people. It is not stated that the child is counted as heir to the murdered man, but this is presumably so. But in spite of the real religious background, Mr. Talbot's statements that the Nigerians believe in the doctrine of Karma and the existence of a super-soul should surely be accepted with caution:

> "The essential idea appears to be that of a spark of Divinity, or a monad, which exists in a very high spiritual state—with God, as it is put; an Ego, which sends down emanations through various planes and finally on to the earth. This stream of consciousness manifests itself in physical, ethereal, mental, and spiritual bodies by means of which it gains experience and gradually evolves from a condition which, though pure and full of possibilities, was only embryonic, into a developed perfection. There is a general credence among the wise or initiated in the evolution of a man from a stone up to divinity, and it is no doubt partly owing to this cause that the power of metamorphosis is believed in and that so much of the folklore consists of stories in which animals are endowed with almost human attributes. The acceptance of the idea of the immortality of the soul implies also a trust in morality" (vol. 2, p. 279).

It would have been more to the point had the author quoted details in the form of specific actions, ceremonies, and verbal formulæ, in support of these statements, instead of extracts from the writings of Oliver Lodge, MacDougall, and William James. Indeed, his own beliefs appear at times to impede his critical faculty, so anxious is he to give 'explanations' in terms of clairvoyance, spiritualism, metamorphosis, bilocation, and other so-called metapsychic phenomena, for the strange happenings such as communication with the dead, change into were-animals, persons seen at a distance, etc., devoutly believed by the natives to be true, and attested by them in law courts.

According to Mr. Talbot, the complexity of Nigerian culture is due to foreign influence, but on this subject he is very difficult to follow, for he quotes examples impartially from Egypt, Crete, the Hittites, Babylon, Greece and Rome, the Etruscans and Carthaginians, from Crô-Magnon and from Mexico, nor is it clear whether analogous conditions are noted or direct influence inferred. On the other hand, comparatively little attention is paid to contact with the east and north through the great Negro kingdoms of Songhai and Melle. Since Mr. Talbot leans strongly towards foreign influences, it is a pity that he has not tabulated the intrusive elements in culture and indicated their possible routes.

Apart from these two features and the neglect to separate theory clearly from fact, which may be regarded as blemishes by critically minded readers, these four volumes contain a mass of interesting material, a large proportion obtained at first hand. There are some interesting notes on animal 'affinities' possessed by individuals or families; the correlation of such beliefs to more orthodox totemism, and the part played by re-incarnation in both sets of beliefs, has yet to be worked out in detail. Southern Nigeria would appear to be a fruitful field for research.

The heads of most of the great States are divine or semi-divine personages, hedged about with powerful taboos, while some suffer a ceremonial death—the supreme penalty of divinity—lest they grow feeble and the land suffer accordingly.

The illustrations are excellent, and of unusual interest, especially those of the images of the secret societies, and of monoliths; while the diagrammatic distribution maps, and the tables of customs at the conclusion of most of the chapters, are of great value.

B. Z. S.

Theories of Quanta.

The Quantum and its Interpretation. By Prof. H. Stanley Allen. Pp. xiii + 274. (London: Methuen and Co., Ltd., 1928.) 12*s*. 6*d*. net.

IN this book Prof. Stanley Allen gives an account of the quantum as it appears to an experimental physicist with strong theoretical interests. It differs from most books on the subject, first in omitting most of the mathematical proofs, and secondly, in not being confined to those theories which have enjoyed, or are enjoying, the sunshine of orthodox approval. The book is divided into three parts, of which the first—called "Fundamental Facts and Principles"—contains an account of the main facts and ideas in the various departments of physics, including magnetism, where Planck's constant makes its appearance. Prof. Allen has been very successful in giving an account of this work, largely on historical lines, well suited for the numerous students of physics whose mathematics is not strong enough to enable them to follow long calculations without losing the thread.

The only serious criticism one has to make is that it is a little too condensed for a student reading alone. For use in conjunction with lectures or other teaching it is admirable and fills an important gap. Apart from semi-popular works, most existing books are either too mathematical, too detailed, or both, for the average honours student. Prof. Allen explains both the original Sommerfeld quantum notation and the new Landé-Sommerfeld system. So much has been written in the former notation that some reference to it is necessary, but it is to be hoped that the confusion inseparable from two notations will not be continued by the text-books a moment longer than can be helped, now that substantial agreement has been reached.

The second part of the book is of a more speculative nature, and consists largely in an account of some of the more special theories, such as Whittaker's magnetic wheel, and the theory of unit magnetic tubes due largely to Allen himself. The third part is mostly a development of the first, including mention of a wide range of theories. There is a good deal not usually found in text-books, such as, for example, an account of Lewis and Adam's work on the numerical relation between h, c, and e. There is also a brave and not unsuccessful attempt to give a general idea of the matrix theory in its various forms. Indeed, the author has shown throughout great skill in giving the main lines of mathematical arguments without going into details. There is a brief but clear treatment of wave mechanics.

It is naturally the second part of the book which most invites criticism. The theories there described, however successful in their particular spheres, seem unlikely to be able to give a complete explanation of all the varied phenomena which involve Planck's constant. Indeed, from his introductory remarks, the author seems to admit as much, but he claims, and probably rightly, that some of the ideas they contain are likely to find a place in the final theory. This is especially true of the statical theories originally devised to explain chemical combination. The wave theory indeed marks a definite move in this direction, and recent work suggests the hope that we may soon have an adequate theory of at least the simpler molecules. Progress in this direction has suffered from the divergent training of mathematicians and chemists. Comparatively few of the former have been brought into sufficiently close touch with the chemical evidence to appreciate its weight and variety, and the latter do not usually put their theories into a form which lends itself to exact quantitative results. It cannot be too strongly emphasised that the chemical and spectroscopic results are equally important aspects of the same problem. The experience of the last few years has shown that very varied theories can account for most of the spectroscopic facts with surprising success, and in spite of the triumphs of the wave theory, there is no certainty that the list is exhausted.

Much the same holds on the chemical side. It seems that the data in either branch are of too similar a character to discriminate sharply between a wide range of theories. The wave theory has indeed been much strengthened by predicting the otherwise unexpected diffraction of free electrons, but it should be remembered that the same could have been said of the old orbit theory and the Stern-Gerlach experiment, which is now equally well explained on the wave view. It is a better test of the fundamental truth of a theory that it should cover the simple facts over a wide range than the details of a special branch. The number of separate facts in, for example, spectroscopy, is apt to seem larger than it really is, owing to the enormous wealth of slightly varying examples. One will not feel confident that physics has finished with its period of Central American government by yearly revolution, until the ruling theory draws support from both parties in the State.

Prof. Stanley Allen devotes a chapter to an account of several theories of radiation which have been devised to explain the photo-electric paradox. The theories of guided quanta, propounded in different forms by Sir J. J. Thomson and L. de Broglie, get over the difficulty of reconciling photo-electric and interference phenomena by supposing the quanta to be systems or particles constrained to move along a Poynting vector of the classical wave system. It seems fairly certain that the solution of all problems in which many quanta are concerned can be found by treating the radiation as classical waves, reacting with the atoms in the manner considered by Schrödinger, except that for the interchange of energy between matter and radiation, and conversely, the intensities of the waves must be 'interpreted,' to use Darwin's term, as meaning the probabilities of the presence of a quantum which receives or loses energy as a unit. This purely mathematical treatment does not give any picture of what a quantum is, and it was to satisfy the instinctive desire that most experimental physicists feel for such a picture that the above theories, and the others described by Prof. Stanley Allen, were devised.

The crux is to give a detailed explanation of absorption and emission of radiation. If the theory can also explain the value of the non-dimensional quantity hc/e^2, so much the better. All such models imply the quantum as a 'something,' which must apparently be of small size, moving in a definite path. The best evidence for this is probably the Geiger-Bothe result, which follows immediately if quanta are like the particles of ordinary dynamics, and seems to require very special assumptions on any other view. In addition, most other views would make the conservation of energy only statistically true, and while this would get over certain difficulties, it is not likely to be accepted while any loophole of escape remains.

None of the models considered is completely satisfactory in detail, and many would lead to serious difficulties in other parts of quantum theory. They contain, however, some very promising features, and Prof. Stanley Allen has rendered a valuable service in bringing them together so that their strong and weak points can be compared.

G. P. THOMSON.

The Quest for Life.

Why I Believe in Personal Immortality. By Sir Oliver Lodge. Pp. viii + 152 + 4 plates. (London, Toronto, Melbourne and Sydney: Cassell and Co., Ltd., 1928.) 5*s*. net.

THE present volume provides in a brief and concise form an account of the basis of what Sir Oliver Lodge calls his belief in personal immortality. A few new incidents are included for which the author pleads a 'supernormal' interpretation, but taken broadly, there is nothing in these which would compel the acceptance of that interpretation by unbiased minds.

The main point on which the discussion turns is Sir Oliver's view of the brain as the 'organ' of the mind. He conceives the mind or the soul in its early stages as 'unidentified,' by which he means, it would appear, that in this form it possesses none of the attributes of humanity, not having been yet incarnate. The psyche or mind is then imagined as leaking into the body destined to receive it. After a period of incarceration in matter, during which time the material body is used by the mind, the death of the former intervenes, and the now identified soul goes back whence it came, but this time carrying with it all the powers, experiences, and memories accumulated during its earth life. Thus, according to this view, the body is animated by a permanent entity which, seemingly devoid of personality at the beginning, acquires a personality through the hazardous adventure of earthly existence. This remarkable point of view (which certainly seems to add to the problem of life rather than to diminish it) is made the basis of the now well-known spiritistic theories whereby the animating entities, once they have obtained conscious personalities, are able to maintain contact with one another, normally through the ordinary channels of communication, and supernormally through telepathy and telergy.

When lesions of the brain occur and the character and desires of the patient are altered, it is not, according to Sir Oliver, because the character has 'really' altered, but because the mechanism through which the real character functions is out of gear and deranged. It would thus appear that in accordance with this theory 'souls' and 'minds' are so intimately attached to their bodies that their progress is directly conditioned by them; for, should the mechanism fail to function, then the soul, which depends upon it for those experiences and memories which it is to carry over to its immortality, cannot fulfil what will doubtless be called its destiny, but will remain either wholly or partly unidentified. Indeed, it would seem that it follows from this argument that it is the body and not the soul that is important, since it is only through the body that the soul can function on this, its first personal plane. How far such a doctrine can be said to be more philosophical than the many which have preceded it is open to question, but as a support for so-called psychic phenomena it has decided advantages.

There is nothing in the book concerning these phenomena more startling or evidential than the records of cases published elsewhere. Moreover, Sir Oliver's rather persistent attacks on orthodox scientific caution regarding these occurrences are not justified and are sometimes unfair. The opposition and general disapprobation which Sir Oliver tilts against are not directed against the phenomena, which are admitted by all who have studied the subject, but against the wild interpretation of them and the faulty experimental methods employed in their investigation. Serious inquiry is, in almost every case, hampered by those responsible for the management of mediums, and the position of the scientific man desiring personal experience is often that of a spectator at performances which are mere travesties of scientific inquiries.

Belief in human immortality is not, it would seem, based on the evidential value of alleged psychic phenomena. In the present work Sir Oliver has partially revealed the true basis of his belief. Repelled by the sordid drama of human existence, by its waste, its greed, and its cruelty, his generous nature seeks another world where man's higher attributes may have a better opportunity. The same view has recently been rather pathetically voiced by a writer for whom Sir Oliver contributed a foreword with the statement that he was sure the messages were genuinely received and would be perhaps a help to people in their search for truth about our future state. After describing the glories of the world behind the veil, the writer tells of the mountains, seas, houses, and gardens of that land, but he adds that there are no storms in that country, no dustbins and no sinks! *Fere libenter homines id quod volunt credunt.*

Relativity.

(1) *The Mathematical Theory of Relativity.* By Prof. Th. de Donder. Pp. x + 102. (Cambridge, Mass.: Massachusetts Institute of Technology, 1927.) 2.75 dollars.

(2) *The Einstein Delusion and other Essays.* By L. A. Redman. Pp. 217. (San Francisco: A. M. Robertson, 1926.) 2.50 dollars.

THE two books grouped together in this notice deal with relativity, but in quite different ways, and whilst the first forms a very important contribution to our knowledge of this subject, the second has only an ephemeral interest and can be disposed of quickly. It consists of a series of essays, the principal one dealing with relativity, the rest with various other topics, mainly mechanical. The tone is severely critical and dogmatic to a degree, not at all justified by the knowledge of the subject matter exhibited by the author. It is sufficient to state as an example that, in the essay on relativity, exhaustive reference is made to numerous popular writings on the subject, but scarcely any to the original publications of Einstein himself or his successors. Surely it is not too much to expect that a critic should show some familiarity with original sources, if he wishes his criticisms to be taken seriously.

The first book, by Prof. de Donder, already well known as the author of "La gravifique einsteinienne" and numerous other publications, is based upon a course of ten lectures delivered at the Massachusetts Institute of Technology during the year 1926. Owing to the restricted space at the disposal of the author, the treatment is very concise and makes considerable demands on the previous knowledge of the reader, but the book will make a strong appeal to all those who can follow the argument.

The first four lectures deal with the geometry and kinematics of relativity, and the next four with the development of the fundamental equations and their application to the mass gravific field, the electromagnetic gravific field and their combination, the electromagnetic mass gravific field. A variational method is used throughout, which constitutes a relativistic generalisation of Hamilton's principle of least action, though in a modified form. The mode of presentation adopted in these chapters offers novel features and advantages from the didactic point of view. The ninth chapter gives applications to restricted relativity, including the determination of the mass formula of the electron, the mechanical force due to the electromagnetic field and the stress and momentum components and energy of that field.

In some respects the tenth chapter on relativistic quantisation is the most important in the book in view of the present state of the quantum theory. The author employs a generalised Hamilton-Jacobi characteristic equation together with a transformation of the characteristic function, analogous to that used by Schrödinger, to derive an invariant quadratic function of the derivatives of a wave function, and by applying his variational method to this invariant deduces a wave equation of a very general type consistent with relativity. By specialising this equation he is able to obtain the fundamental quantisation equation of the point electron, and for a Minkowski field this reduces to Schrödinger's equation. The method is extended to continuous systems, and leads to the interesting result that "Relativity is able, not only to furnish quantisation, but even to show that it is a consequence of the condition of *permanence* of statistical ensembles."

The book is clearly printed and commendably free from misprints, and should be read by every serious student of relativity.

Our Bookshelf.

The Determination of Minerals under the Microscope: with Special Reference to the Interpretation of Interference Phenomena. By Dr. John W. Evans. Pp. xii + 110. (London: Thomas Murby and Co.; New York: D. Van Nostrand Co., 1928.) 7*s.* 6*d.* net.

IN very clear and simple style this book describes the outline to be followed for the complete determination of the optical characters of minerals in thin sections, with some remarks on the application of the same methods to minerals in small grains. The title rightly emphasises the importance attached to the interpretation of interference phenomena, as Chapter vi. on the 'directions image' gives detailed instructions for the determination of optical characters from the interference figures by methods which are neglected altogether in some schools of petrology. The frontispiece gives a good reproduction of the polarisation colour scale seen when a quartz-wedge is viewed between Nicol prisms, both crossed and parallel, as recently published, by Drs. W. R. Jones and A. Brammall. Chapters vii. and viii., on dispersion and 'other determinations,' are less carefully written than the earlier chapters, and the diagrams illustrating the effects of dispersion on the interference figures are liable to be misleading, as it is not clear which of the two kinds of shading used is meant to represent blue colour and which red.

The book is intended primarily for students, and the author has taken great pains to give the student every assistance. It is even explained that ω is called 'omega,' and that "$V_\rho > V_\upsilon$ may be read V rho greater than V upsilon." One hopes that even in these days of non-compulsory Greek this kind of thing is unnecessary. Another attempt to assist the memory of the reader leads the author to speak of crystals as fast and slow instead of negative and positive. This seems an unnecessary departure from a convention which is universal, and is one of the few points of nomenclature in crystal optics on which there is international agreement. The adoption of an analogous device in France to that suggested by the author would lead them to write of positive and negative crystals as 'grands et petits.' These, however, are trivial points. The student equipped with an efficient microscope will find this an admirable laboratory hand-book, and both author and publishers are to be congratulated on its excellence.

Metaphysics and Modern Research. By I. C. Isbyam. With Introduction and Introductory Essay: The Quest of Spiritual Truth, by Louis Zangwill. Pp. xvi + 494. (London: The C. W. Daniel Co., Ltd., 1927.) 15*s.* net.

THIS book is to be welcomed as a definite attempt to estimate the implications of modern research on philosophy. The author claims that his position rests on Plato, Kant, Leibniz, Bergson, and we are certainly in agreement with him when he maintains that recent advance in physical science has weakened materialistic views to an extent not yet generally appreciated. An introductory essay by Louis Zangwill is of special help to the less experienced student in showing him the unexpected paths that have been traversed in the quest of spiritual truth. This treatment is partly historical and has special reference to the philosophers already mentioned.

The work itself really consists of three books—I. "The Ego and Physical Force"; II. "The Ego and Spiritual Truth"; III. "The Self-Seeker and his Search." The argument is sustained largely by duologue, and the position of "I" naturally has to be faced; for surely no philosophical system can ignore the problem of solipsism. An interesting development is the idea of orders of ego, in which Mr. Isbyam postulates ego-entities of the first order—physical force; of the second—the impulse to use it; of the third—the emotions which order these impulses; the fourth order—of purpose; and the fifth—beauty, love, spirit, truth. There is much in Mr. Isbyam's treatment of happiness as discipline of soul, and we believe that to many his advice will be welcomed, to fix attention on those who, because they harbour the spiritual entities so well, can keep their minds adjusted to the never-ending flux of all existing things, with ardour ever new.

The volume is further enhanced for the non-specialist by the inclusion of two appendices on the principles of relativity and quanta.

H. D. A.

La fabrication chimique de l'or. Par Jollivet Castelot. Texte français (traductions anglaise, allemande, espagnole). Pp. 126. (Douai: Chez l'Auteur, 19 Rue Saint-Jean, 1928.) n.p.

M. JOLLIVET CASTELOT claims to have succeeded in preparing gold by the action of arsenic and antimony sulphides on silver at 500–1100° C. M. A. Ballandras, a chemical engineer, has verified this result, obtaining colour reactions varying from light yellowish-black to peach-pink, a dark-black powder with a green reflection, and glossy flakes capable of taking a high polish. M. L. Outon, a pharmacist, has repeated the experiment with amazing results. All these gentlemen are to be congratulated on their spagyric achievements if not on their perception of the ridiculous—the inventor in particular, since although not unaware of the economic advantages of the reaction, he has confined himself to the simple search for truth. The yield of gold appears a little low, but doubtless could be improved. Modifications consist, for example, in the addition of tellurium or tin. It is somewhat to be regretted that alchemical prowess should be dissipated in the preparation of so inexpensive a material as gold, particularly if its manufacture on the large scale is to be ignored; radium, for example, costs a great deal more, and a catalytic or any other means for its preparation which would eliminate the somewhat tedious cultivation from uranium would be much appreciated. Even the production of any metal, however base, from gold itself would at least have about it an engaging air of novelty. M. Castelot "emits the hypothesis that the arsenic acts as a catalyser and the sulphur as a ferment in the transmutation." Such a statement is indeed amazing; more amazing, perhaps, than M. Castelot would admit.

A. A. E.

The Composition of Water. By Prof. J. R. Partington. (Classics of Scientific Method.) Pp. viii + 106. (London: G. Bell and Sons, Ltd., 1928.) 1*s*. 6*d*.

THE editor of these "Classics of Scientific Method" suggests that "a reader who takes up a volume of the series, dealing with a branch of science of which he is ignorant, will be able, without further aid, to trace the steps by which the human mind has passed from chaotic ignorance to ordered knowledge." The first impression of the reviewer was that this purpose had been admirably fulfilled in Prof. Partington's monograph on "The Composition of Water"; but closer study shows that, in order to make full use of the available material, he has thought it necessary to discuss the phlogiston theory, and to tell the story of the 'water controversy,' in which the question at issue was one of priority between Cavendish, Lavoisier, and James Watt. This policy has reduced the value of the monograph as a guide to 'the man in the street,' who does not want to be dragged up every blind alley that has been entered, even by the most distinguished pioneers. On the other hand, the monograph is an ideal one for the serious student of historical chemistry, since the standard is as high as that of the Alembic Club reprints, but the material is presented in the more attractive form of a continuous illustrated narrative.

Selene: or Sex and the Moon. By Prof. H. Munro Fox. (Psyche Miniatures, General Series No. 15.) Pp. 84. (London: Kegan Paul and Co., Ltd., 1928.) 2*s*. 6*d*. net.

THIS interesting book is written for the general reader with no special knowledge of biology; it is intended to arouse interest as well as to impart information on the subject. Prof. Munro Fox deals with the historical and the mythical aspects of the problem before directing the attention of the reader to authentic cases of animals obeying a lunar rhythm in reproduction.

The accounts of the sea-urchin at Suez and of the Palolo worm of Fiji summarise well what is known to science to-day as regards these two animals; but the treatment of the behaviour of the Californian smelt includes only the work of the Thompsons in 1919 and not of Clark in 1925. Clark showed quite clearly that the Californian smelt is a tidal form, that is, makes two spawning runs each lunar month during the breeding season. The possible causes of the lunar rhythm are discussed, such as tide and moonlight.

Apart from the fact that the references to the Californian smelt are now discredited, the book is worth reading for its lucid and concise exposition of the problem.

Does the Earth Rotate? By William Edgell. Reprint. Pp. 69. (Radstock, Som.: The Author, Westfield House, 1927.) n.p.

THIS book is pure paradox; it takes us back to pre-Copernican days, and asserts that the earth is flat and stationary, with the heavenly bodies within a few thousands of miles of it. Incidentally the author quotes astronomical facts incorrectly, giving the earth's rotational speed as 18 miles a second, that being actually the orbital speed. The difficulties alleged about falling bodies with a moving earth were of course in the minds of thinking men centuries ago, but were completely removed by the discovery of the true laws of force and motion.

The only service the book can do is to direct the attention of teachers to some points that may be difficult to beginners, and lead them to explain these points more fully and clearly.

Monomolecular Films.

IN a recent communication to the Société Française de Physique (*cf. Le Journal de Physique et le Radium*, March, vol. 9, p. 378; 1928), Mr. H. Devaux describes a continuation of his beautiful work on monomolecular films, in this case for films on mercury. He states that "Dans les cas, très nombreux, où l'on obtient une lame très mince continue, liquide ou solide, on peut tenter la mesure de l'épaisseur minimum réalisable. Cette mesure m'a donné des résultats satisfaisants quand j'employais le benzine comme dissolvant, par exemple pour l'acide abiétique. Au contraire, pour les substances présentées en dissolution dans l'eau j'ai trouvé des lames toujours trop étendues, qui auraient fait attribuer à la substance un diamètre moléculaire très inférieur au diamètre théorique. En voici des exemples :

Lame de saccharose	0,20 à 0,40.10⁻⁷	au lieu de	0,72,	diamètre théorique.
Glucose . .	0,14 à 0,21	„	0,58,	„
Glycérine . .	0,06 à 0,08	„	0,50,	„
Gomme arabique .	1,2 à 1,3	„	?	

"Résultats analogues avec la dextrine, l'amidon, l'albumine (environ de 1,5.10⁻⁷), le tanin, l'acide picrique.

"Il est évident que pour toutes ces substances l'emploi de l'eau avait provoqué l'altération du mercure, de sorte qu'une impureté expérimentale augmentait indûment la surface."

Since 1926 we have been investigating thin films of various substances on mercury, the original object being to obtain further information on the molecular dimensions of cellulose and its derivatives. The investigation was extended to cover other 'high molecular compounds,' and the results seem of sufficient interest to permit brief description of the method and of their relation to Mr. Devaux's conclusions. The method consisted in allowing drops of solutions of the substances of varying concentration to spread on a mercury surface cleaned by the sweeping procedure, the amount of substance being insufficient to cover completely the liquid surface. The film area was developed with talc powder and measured by a planimeter. On plotting the thickness of the film calculated by *assuming* the density of the massive material against concentration, a point is arrived at where this thickness value becomes independent of the concentration (or dilution). The limiting values for cellulose nitrates out of *acetone* were of the order 3 to 5 A. The value found for stearic acid out of ether at 25° was 22 to 24 A., for oleic acid 11·2, for elaidic acid 12·2 A., for [illegible]-capric acid 13·6 A.

These results indicated that the fatty acids gave values comparable with those obtained by Langmuir, Adam, and others, so that these substances were apparently ordering themselves to oriented monomolecular films, not quite in the closest packing possible, but approaching it. On the other hand, the very low values for the 'high molecular' bodies either mean a casual net-work structure, of great porosity, or a molecular dimension which cannot be the *length* of the molecule, but may be the thickness of a polymeric chain or sheet. The former conclusion is in disagreement with the reproducibility and the behaviour of the films to compression by an encircling oil film. The latter view seems in accord with certain theories at present developing on polymerisation, and with the atom-group orientation theory of colloid micelle formation suggested by one of us in a previous letter to this journal ("The Nature of the Emulsoid Colloid State." S. E. Sheppard, NATURE, Mar. 17, p. 73; 1921).

By the same method we have obtained values of the minimum thickness for proteins out of water of the order 6 to 7 A. This is in good accord with the values for protein films on water obtained by E. Gorter and F. Grendel (*Trans. Farad. Soc.*, **22**, p. 477; 1926).

In view of the similarity of our results in non-aqueous solution to those obtained in aqueous solution, we suggest that Mr. Devaux's results do not necessitate his conclusion, "pour toutes ces substances," etc.

The tendency for strongly bipolar molecules, such as the fatty acids, to end-on orientation, at either a water or mercury surface, need not be expected in more complex bodies, such as the carbohydrates and proteins, which possess a multipolar structure, relative to simple dipoles. This conclusion is not incompatible with Mr. Devaux's suggestions concerning the effect of ionisation, and is in good accord with his remarks in a previous communication (Communication to the Société Française de Physique, Séance du 17 Février, 1928, *Journal de Physique*, p. 348; 1928), concerning the formation and function of monomolecular films at the surface of living cells. We expect to present this material in conjunction with some work by Mr. A. H. Nietz at the Symposium on Polymerisation of the American Chemical Society in September of this year.

Active Nitrogen.

DR. H. SPONER, in an article published some time ago (*Zeit. f. Phys.*, vol. 34, p. 622; 1925), advanced the hypothesis that active nitrogen is simply an atom of nitrogen, basing her argument on the parallel properties of active nitrogen and active hydrogen. The hypothesis seems to have found favour with many physicists. Now it is known that active hydrogen shows Balmer lines strongly, and if active nitrogen is also atomic in structure, this may also show the lines of atomic nitrogen. In order to test this point we have photographed the spectrum of active nitrogen in the near infra-red, after an exposure of 42 hours on neocyanine plates. A new band system, extending from 7500 A. to 8900 A., has been discovered. The well-known group of lines of atomic nitrogen discovered by C. C. Kiess (*J.O.S.A.*, vol. 11) about the region 8200 A. is absent, though the exposure was long enough to photograph a weaker band in the vicinity.

This new band system photographed by us for the first time in the spectrum of active nitrogen, was first noticed by A. Pfund (*J.O.S.A.*, vol. 9, p. 193) and Coblenz, a few years ago in their investigations of the infra-red radiations of nitrogen by the galvanometric method, and recently Poetkar (*Phys. Rev.*, Dec. 1927) has photographed it by using ordinary nitrogen discharge tubes. We have also obtained these bands in the ordinary discharge tube of nitrogen. There is no doubt that they owe their origin to the N_2-molecule. There are some indications that this band system is present in the solar spectrum, and may provisionally be identified with the band noted by Meggers about 8230 A.; and is due to the absorption of solar light by atmospheric nitrogen. Prof. M. N.

Saha is of opinion that these bands may owe their origin to the transition of the valency electron of one of the atoms to the metastable state (${}^4S_1$, ${}^2D_2$ . . .), and hence they occur in the infra-red. According to Hund and Mullikan, such transitions are not only allowed in the molecular spectra, but also occur very strongly. These bands are therefore presumably analogous to A, B, α bands of oxygen, which are obtained in absorption and must therefore correspond to the forbidden electron transitions of the oxygen atom. But this suggestion can be tested only by a laboratory experiment on the absorption bands of nitrogen. Without going into details regarding the nature of active nitrogen, we are inclined to the view that it is a diatomic rather than a monatomic molecule of nitrogen. An attempt is being made to photograph the spectrum of active nitrogen in the Schumann region in search of the resonance lines of nitrogen.

Our attention has been directed to a note of Prof. J. C. McLennan, and Messrs. R. Ruedy and J. M. Anderson, published in NATURE of April 7, on the spectra excited by active nitrogen. These authors could easily obtain the lines of zinc and mercury corresponding to 8·4 volts, but were unable to excite the lines of either krypton or xenon. From this fact they conclude that only those substances become luminescent which combine chemically with nitrogen, and hence the activity is to be ascribed to chemiluminescence. We wish to point out that the resonance lines of both krypton and xenon, discovered by G. Hertz (*Naturwiss.*, p. 648 ; 1926) all lie in the Schumann region :

		Resonance Potential.
Krypton . .	1235·8	9·99
	1164·9	10·66
Xenon . .	1469·5	8·40
	1295·7	9·53

Prof. McLennan and his collaborators evidently did not work in this region. The next higher group of lines lies in the infra-red, and requires a potential of about 11 volts for excitation. It is not, therefore, surprising if they failed to obtain any impression of these lines on their plates, because on the present-day theories of active nitrogen, it is loaded to an energy content of about 11·4 volts.

We also feel, though here we tread on rather delicate ground, that the exposure of 12 hours given by these authors was not enough to bring out lines of inert gases if any were present, for they do not seem to have noticed the new band spectrum of active nitrogen in the infra-red, which we have photographed. So that the conclusion of Prof. McLennan and others regarding the chemical origin of the phenomenon associated with active nitrogen does not appear to be quite justified.

Is Crystal Reflection of X-Rays entirely a Classical Phenomenon?

ACCORDING to recent papers by Waller (*Phil. Mag.*, 4, 1228) and Wentzel (*Zeit. f. Phys.*, 43, 1, and 43, 779), the regular reflection of X-rays can be treated as a purely classical phenomenon and the modified scattering of the Compton effect can be disregarded. If this is so, then the values of the atomic structure factor for a given atom (or F_n values) at various angles of reflection have the property that

$$-(1/Z)\sum_{n=1}^{n=\infty}(-1)^n F_n \ngtr \tfrac{1}{2} \quad . \quad . \quad . \quad (1)$$

where F_n is the F value for the nth order reflection from planes of which the grating space is D, and Z is the number of electrons in the atom. The proof is indicated as follows: Let an electron be at a distance a from the centre of an atom, this centre being in a crystal plane and a being perpendicular to the plane, then (see Compton, "X-Rays and Electrons," p. 121) the structure factor for this electron is $\cos(4\pi a \sin\theta/\lambda)$. If in addition the centre of the atom is vibrating, due to heat motion, and carries the electron with it, the structure factor becomes

$$\exp.\,(-b\sin^2\theta/\lambda^2)\cos\,(4\pi a\sin\theta/\lambda).$$

For reflection we have $n\lambda = 2D\sin\theta$, and hence

$$F_n = \exp.\,(-\alpha n^2)\cos\beta n \quad . \quad . \quad . \quad (2)$$

where $\alpha = b/4D^2$ and $\beta = 2\pi a/D$. Substituting in the left side of (1), the series may be written

$$S = \sum_{n=1}^{n=\infty}[\exp.\{-\alpha(2n-1)^2\}\cos\beta(2n-1) - \exp.\{-\alpha(2n)^2\}\cos\beta(2n)] \quad (3)$$

since Z in this case is unity. By Cauchy's theorem $S \ngtr I$ where

$$I = \int_0^\infty[\exp.\{-\alpha(2x-1)^2\}\cos\beta(2x-1) - \exp.\{-\alpha(2x)^2\}\cos\beta(2x)]dx. \quad (4)$$

Evidently

$$I = \tfrac{1}{2}\int_0^1 \exp.\,(-\alpha x^2)\cos\beta x\,dx. \quad . \quad . \quad (5)$$

By the mean value theorem

$$I = \tfrac{1}{2}\exp.\,(-\alpha u^2)\cos\beta u \quad . \quad . \quad (6)$$

where $0<u<1$. Now $\exp.\,(-\alpha u^2)<1$ for $\alpha>0$ and $\cos\beta u \ngtr 1$. Hence $I \ngtr 1/2$ and also $S \ngtr 1/2$, so that (1) is proved.

We have plotted the F values as found by Havighurst (*Phys. Rev.*, 28, 875) for (Na + Cl) against $\sin\theta$ and drawn a smooth curve passing through the experimental F values and through an F value of 28 for $\sin\theta = 0$. For the large angles we have extrapolated to $F = 0$ at $\sin\theta = 0·81$. We have read off sets of F values for different values of D, that is, for different values of $\sin\theta_1$, the value of $\sin\theta$ for first order reflection and have calculated the values of the left side of (1), which we shall represent by A, for various values of $\sin\theta_1$. We obtain the following table:

$\sin\theta_1$.	A.
0·05	0·497
0·10	0·558
0·126	0·487
0·15	0·430

For $\sin\theta_1 = 0·10$, A is definitely greater than 1/2 in opposition to the requirement of the classical theory as given in (1). This matter will be discussed more fully in a paper appearing elsewhere.

The Palæolithic Implements of Sligo, Ireland.

THE communication of Profs. Jones and Boswell in NATURE of June 2 does not, in my opinion, supply good reason for departing from my announced intention to wait until the autumn of this year before replying to criticisms and detailing the geological evidence on which my claim is based. A paper will then be read before the Society of Antiquaries of London. Nevertheless, there are one or two statements in their letter upon which I will briefly comment now.

At Rosses Point, Profs. Jones and Boswell have ascertained, by counting, that there still remain ten slabs of the cherty roof-blocks of large size. They compare this number with the twenty-six slabs of the re-deposited dolomitic floor-stone, and appear to attach importance to the latter's preponderance. Of course there is a preponderance. Furthermore, this preponderance will tend to become greater as time goes on and as more and more of the floor-stone becomes detached and re-deposited by the waves during storms. If Profs. Jones and Boswell were to study my photograph of the site, taken before any of the blocks had been disturbed, they could draw the following section:—

(a) Re-deposited dolomitic floor-stone.
(b) Collapsed roof-blocks of cherty limestone.
(c) Flakes, implements, and cores.
(d) Dolomitic floor-stone, *in situ*.
(e) Cherty limestone.

Such a section bears an interpretation alternative to that offered by them.

Profs. Jones and Boswell give their opinion that rapid coastal erosion is taking place in the Sligo area, and in support of this contention they instance, on Coney Island, a concrete emplacement now overhanging the cave at the north-west corner of the island, which, they state, once formed the base of a beacon since moved inland owing to encroachment by the sea. If they had sought their facts from the builders (as I have done) they would have ascertained:

1. The emplacement did not serve, and was not intended to serve, as the foundation for a beacon.

2. It was a platform made flat for the use of the men who pump sea-water for the containers of the beacons situated farther inland.

3. The cave was in existence immediately below the emplacement at the time of its building.

4. Poteen used to be made there!

All we can say with certainty is that the front of the cave has given way along a joint-plane subsequent to the building of the emplacement, and that there is no evidence of a recent date for the formation of the cave in question. There have been occasional falls of cliff along the Carboniferous Limestone coast-line of Gower, Wales. But Paviland Cave is palæolithic.

I may say that I have obtained additional archæological and geological evidence in support of my claim, but, with regard to the cultural age of the implements (as I took the opportunity to inform the Royal Irish Academy's delegation in April), it is not improbable that they will prove to be older than originally suggested. The impression I first gained was that the industry should be correlated with the massive Chellean culture stage as typified at Cromer, Norfolk. Though my opinion, in this respect, differs from that of my collaborator, Mr. Reid Moir, the fundamental importance of my claim—*i.e.* to have discovered traces of palæolithic man in Ireland and to have established an inter-glacial period for that country—remains unaffected.

J. P. T. BURCHELL.

June 6.

The Buoyancy of Whales.

I AGREE with Sir Sidney Harmer (NATURE, May 12, p. 748) that as the whale descends its chest is compressed and the density of its body is consequently increased. It is owing to this very fact (that is, its increased density) that the whale has difficulty in regaining the surface after descending to a great depth, and that there is consequently a limit to the depth to which it can safely descend.

Compression of the chest, however, does not account for all the phenomena. If nothing else took place, the dead whale would float when raised to the surface, and this is not the case, at any rate, not so far as I know. In explaining the facts it seems necessary to postulate the absorption or escape of the lung air. Death being due to asphyxia, as I am about to show, the latter possibility (that is, the escape of the lung air) seems not unlikely.

The whales I spoke of were not allowed to sink to the bottom, but were suspended by the whale-line and were hauled up as soon as possible. In whaling language they 'died on the first harpoon'; that is to say, were only harpooned once, and after 'sounding' or going vertically down to a great depth, died under water. They doubtless died from drowning or asphyxia, as the whalers say. There is no other way of accounting for their death. The pressure of the water has evidently no injurious effect on them, and the injury done them by the harpoon—at any rate by the hand one—is not serious enough to cause death.

Sometimes, however, the Greenland whale died under water "on the third or fourth harpoon," when it was already far spent and about to receive the *coup de grâce* with the lance. A case of this kind came under my notice in 1886. It is recorded in the *Zoologist* of 1887, p. 97. Briefly, the whale received a fourth gun harpoon, descended a few fathoms, died under water, and floated up dead. Strange to say, it came up tail first. Its death seemed to be due to syncope, and the pressure of the water at the trifling depth at which it died did not seem sufficient to squeeze the air out of it. Consequently it floated up.

Sir Sidney Harmer seems unwilling to believe that whales use their lungs for hydrostatic purposes. I have shown that in recently dead whales the tendency of the body to float or sink depends on the state of the chest and lungs. It seems reasonable to suppose that the same is true during life. To arrive at the truth it is necessary to watch the whale when it is motionless, not when it is swimming about.

I have mentioned that the Greenland whale sometimes lies motionless at the surface with a part of its head above water and with its back awash. Scoresby tells us that when it is extended in this manner it "can sink downwards in the space of five or six seconds or less beyond the reach of its human enemies," and Beale, speaking of the sperm whale, says, "occasionally when suddenly disturbed the whale has the power of sinking quickly and directly downwards in the horizontal position."

In conclusion, I think the air in the lungs of the whales in the intervals between the respirations must be in a state of compression, and that it is owing to this that each time the animal breathes an appearance is produced resembling a puff of steam escaping from a boiler.

R. W. GRAY.

Exmouth, May 31.

Physics and Metaphysics.

THE writer of the review of "A Short History of Physics" (NATURE, May 26) suggests an interesting speculation (p. 824) as to whether the great physical scientists "have not usurped the place of the metaphysicians," since "some modern theories make almost impossible demands upon the imagination of those without more than a fair amount of mathematical knowledge."

On the other hand, Mr. Selby's illuminating summary of "The Quantum Postulate and the

Atomic Theory," p. 828 of the same issue, indicates an interpretation of physical phenomena essentially the same as the older physiological theory of experience. There is nothing metaphysical in the conclusion that the limiting subjective unit is a *minimum sensibile*, for the individuality associated with events is still our three-dimensional brain-consciousness. If there be metaphysical regions, that is, states of energy, beyond or within those we term physical, we should have to evolve finer sense perceptions in order to become aware of them; and what is now hypothetically metaphysical would have become physical. Present interpretations of physical theories, however, do not appear to suggest the possibility of such evolution.

That one state of matter permeates grosser states of lower atomic velocity is a fact quite unrelated to our present powers of sense perception. We can enhance these powers to some extent by means of radio instruments, and experience a vicarious sensation of being in two places at once; but we cannot see *simultaneously inside and around* our physical bodies or the earth, and, therefore, we are unable to know what, if any, is the subjective state of high-power radioactive substances. Absolute permeability, absolute velocity, absolute time or absolute consciousness is as incomprehensible to our present organs of perception as 'absolute size'—a contradiction in terms, for size can relate only to a three-dimensional form of physical matter in space, and particles must become blended with energy at infinity. A formless, synthetic, immaterial substance of absolute and, therefore, ubiquitous density would be a state of absolute subjectivity, 'absolutely' *metaphysical* for us.

May 25.

Activation of Hydrogen by Electric Discharge.

MY attention has just been directed to the correspondence under this heading in NATURE of Jan. 21 and Mar. 10. Dr. Lunt has kindly summarised the experimental evidence which leads to the rejection of explanations of the type proposed by Mr. Glockler, and in this connexion I have nothing to add.

It is important to note, however, that in a large number of experiments, described very briefly at the commencement of my paper and in greater detail in the thesis, no activation could be detected. It appears that evidence of activation may be obtained only when the detecting agent is sufficiently close to the discharge tube and at pressures below about 5 cm. of mercury. Paneth and his co-workers, in a paper published at the same time as mine, also report failure to obtain active hydrogen by many of the methods described in the literature of the subject. It seems probable, indeed, that the greater part of the previous work describing methods of preparation and properties of active hydrogen other than monatomic hydrogen obtained at extremely low pressures may prove to be without value. If this be so, my subsequent experiments, together with those of Dr. E. J. B. Willey, who reports the formation of active hydrogen in the 'condensed' discharge as used for the production of the nitrogen after-glow, constitute the principal evidence for the existence of this substance. Further details concerning the active hydrogen which Dr. Willey has obtained would, therefore, be of great interest.

In the March issue of the *Journal of the American Chemical Society*, Messrs. Smallwood and Urey also describe unsuccessful attempts to prepare active hydrogen by the usual methods. In their paper it is stated that my results are open to criticism on the ground that I did not sufficiently guard against the possibility of sulphur dust being blown back into the discharge. This is incorrect, for adequate precautions were taken to prevent any accident of the nature described.

Subsidiary Rectangles as Applied to the Formation of Magic Squares.

IN NATURE of Jan. 14 I gave an 'associated' rectangle 8 × 3, which is the smallest rectangle that will also provide the property, that the diagonals one way also sum to the same amount as the rows. I give below a similar rectangle in the smallest possible numbers (non-consecutive).

In NATURE of Feb. 4 I gave the smallest similar rectangle with consecutive numbers, 9 × 3 for order 27.

As the diagonal property is not necessary in order 27 with rectangles 9 × 3, and order 30, with rectangles 10 × 3, can only be constructed with non-consecutive numbers, order 33, with rectangles 11 × 3, is the smallest order in which the diagonal property is essential in the rectangles 11 × 3, with consecutive numbers, for the formation of associated pandiagonals.

I give the three additional rectangles, where in each case the diagonals from left to right sum to the same amount as the rows, and the rectangles are each associated:

8 × 3

12	20	18	11	3	27	19	2
4	13	23	6	22	5	15	24
26	9	1	25	17	10	8	16

112 × 42

10 × 3

20	25	6	2	19	11	15	4	31	27
23	22	14	29	8	24	3	18	10	9
5	1	28	17	21	13	30	26	7	12

160 × 48

11 × 3

Rainbow Visible after Sunset.

IT may be of interest to record that about sunset on Monday, June 4, there was a fine rainbow here which persisted until the sun was well below the horizon. The last trace of it vanished at $20^h\ 11^m$ G.M.T., at which time the altitude of the true sun was approximately *minus* 1° 30′. Making a generous allowance for refraction, this would still put the upper limb of the apparent sun very appreciably below the horizon. This is perhaps the more remarkable in that there was a low bank of cloud along the western horizon. The great altitude of the top of the bow was very striking, and it did not, of course, reach down to ground level, but faded out at a considerable height, which there was not time to measure. My longitude and latitude were $4^m\ 28^s$ E., 51° 21′ N.

The Physiological Effects of Flying.[1]

By Group-Captain Martin Flack,
Director of Medical Research, Royal Air Force Medical Service.

The first observations upon the effects of flying seem to have been made in 1783, when some sheep and fowls were sent up in a balloon to a height of several hundred feet. Apparently, upon its descent, the observers were delighted to find that the aerial flight had induced no ill-effects. In December of this year, however, after an ascent to about 10,000 feet, a human observer is reported to have experienced considerable discomfort from the effects of cold as well as pain in the right ear.

The stimulating effects of low altitudes are recorded in a handbook on aeronautics published in 1786. "The spirits are raised by the purity of the air and rest in a cheerful composure." The author noted that all worries seemed to disappear as if by magic, so that ballooning came to be regarded as having a therapeutic value. This stimulating effect of altitudes up to 10,000 feet is still well known, many pilots stating that they experience a great desire to sing.

Between 1783 and 1903—the date of the first flight of the Wright brothers—the study of the effects of altitude was the chief point of physiological interest in aeronautics; but with the coming of the aeroplane many other problems have come into existence. Of first importance are those connected with the ability of man safely to fly a machine, of which he himself represents at present the controlling and co-ordinating mechanism. In addition, however, we have the question of the effects of flying from the point of view of the ordinary passenger.

As a general rule, passenger flying consists in what is known as 'straight flying,' no 'stunts' or aerial acrobatics being indulged in. The machine takes off, rises to a thousand feet or so, and proceeds direct to its destination. To many, the idea of aerial progress in a state of unstable equilibrium appears fraught with peril compared to usual forms of motion upon the earth's surface. Yet, with the increasing safety of machines, aviation must now be considered little if any more dangerous than motoring, especially in these days of speed and congested traffic. All machines for public transport are most carefully tested and inspected, and designers and constructors of aeroplanes are constantly seeking ways and means of making flying more and more safe.

An opinion as to the security of flying must not be formed from the number of accidents which occur in military flying. Such flying is totally different from civilian flying, involving considerably greater risks. The comparative safety of civilian flying is in part attributable to the careful medical selection of pilots. Pilots are not permitted to carry passengers or goods without the most searching medical examination, and are not passed for service until they have received a certificate of airworthiness in exactly the same manner as the aeroplane itself. The British company, Imperial Airways, Ltd., has recently carried more than 60,000 passengers and flown more than 3 million miles without serious accident. This point is emphasised, because the enjoyment of flying as passenger depends largely as to whether or not the passenger enjoys a feeling of security.

The other chief factor is the state of the atmosphere. If the weather is 'bumpy,' a passenger may become 'air-sick,' more especially when travelling in an enclosed cabin. As with sea-sickness, many people anticipate being 'air-sick,' and in this frame of mind the malady is prone to occur. Save in exceptionally bad weather, there is no reason why the average person should be 'air-sick,' the number of individuals liable to air-sickness being considerably less than those liable to sea-sickness. The best guide as to whether one is liable to air-sickness is previous experience in regard to swings, trains, and scenic railways. Only those who are liable to discomfort nausea on these are likely to suffer from air-sickness. There is no direct connexion between air-sickness and sea-sickness save perhaps that the person who becomes severely and intractably sea-sick is possibly likely to suffer from air-sickness. The subject who is just ordinarily sea-sick will not necessarily be 'air-sick.' The liability to air-sickness among the general population is considerably over-rated. Nor, it must be emphasised, is there any connexion between 'giddiness' when looking down from a height and a liability to 'air-sickness.'

At the heights of average aerial travel, that is, up to five or ten thousand feet, there are no effects from altitude upon the average passenger, nothing beyond a slight deepening of breathing being noticed, frequently attended, as already noted, by an exhilaration which often manifests itself in a desire to sing. Civilian passenger machines do not ascend high enough to induce anything akin to 'mountain sickness,' neither are the average altitudes reached sufficient to induce harm in people who are suffering from lung or heart ailments of such a degree as to enable them to pursue an average everyday life on the ground.

With regard to flying as pilot, various points must be taken into consideration, since it is upon him that the safety of the aeroplane rests.

Simple flying calls for certain co-ordinated limb movements which are initiated as the result of sensory impressions. Of such impressions those of vision are the most important, since without good visual judgment accurate flying is not possible. In fog and cloud flying, a pilot has to rely upon the information obtained from instruments by the use of his eyes. The same is true in a large measure of night flying, although here a certain amount of visual information is generally also available from external sources (horizon, stars, etc.). In all stages of flying experience, therefore, a pilot is dependent upon visual information, gathered either from objects outside or from instruments within the machine. In particular this is true during the stage of training, when all co-ordinated movements are initiated consciously. With growth of experience the pilot derives an increasing amount of information from the nerves of 'deep' sensation, namely, the 'feel' of the control column, rudder bar, and seat, and, as a result, comes in time more or less automatically to initiate the appropriate co-ordinated movements necessary for the accurate control of his machine.

---

[1] Substance of two lectures delivered at the Royal Institution on Mar. [illegible] and 29.

Information is also derived from the 'feel' of the wind and varying air currents upon the face. Auditory sensations, however, do not play a great part in flying, although good hearing is necessary for the correct appreciation of the 'note' of the engine, as well as for the reception of wireless and so forth.

Besides the faculty of correct perception, a pilot must be capable of accurate co-ordinated performance with his limbs as the result of his perception. Delicately co-ordinated movements of arm and leg are necessary for the accurate control of an aeroplane. Some individuals are incapable of achieving this delicacy and are consequently heavy handed or heavy footed, or both. Other individuals are incapable of combining arm and leg movements with sufficient accuracy owing to an inability to perform successfully two relatively simple movements at the same time. The examination of the responses by means of a special apparatus—the Reid apparatus for testing flying aptitude—for the purpose is of great value in ascertaining a pilot's powers of performance.

Lack of aptitude for flying, therefore, may be due either to defective afferent impressions—chiefly from the eyes and the muscles, or to defective co-ordinated movements.

Further, to be a safe pilot, an individual must possess accuracy of judgment and coolness in emergency, also great powers of physical endurance to enable him to withstand high altitudes or long hours, as well as the effects of quick rotary movements in aerobatics and the effects of gravity after diving quickly or when rapidly turning at full speed at a sharp angle.

The effects of altitude call for especial consideration from the point of view of the pilot. In addition to the effects of diminution of oxygen supply, the effects of extreme cold and the actual diminution of the air pressure have to be considered.

The main effects of diminution of pressure in itself are due to the expansion of the air enclosed within the middle ear. This tends to expand as the pressure is reduced, but the pressure of such air is, generally speaking, automatically adjusted by swallowing. Therefore, only subjects suffering from catarrh of the Eustachian tubes leading from the throat to the middle ear are likely to suffer any inconvenience from this cause. The same is true when atmospheric pressure is again increased on coming down from average heights (1000-2000 feet). The movement of swallowing again automatically adjusts the pressure. When descending from greater heights, the increased pressure on the ear drum through the outer ear may be counterbalanced within the middle ear by gently blowing up the ear drums, while holding the nose, by the movements of forced expiration, a device well known to all pilots. Where Eustachian obstruction exists, however, a pilot may suffer considerable inconvenience during descents, especially if undertaken too rapidly. Diminution of pressure also causes any gas within the intestines to expand. Although in some cases this may affect breathing by hampering the action of the diaphragm, generally speaking, as the amount of this gas is not normally large and its expansion induces peristalsis of the bowels, it is soon voided from the body and inconvenience from this cause is rare. The idea that at great heights there is a danger of trouble arising in the body from the release of gases into the blood owing to the diminution of pressure, such as takes place in the diver or compressed air worker, is erroneous. In the case of airmen the diminution of pressure at present is not sufficiently great or rapid to bring about any liberation of gases held in solution in the blood plasma.

Since 1878 it has been known that the chief cause of 'mountain sickness' or 'altitude sickness' is lack of proper oxygenation (anoxæmia) of the body owing to the rarefaction of oxygen in the air breathed. Experiments conducted in rarefaction chambers, as well as at high altitudes, such as Pike's Peak and Monte Rosa and the Andes, have fully proved this point. In respect of life at high altitudes, however, a certain degree of bodily acclimatisation takes place after the first few days, which is not the case in respect of flying. In an aeroplane, the length of stay at high altitudes is not sufficient to induce any acclimatisation, beyond possibly a transitory concentration of the blood plasma. This will be appreciated when it is realised that a man who flies 240 hours yearly in reality only passes 10 days out of 365 reaching and returning from his maximum heights.

In high flying the cause of trouble is the demand by the body for a normal supply of oxygen under conditions where the head of pressure of the 'pressure feed' is failing. At 19,000 feet, although the percentage composition of the air is unaltered, the total atmospheric pressure is only half normal; that is, the pressure which drives the oxygen into the blood is only half the normal, and accordingly the body will receive only half the amount to which it is accustomed—actually less, since here no allowance is made for the pressure of water vapour. The gradual failing of the pressure feed of oxygen to the body with increasing height necessitates deeper and deeper breathing to get in the required amount of oxygen and a proportionately quicker rate of heart beat to keep up the circulation of the blood, which carries the oxygen to the seats of combustion. For this work alone, more and more oxygen is required in an atmosphere in which oxygen is progressively diminishing. This throws a certain strain upon the muscular mechanism of respiration and upon the circulation; a strain which is increased owing to the relatively immobile position of the pilot. Unless, however, such strain is unduly severe or prolonged, it is readily tolerated by the body up to heights of 18,000 or 19,000 feet, provided that the respiratory and circulatory mechanisms are properly tuned up.

If the embarrassment of the respiration and circulation were the only effects of altitude, then until this became really excessive, the administration of oxygen to pilots, although an advantage as conserving the normal action of the lungs and heart, would not be altogether a necessity. A more subtle, and therefore often a less appreciated, danger exists which renders the administration of oxygen necessary, namely, a dulling of perception and judgment in addition to a gradually increasing general muscular weakness.

This dulling of perception and judgment begins lower, in most people after 12,000 to 15,000 feet. The pilot himself may not be, and usually is not, aware of it, and even possibly has an extra feeling of confidence. This may be exemplified by an observer who, during the War, returned from high flying reconnaissance, thoroughly pleased with himself, only to find later that he had taken 18 photographs on the same plate; and by a pilot, who, meeting enemy aircraft at 19,000 feet, in spite of the protests of his observer, cheerfully waved his hand to them but took no further action. Nearly all pilots notice the tendency to somnolence at high altitudes; many have difficulty in finding their way, being able to see the ground but not to read their maps. As a rule, scout pilots are less affected by altitude than high reconnaissance pilots, since they do not maintain high altitudes for the same length of time. At great heights it takes longer to see, to hear, and to act. The lessening of muscular power is more obvious; most pilots are aware of the difficulty of swinging a gun or even drawing the shutter of the camera at very high altitudes.

With aircraft going possibly to 30,000 feet or more, the danger to the pilot is greatly increased, and the use of oxygen is absolutely necessary. The effects of altitudes of 25,000-28,000 feet have been long known. Glaisher in 1862 noticed that at 26,000 feet, although he could see his instruments, he could not read them. Shortly afterwards he became paralysed in his hands, as did his assistant, who, however, managed to pull the valve rope with his teeth. In 1875 three Frenchmen, Croce, Spinelli, and Tissandier, made their famous ascent, only Tissandier surviving. Although warned of the necessity of using oxygen, they were all paralysed before they realised the necessity of taking it. Tissandier gave a graphic account of his experience, from which the following is quoted: "At 26,000 feet the condition of torpor which comes over one is extraordinary. Body and mind become feebler little by little, gradually and insensibly. There is no suffering. On the contrary, one feels an inward joy. There is no thought of the dangerous position; one rises and is glad to be rising." The balloon ascended to 28,820 feet, and then descended.

Recently, in November 1927, Capt. Gray, of the United States Army Aviation Service, after ascending to 42,470 feet, lost his life during the descent at about 29,000 feet owing to his oxygen running out, probably owing to a miscalculation in the time of climbing and descent.

Oxygen abolishes the troubles of altitude which are due to oxygen want. The man with oxygen perceives and acts far more quickly and accurately than does the man without oxygen. It is for this reason that during the War all long-distance bombers and high photographic aircraft, both enemy and British, were eventually equipped with oxygen apparatus. On such aircraft the use of oxygen is an absolute necessity if really efficient service is to be rendered.

When oxygen is carried it should be used throughout the flight, beginning before the aircraft leaves the ground. It should not be reserved until the individual feels he wants it, since the effects of want of oxygen which matter most are apt to be unnoticed by the individual.

The best method of taking oxygen is by means of a mask. This is more satisfactory than by a pipe, because it ensures a larger amount of the oxygen delivered reaching the lungs; moreover, there is not the same danger of the tube being blocked by frozen condensation, water, or saliva. Further, a mask also protects the face from frostbite. Instead of the usual mask some prefer a combination of mask and pipe, since it can be discarded more quickly should this be necessary.

The advantages derived from the use of oxygen at high altitudes may be summarised as follows:

1. It keeps a man alert and in a condition in which quickness of perception, accuracy of judgment and action are preserved to the full.
2. It gives a man more power to control aircraft, and gives the tactical advantages of height without its disadvantages.
3. It abolishes the disagreeable symptoms—headache, lassitude, etc.—which are so frequently experienced during and after flights at high altitudes.
4. It keeps the heart and respiration efficient for a much longer period and prevents their overstrain.
5. It helps to keep the body warm.

In addition to the effects of oxygen want, the effects of the cold of altitudes must also be borne in mind, since these in themselves tend to throw added strain upon the respiratory and circulatory mechanisms as well as inducing numbness and sensations of fatigue.

For success in flying, therefore, nervous stability, respiratory and circulatory efficiency are essential. It must be recognised that flying, especially military flying, imposes a very definite stress upon the body, especially when flights are made without the aid of oxygen for long periods at relatively high altitudes. When to this is added the stress of offensive and defensive warfare in the air, it is obvious that bodily strain or breakdown as the result of stress is likely to ensue if too prolonged.

The Correlation of Solar and Terrestrial Magnetic Phenomena.

By Prof. Sydney Chapman, F.R.S.

SCHWABE'S discovery of the eleven-year sunspot cycle was soon followed by the recognition of a parallel cycle in the variations of the earth's magnetic field. Since then long series of solar and terrestrial observations have been accumulated. Magnetic observations, though still generally made in the manner introduced by Gauss, have been extended widely over the earth, while remarkable developments in the technique of solar observation have provided a wealth of detailed knowledge of solar phenomena. Yet although great advances have been made in establishing correlations between the two sets of data, some of the principal relationships remain obscure, and some important lines of investigation have yet received little attention.

The great complexity of both sets of phenomena accounts for this position of affairs. As regards the magnetic variations, observations over many years had to be collected from numbers of widely separated observatories, each contributing three distinct continuous records (for the three components of magnetic force) before it was possible to grasp the main features of the phenomena, and distinguish between what is characteristic of a general world-wide system, with its intensity waxing and waning more or less as a whole, and what is merely transient and local. As regards observation of the sun, though any terrestrial observatory has the whole solar disc at once in view, it has required the work of generations of observers to afford our present immense but incomplete knowledge of the remarkable happenings over that great surface.

In the detailed study of the relationships between the two groups of phenomena, statistical methods based on the use of the Wolf-Wolfer sunspot numbers have been very fruitful. These numbers characterise the state of the sun's surface on each day in one important respect, namely, the number and area of the dark and relatively cold regions of the surface. Daily areas of the bright patches called faculæ, though available in the volumes of Greenwich observations, have been less used: there is a considerable degree of correlation between them and the sunspot numbers. Such 'daily character' figures for the sun have been compared with magnetic data chosen to represent the character of a day from the magnetic point of view. At first the magnetic data used for this purpose were generally drawn from the records of a single observatory (such as the daily range in the magnetic declination), but the need for some index less dependent on local and accidental changes at a single station gradually became felt. About twenty years ago a scheme was put into operation by which many observatories contribute data on which international daily magnetic character figures are based. These are designed to represent the degree of world-wide magnetic activity or disturbance present on each Greenwich day; they are not founded on any definite physical estimate of the degree of disturbance, but on a general impression of the smoothness or irregularity of the continuous records at each observatory. Attempts have been made, and are continuing, to devise a practicable quantitative method of assigning such figures, but no plan has yet met with general approval.

While the present system certainly has defects, in that in different years, or even in different months of the same year, the same character figure may be used for days experiencing different amounts of disturbance, yet these magnetic figures have proved of great value in the study of solar and terrestrial relationships. The outstanding example of their usefulness is Chree's demonstration, based upon them, of the tendency for unusually quiet or unusually disturbed magnetic conditions to recur after the lapse of one or more solar rotation periods. This 27-day recurrence tendency had been recognised by Maunder (and by some earlier workers), who brought forward very strong evidence in support of it, drawn from the Greenwich records of magnetic storms; but conviction of its reality became general only when Chree's important work confirmed it in an indisputable way.

This recurrence tendency throws light on the failure to find much correlation between the *daily* magnetic character figures and the *daily* sunspot numbers, a failure which at first sight seems remarkable in view of the increase in frequency of magnetic disturbance in years of high sunspottedness. The recurrence tendency, as clearly interpreted by Maunder, shows that the solar agent that produces terrestrial magnetic disturbance must proceed from some limited region of the sun's surface, and travel outwards from the sun in a confined stream, affecting the earth only when it is swept over by the stream, which rotates with the sun (though of course lagging behind the radius through the point of emission). Magnetic disturbance is, therefore, an indication of the impingence upon the earth of some solar emission, which must be of a corpuscular nature; nothing happens when the sun is not emitting the corpuscles, but, equally, nothing happens upon the earth even when the streams are issuing from the sun, except when they chance to encounter the earth. Even if sunspots were the source of such streams, the daily sunspot numbers would not be expected to show a close correlation with the daily magnetic character figures, because a spot contributes to the sunspot number during the whole period of its passage across the visible disc of the sun, whereas the supposed streams issuing from it would appear capable of affecting the earth during at most two or three days.

It is certain, however, that the streams in question do not always issue from sunspots, because magnetic storms are sometimes observed when sunspots have been absent from the sun's disc for some days. Moreover, modern theories of the sun's atmosphere render it likely that corpuscular emissions are due to a local and temporary rise in the radiation pressure, arising from an unusually bright region of the surface. Pike has shown that a dark region or spot behaves like a centre of attraction rather than of repulsion; chromospheric matter tends to flow towards it and not away from it. This accounts for the arched forms shown by many prominences; it would seem that the apparent attraction of the dark spots, and the deflecting influence of the magnetic fields associated with them, must often prevent the ejection of chromospheric matter right away from the sun. The frequency of such complete expulsion, as judged from the records of magnetic disturbance, is somewhat difficult to explain on the basis of our present knowledge of solar atmospheric conditions; but it would seem likely that bright regions associated either with no dark spots, or with several small dark spots rather than one or two large ones, would offer the most favourable conditions. This inference seems to be in agreement with a recent examination by Greaves and Newton of the solar conditions prevailing at the time of the greatest magnetic storms observed at Greenwich.

Whatever may prove to be the local conditions causing the emission of corpuscular streams from the sun, the emitting regions have the best chance of affecting the earth when they are fairly near the centre of the sun's disc. Consequently, the magnetic character figure for any day is likely to be associated with the presence of bright regions, perhaps of some special type, near the centre of the sun's disc, not necessarily on the same day but rather at a date preceding it, by an interval equal to the time taken for the solar agent to travel from the sun to the earth. The length of this interval is unknown, but there are some grounds, both theoretical and observational, for estimating it as from two to four days. As a means to a clearer understanding of the mode of action of the sun in producing magnetic disturbance, it is desirable to have a new set of solar daily character figures having special reference to the presentation of bright solar regions towards the earth. The Solar Physics Commission of the International Astronomical Union, and the International Research Council's Committee on Solar and Terrestrial Relationships, will discuss this proposal at Leyden in July, and it is to be hoped that some simple scheme will be devised for choosing solar daily character figures which will prove to be more closely correlated than the daily sunspot numbers are with the daily magnetic character figures.

There appears to be need also for a second set of magnetic character figures, or, as it is convenient to term them (to distinguish them from those already assigned under the international scheme), daily magnetic indices. The present character figures represent the degree of magnetic disturbance, but there are daily variations which go on independently, whether disturbance is present or not; the disturbance changes are simply superposed on the other daily changes, which are seen in their pure form on quiet days. For the sake of brevity it is convenient to refer to the two sets of changes, and the corresponding varying magnetic fields, by the symbols *D* (disturbance) and *Sq* (the solar diurnal variations seen in isolation on quiet days, though coexisting with disturbance on other days). The *D* and *Sq* fields both show a variation of average intensity in rough parallelism with the sunspot cycle, but in most respects they are strikingly different—in their distribution over the earth (and the change in this distribution throughout the year), and in their fortuitous variations of intensity from day to day. The fortuitous variations of intensity of *D* are represented by the magnetic character figures, but at present we have no index of the day-to-day variations of intensity of the *Sq* field. In the latter case the range of variation is much less than for magnetic disturbance, but the changes are both interesting and important; as yet very little attention has been given to them. They appear to be correlated only slightly with those of *D*.

In various papers I have indicated reasons for believing that the *D* and *Sq* fields are associated with different types of solar emissions, the variations of which determine the changes of intensity of *D* and *Sq*. As already stated, the *D* variations depend upon the impingence on the earth of corpuscular streams from the sun, while *Sq* appears to depend on the sun's ultra-violet radiation. In both cases the solar influence is exerted largely by the ionisation which it produces in the earth's outer atmosphere. If this hypothesis is correct, changes in the sun's ultra-violet radiation will affect the intensity of the *Sq* variations all over the earth. This appears to be the case with the eleven-year changes of average intensity of *Sq*, and is probably true also for the fortuitous variations, though this has not yet been definitely established. The difference between the nature of the solar influences which determine *D* and *Sq* renders natural the contrast between the character and changes of these two magnetic phenomena; it also indicates the desirability of a daily index of the intensity of *Sq* as well as of disturbance. One immediate application of such indices would be their comparison with the measurements of the sun's ultra-violet radiation which were commenced by Pettit at Mount Wilson in 1924; this work has shown that the radiation may vary considerably from day to day, and there is also an indication of a long period variation following the sunspot cycle. It is important to ascertain how closely the day-to-day variations of this radiation are in agreement with those of *Sq*.

Many other phenomena which, like *Sq*, are associated with the upper atmosphere, should also be compared with the variations of *Sq* as well as of *D*; among them may be mentioned the ozone content, the intensity of the luminosity of the night sky in different spectral regions, and the transmissibility of radio waves of different frequencies. It will also be of interest to examine the correlation between the changes of *Sq* and *D*; it may well be that the sun's ultra-violet radiation will show a close correlation with the sunspot numbers and the proposed new solar character figures for bright regions near the centre of the sun's disc, and that the comparative lack of association between *Sq* and *D*, and the greater range and abruptness of the changes in the latter, are due to the special feature that these depend on the conjunction of the earth with a limited solar stream.

For these reasons it seems likely that in time international co-operation will be desirable to assign to each day a magnetic index referring to the intensity of *Sq* on that day; but before such a proposal can profitably be discussed in detail, preliminary investigations of the *Sq* variations are necessary to ascertain how they affect different magnetic elements and different observatories. Mr. J. M. Stagg is at present co-operating with me in the first of such studies, confined to data from Greenwich and Eskdalemuir, on purely quiet days.

Obituary.

DR. JOHN HORNE, F.R.S.

IT is seldom that the death of a man more than eighty years of age can so truly be described as an irreparable loss to his science as can be said of John Horne, who has passed away with full mental powers and while completing a work on the geology of Scotland, which would no doubt have been a masterly digest of the voluminous and scattered literature, a luminous statement of the problems, and have been inspired by his contagious enthusiasm.

John Horne was born beside the Campsie Fells, near Glasgow, on Jan. 1, 1848. He was educated at the High School and University of Glasgow, but he did not graduate, as at the age of nineteen years, on the establishment of the Scottish Geological Survey in 1867, he was appointed one of the original members of the staff. His life was spent in its service, and after his retirement he often acted as its unofficial adviser.

Horne's two most important contributions to geology were his preparation of the memoir on the geological structure of the North-west Highlands of Scotland, which was written by himself and five colleagues, and the large volume, in collaboration with Peach and Teall, on the Silurian rocks of Scotland (vol. 1, 1899), which described in detail the structure of the Southern Uplands. In both cases Horne convinced Sir Archibald Geikie that Lapworth's interpretations were correct, and thus led to the abandonment of the previously accepted theory of the structure of north-western Scotland and to the scrapping of the Survey maps of large parts of the Southern Uplands.

Horne worked on all branches of Scottish geology. He was probably most interested in the pre-Palæozoic rocks and in glacial problems, and he was the author of the report of the British Association Committee supporting the direct marine origin of the high-level glacial clays at Clava. His greatest single achievement was his administration of the Geological Survey of Scotland from 1901 until 1911. He was a tactful genial chief who gained the enthusiastic support and affection of all his staff; he was an active reformer and secured the great improvement in the Scottish maps by the introduction of colour printing. His success in gaining the confidence of the Scottish coalowners secured for the Survey full and harmonious co-operation with the mining industry. In his association with others he was helped by his keen sense of humour; he had an inexhaustible fund of racy anecdotes, which he told brilliantly. His death will be widely felt as a personal loss, for he had great gifts of friendship. He was respected and beloved by all who knew him well.

The wide recognition of the importance of Dr. Horne's work is shown by his many distinctions. He was elected a fellow of the Royal Society in 1900; he was LL.D. of three Scottish universities; he was president of the Royal Society of Edinburgh (1915–19), president of the Geological Section of the British Association at the Glasgow meeting in 1901, chairman of the council of the Royal Scottish Geographical Society, and he received the Wollaston and Murchison Medals of the Geological Society.

While on the Survey, Horne formed his beautiful and fruitful friendship with B. N. Peach. They first worked together in southern Scotland, but as Horne was dissatisfied with the official treatment of some of their results, he persuaded Peach to join him in some unofficial work; to go as far from Edinburgh as was possible in Scotland, they selected the Orkneys and Shetlands. His literary co-operation with Peach began with short papers in 1880 on the glacial geology of the Orkneys and Shetlands and on the North-west Highlands in 1883; it was continued in important memoirs on the Orkneys and Shetlands and Caithness, the Canonbie coalfield, and the volcanic rocks of the Old Red Sandstone.

According to a popular fallacy, Horne was the patient persevering plodder, whose main usefulness was as the amanuensis of his brilliant associate. Horne brought to the work keen insight, a sound, steady judgment, and powers of searching criticism which he applied remorselessly to every problem on which he worked. He was the leader in their joint work. After their retirement from the Geological Survey, Peach and Horne began together a "Geology of Scotland," which was put aside time after time because Horne would not accept some of Peach's views and could not get a satisfactory statement of his opinion for publication. The book was taken up again after Peach's death two years ago, but the interval has not been sufficient for its completion. The manuscript, it may be hoped, is sufficiently far forward for publication, for it should prove of the greatest value to geology, and a worthy monument to its author.

Horne's name will endure beside those of Lapworth and Judd as the men who, by their accuracy of insight and originality of conception, have left their mark most deeply on Scottish geology.

J. W. GREGORY.

MR. W. E. PLUMMER.

BY the death, on May 22, of Mr. William Edward Plummer, Director of the Liverpool Observatory, at the age of seventy-nine, there passes an astronomer of a bygone generation who did his full share of work for the science. His work lay in various fields, and it was his fortune to be one of the earliest of those who practise the newer astronomy of the photographic plate and its measurement.

Greenwich Observatory has been the nursery of many who have proved to be competent astronomers and have held responsible positions in other British or Colonial observatories, and Plummer was one of these. In 1864, at the age of fifteen, he obtained employment as a computer in the Royal Observatory, and spent four years, doing the routine arithmetic known as reduction of observations, when he was recommended for a post then vacant in Mr. Bishop's observatory at Twickenham. This was a private observatory built by Mr. George Bishop, a successful business man, at his house in Regent's Park, London, made famous in the middle of last century by the labours of Dawes, Hind, and others, whose services he retained consecutively as observers, which on the death of the founder in 1861 was removed to Twickenham by his son George Bishop, junior. In 1853, Hind, who was then in charge and had been specially active in the discovery of minor planets, was appointed Superintendent of the *Nautical Almanac* Office, but he nevertheless continued to exercise a general superintendence of the observatory, the actual observers being in succession Pogson, Vogel, Marth, Talmage, and, after 1868, W. E. Plummer.

Though Hind was then acting in an advisory capacity, it seems evident that Plummer was responsible for the actual conduct of the observatory, and to him, therefore, must be given the credit for the results, though he always acknowledged his indebtedness to Hind for whatever skill he had as an observer. It was an avowed principle of the elder Mr. Bishop that the observatory "should do something," and during Plummer's tenure of office the subject selected was apparently cometary astronomy, and so early as 1870 a paper was contributed to the *Monthly Notices of the Royal Astronomical Society*, "On the Orbit of the Comet of 1683," that Plummer had recomputed from Flamsteed's observations at Hind's suggestion. This was followed by other papers of similar kind, and though the preparation and publication of engraved charts of the stars within 3° of the ecliptic, which had been a staple work of the observatory, was continued, the computation of elements of orbits of comets, ephemerides, and other cometary investigations, formed a large part of Plummer's work during the six years he was at Twickenham.

Mr. Bishop's observatory was closed at the end of 1876, but in 1874, Plummer had been chosen by the Rev. Charles Pritchard, Savilian professor of astronomy at Oxford, as his assistant in the University Observatory which was then being built, his appointment dating from September 1874, though he began to give help on the completion of the establishment earlier. His work at Oxford was naturally the carrying out of the researches initiated and organised by the professor; measures of photographs of the moon, wedge photometry that was used for the determination of the magnitudes of all naked-eye stars from N.P.D. 0° to 100°, which was published as the "Uranometria Nova Oxoniensis," and photographic stellar parallaxes, all of which were pieces of work of a novel kind requiring skill and resource in their prosecution. The last named may be the first research of the modern type which depends on the measurement of photographic plates. He represented the Oxford University Observatory at the meeting of the Permanent Committee of the Astrographic Chart in Paris in 1891, when decisive points for beginning the work were settled.

There is ample evidence of the esteem in which Plummer was held by Prof. Pritchard and how much his work was appreciated. The University of Oxford recognised the value of his services by bestowing on him the honorary degree of M.A. Two rather extensive investigations were made by him and published under his own name whilst at Oxford; in the *Monthly Notices* for February 1881 he discussed the motion of the Companion of Sirius, comparing its observed positions with those given by the orbit predicted from the variations in the position of the primary, and arrived at the conclusion, before suggested, that the small star observed may not be actually the perturbing body; the other was a determination of the solar motion from stellar proper motions, published in vol. 47 of the *Memoirs R.A.S.*, which modified previous results similarly obtained only slightly.

In 1892, the year before Pritchard died, Plummer was invited by the Mersey Docks and Harbour Board to be Director of its observatory at Bidston, Birkenhead, and here he remained until the end of his life. The duties of the post are mainly connected with the needs of the port, and include the determination of time, the testing and rating of chronometers for the mercantile marine, the keeping of meteorological records, and attention to a seismograph. But besides the instruments that these tasks require, the observatory possesses an 8-inch equatorial, and for many years this was used for the observation of comets as they appeared, of occultations of stars, and for other purposes, but circumstances of the War and Plummer's advanced age prevented such observations recently. He contributed the annual report on cometary astronomy to the *Monthly Notices* up to the year 1912, and wrote papers on the same subject for the local astronomical society, in which he took much interest, being its president for several years. He held the honorary position of reader in astronomy in the University of Liverpool, and his efforts in the cause of local scientific education received recognition by the award to him of the Kingsley Medal by the Chester Literary and Philosophical Society.

Plummer took an early interest in seismology, and was for many years a member of the Seismological Committee of the British Association. Before the beginning of his final illness, he co-operated actively in the foundation of the Tidal Institute, the work of which is already proving to be of importance.

Mr. Plummer leaves a family of two sons and a daughter: the elder son, Prof. H. C. Plummer, was Royal Astronomer of Ireland in the years 1912-21, and is now professor of mathematics in the Military College of Science, Woolwich.

DR. EDGAR WILLIAM WILLETT, who died at Hartfield, Sussex, on April 12, aged seventy-two years, was a son of the late Mr. Henry Willett of Brighton, and inherited his father's interest in geology. In 1881 he explored the mammal deposit in the Purbeck Beds at Swanage, and read a paper on a jaw of Triconodon to the Geological Society. In 1901 he investigated the occurrence of glossy flint implements in a gravel pit in Savernake Park, and read a paper on the subject to the Royal Anthropological Institute.

WE regret to announce the follow

Mr. Cyrus C. Adams, of New York, and formerly associate editor of the *Bul* American Geographical Society, aged seventy years.

Dr. Bird T. Baldwin, head of the Iowa Chi. Welfare Research Station at the University of Iowa, and a past secretary and chairman of Section Q of the American Association for the Advancement of Science, on May 12, aged fifty-three years.

Prof. Gaetano Lanza, Cavaliere dell' Ordine dei Santi Maurizio e Lazzaro, emeritus professor of theoretical and applied mechanics at the Massachusetts Institute of Technology, on Mar. 21, aged seventy-nine years.

Prof. R. Lepetit, president of the Italian Society of Chemical Industry, known for his work on the synthesis of indigo and for the production of 'Italian green,' on Mar. 27, aged sixty-two years.

Prof. I. P. Roberts, formerly professor of agriculture, dean of the New York State College of Agriculture, on Mar. 17, aged ninety-four years.

Dr. Joseph Nelson Rose, associate curator of botany in the U.S. National Museum, an authority on the Cactaceæ and other Mexican and South American plants, on May 4, aged sixty-six years.

Prof. Arthur Schonfliess, of the University of Frankfurt on Main, the well-known mathematician, author with Prof. Nernst of "Einführung in die mathematische Behandlung der Naturwissenschaften," which has run into ten editions, on May 27, at the age of seventy-five years.

News and Views.

THE physical inheritance of man having been placed in proper relation to its animal ancestry, Sir Arthur Keith turns to man's mental attributes, and at the University of Manchester on May 9 delivered what may be regarded as a supplement to his British Association address at Leeds. The spiritual characteristics of mankind have always proved the most obstinate to be enrolled under the banner of evolution, and Sir Arthur's frank statement of his conclusions has given rise to much newspaper controversy, some of which scarcely did justice to his views. The Manchester lecture appears under the title "Implications of Darwinism" in the *English Review* for June; but the title might as well have been "The Uniqueness of Man's Spiritual Attributes," for care is taken to show that the crude mental inheritance derived from his animal ancestry is overlaid in man by a more perfected control. It comes to this: that while man's brain, and with it man's mentality, are grounded upon those of his ancestral apes, the balance has been altered by the expansion and finer development of the brain matter, so that what are looked upon as higher centres predominate over the lower or crude animal centres.

SOME of the specific points made by Sir Arthur Keith may be instanced. He rejects duality in the brain: there is here no compound of substance and spirit, but a living organ and its essential manifestation—"mind, spirit, soul are the manifestations of a living brain just as flame is the manifest spirit of a burning candle." Human nature is in its basis animal. There is the same sort of drive induced by the primary instincts of hunger or sex, and the more primitive the race of mankind the more bestial is the response to the urge. But repression is the normal means of human progress, and the higher the stage of civilisation the more the elemental instincts are held in control by the development of the higher powers of reason. Yet a complete rationalising of mankind is impossible and undesirable, since a complete subordination of the primary instincts would mean race suicide. "Our aim should be not to eradicate the animal propensities within us, but to bend them so as to serve best the interests of both individual and country."

ALTHOUGH the British School of Archæology in Jerusalem was established in 1919 only, it has already done much valuable work in archæological exploration. The discovery of the Galilee skull is alone of sufficient importance to justify its existence. It has, however, done much more. As the headquarters of British students and in some sort a centre of British society in Palestine, it has both served science well and also enhanced British prestige among the people in a way that is difficult for those unacquainted with conditions in the Near East to appreciate. Under the Directorship of Prof. John Garstang, the School was also responsible for the functions of a department of antiquities, but the double duties were made distinct in 1926, when a separate organisation for the record and preservation of archæological remains was set up. In the following year the Government grant of £500, upon which the School had been largely dependent, was discontinued. Now, therefore, the School is entirely dependent upon untary subscriptions, and there is considerable danger that its activities may come to an end unless a guarantee can be obtained that an adequate annual sum will be forthcoming. An appeal has been issued asking for a sum of £1150 per annum, but the particulars given in the statement show that this is sufficient for bare maintenance only, and that for anything like effectual performance of its functions, at least £2000 per annum is required. It would be less than creditable to Great Britain if the School of Archæology in a mandated territory, in which other nations maintain centres for organised research, had to be discontinued. Further, Palestine, it is scarcely necessary to point out, is a country not only intrinsically of the greatest archæological and historical importance, but it is one to the culture of which the English-speaking peoples owe much through the traditional position of the Bible in their life and literature. Subscriptions may be sent to the British School of Archæology in Jerusalem, c/o Palestine Exploration Fund, 2 Hinde Street, London, W.1.

FURTHER broadcast messages from General Nobile give an account of the wreck of the *Italia*. The airship appears to have lost buoyancy and descended rapidly, striking the ice. More than half the crew reached the ice in safety, although two were injured. The wreck, with the remaining seven of the crew, was carried onwards. These men are probably on the ice to the east of the main party, but their position is unknown. The greater part of the expedition's stores is with them. Whether the shipwrecked men reach land or remain on the drifting ice, their rescue is not improbable provided they manage to secure food from seals or polar bears. General Nobile, however, seems to lack firearms, and there is no one with the party who is versed in Eskimo methods of hunting. Captain Sir Hubert Wilkins, writing in the *Times*, points out that the expenditure of energy of the shipwrecked men will be small if open water prevents their travelling over the pack and that consequently a small amount of food should suffice. The large aeroplanes now on their way to Spitsbergen will be useful in locating the parties and dropping food and firearms, but a combination of the efforts of ship and dog teams indicates the most likely road to safety.

THE British Non-Ferrous Metals Research Association has just published its eighth Annual Report, from which it appears that its expenditure on experimental work during 1927 amounted to no less than £20,000. As an example of the practical results obtained, the research on lead cable sheathing has led to the discovery of ternary alloys which are greatly superior to the usual sheathing material, and the Post Office has now ordered a new submarine cable to be sheathed with one of them, and manufacturing production has been begun. These new alloys have been protected by patent. The work on alloys suitable for exposure to high temperatures has also made important progress, and is closely connected with an investigation of the causes of wastage of locomotive firebox stays, a subject of great importance to railway engineers. The systematic study of the effect of various impurities on copper, and application of spectroscopic methods to the laboratory analysis of metals and alloys, are among the other interesting subjects of research in hand. It has been the experience of this and other research associations that the direct communication of the results of laboratory research to manufacturers does not always lead to their full utilisation, and it has been found desirable to set up a new Development Section, the function of which is to assist members to apply in their works the scientific results obtained by the investigators. This Section, staffed by qualified men, has already proved a great success, and its work will be followed with interest by all who are concerned with the proper utilisation of the results of science by industry. It is certain that the gap exists, and this effort to bridge it deserves success.

AN earthquake of moderate intensity was recorded at Kew Observatory at 6 hr. 26 min. 18 sec. G.M.T., on June 15. The epicentre was about 7000 miles away, but the initial impulse was too small to give any indication of the bearing. The earthquake that disturbed the greater part of southern Mexico late in the evening of June 16 was registered at Kew Observatory on June 17 at 3 hr. 31 min. 49 sec. G.M.T. The records indicate that the epicentre must have been under the Pacific Ocean off the coast of Mexico (near lat. 15° N. long. 100° W.). The earthquake was evidently of a strength far greater than the first accounts seem to indicate. From the seismogram obtained at the Government station at Tacubaya it is inferred that the epicentre lay 262 miles south-east of Mexico City, and this agrees nearly with the statement that the damage was greatest in the town of Oaxaca, which lies about 230 miles south-east of that city. It is probable, however, that the focus extended a considerable distance to the north-west of Oaxaca, for in Mexico City many lightly constructed houses collapsed and water-pipes burst, while the shock continued of great strength for about four minutes. At the Oxford University Observatory, a great earthquake, with its epicentre 82½° distant and probably in Central America, was recorded at 3.20 A.M. on June 17.

THE Bill to regulate the date of Easter Day and days dependent thereon came before the House of Commons on June 15 and received a third reading. The Bill as it now stands provides that Easter Day shall be the first Sunday after the second Saturday in April in the calendar year next but one after the commencement of the Act and in all subsequent years. A further clause provides that the Bill shall come into operation on a date to be fixed by Order in Council, but not until a draft Order has been approved by both Houses of Parliament.

AT the invitation of the Rector and the Senate, Sir J. C. Bose delivered a series of two lectures before the University of Vienna on June 9–11. The first, on "The Plant as a Sensitive Structure," illustrated by experiments, demonstrated identical physiological mechanism in plants and in animals. The second, on "The Action of Drugs and Alkaloids on Pulse-Beats of Plant and Animal," was given before members of the Faculty of Medicine, who were greatly interested in the effect of new Indian drugs on the animal heart, demonstrated by the resonant cardiograph, recently constructed at the Bose Institute. Much interest was also shown in the extreme delicacy of a battery of new instruments by which the activities in the interior of the plant may be shown. The infinitesimal contraction recorder measures the contraction of a single cell under stimulation; the pumping action of the active layer in propulsion of sap in plants was visibly demonstrated by an apparatus which magnified invisible cellular pulsations more than a million times. In recognition of the importance of his discoveries in advancing knowledge of plant physiology, Sir J. C. Bose has been elected a foreign member of the Academy of Sciences, Vienna.

Prof. Ruggles Gates, professor of botany at King's College, London, sails for Canada on June 23 on an expedition down the Mackenzie River. A permit has been received from the Canadian Government to carry on botanical and anthropological investigations in the North-West Territories and Mackenzie River District. He is taking a cinema camera and 3000 feet of film, in addition to photographic apparatus and collecting materials, which will be admitted free of duty. The intention is to compare the flora of this region with the tundra of Russian Lapland, and to make an anthropological study of Eskimo and half-breeds in comparison with the Ojibway Indians of Northern Ontario. It is hoped to include in this study the blood groups, as well as skin, hair, and eye characters. The Royal Botanic Gardens, Kew, is supplying plant-drying apparatus, and the Governor of the Hudson's Bay Company has made a grant towards the expenses of the expedition. Mr. K. Mellanby, a young botanist from Cambridge, will accompany Prof. Ruggles Gates.

In December last there was published in New York the first number of an illustrated monthly journal bearing the name *Evolution*. It has the active support of the leading biologists of the United States. Its editors announced in the first issue that *Evolution* "will carry the positive message of facts from every field of natural science and leave it to the reader to make his own mental readjustment." A survey of subsequent issues shows that this policy is being successfully carried out by zoologists and anthropologists of the highest standing, and for the modest sum of ten cents the American public can learn what scientific men have to teach concerning man's origin. The chief aim of *Evolution* is to deprive "fundamentalists of having a strategic advantage in their nearness to the public ear, men of science being separated from the masses by their vocabulary, dislike of publicity, and absorption in work." It is, perhaps, too much to hope that this new venture will gain the ear of Fundamentalists, but it will certainly provide its readers with sound science plainly stated, and hence we wish it every success.

In connexion with the physical and chemical survey of the coal resources of Great Britain, the Department of Scientific and Industrial Research has recently appointed a committee to deal with the South Wales Coalfield. The committee includes representatives of the Monmouthshire and South Wales Coal Owners' Association, the South Wales Institute of Engineers, the Geological Survey of Great Britain, and the Department of Scientific and Industrial Research. Similar regional committees are already at work in Durham and Northumberland, Lancashire and Cheshire, South Yorkshire, Nottinghamshire and Derbyshire, North Staffordshire, and in Scotland. The object of the survey is to investigate the characteristics of the various coal seams with the view of their utilisation to the best advantage. Local laboratories are established in each area for the examination of samples and, when necessary, large scale investigations are carried out at H.M. Fuel Research Station or elsewhere. The work of each committee is to advise as to which seams should be investigated, to recommend what large scale work should be undertaken, and to bring to the Department's notice any problems of particular local interest which may require investigation.

For fifty-eight years the Pharmaceutical Society of Great Britain has published annually a *Year-Book of Pharmacy*. The interest taken in pharmaceutical and pharmacological research and the development of the pharmacological activities of the Society, indicated by the recent establishment of pharmacological laboratories, have rendered it desirable that recent work should be published or reviewed more promptly than can be the case with a yearly publication. The Society is therefore issuing a *Quarterly Journal of Pharmacy and Allied Sciences*, incorporating the *Year-Book of Pharmacy*, the first number of which we have recently received. The first 60 pages are occupied by original papers on pharmacology and pharmacy: the remaining 100 pages are devoted to abstracts on the chemistry of drugs, pharmacognosy, pharmacy, pharmacology and therapeutics, clinical tests and new remedies. Among the papers in the first part, the following may be noted: the pharmacological assay of digitalis by different methods, by J. W. Trevan, E. Boock, J. H. Burn, and J. H. Gaddum; a method of assay of the antirachitic vitamin D, by K. H. Coward; the growth-promoting properties of vitamin D, by A. L. Bacharach; strychnine hydrochloride: its composition and solubility, by J. E. Driver and S. P. Thompson: the solubility and rate of solution of arsenious oxide B.P., by G. E. Trease. In her paper Dr. Coward advocates the use of a 'unit' of vitamin D activity: it is suggested that the standard be a stable preparation of irradiated ergosterol, and that 0·0001 mgm. of this preparation be taken as the 'unit.' This quantity will suffice to give healing of rickets in rats maintained on a rachitic diet, when administered to the animals daily for 10 days. The *Journal* should be read by all pharmacists and pharmacologists: it should be especially useful to those interested in the methods of biological assay, which are assuming an increasing importance in pharmacology. We shall await further numbers with interest.

The King has approved of the following title being taken by the Right Hon. Sir Alfred Mond, Bart.: Baron Melchett of Landford, in the County of Southampton.

The Institution of Electrical Engineers will hold a conversazione at the Natural History Museum, Cromwell Road, S.W.7, on Thursday July 5, at 8.30 P.M.

Prof. J. C. McLennan, professor of physics in the University of Toronto, will deliver the Bakerian Lecture before the Royal Society on June 28; he will take as his subject "The Aurora and its Spectrum."

The diploma of honorary membership of the University of Innsbruck has just been conferred on Mrs. Ogilvie Gordon in recognition of her valuable geological researches on the Dolomites of South Tyrol. Mrs. Ogilvie Gordon has also been nominated as an honorary correspondent by the Geological Survey of Austria.

The appointments to scientific and technical departments made recently by the Secretary of State for the Colonies include a cotton investigator, Mr. T. C. Cairns, and a game ranger, Captain J. Minnery, to Tanganyika Territory; a live-stock officer, Mr. W. D. D. Jardine, to Kenya Colony; an assistant conservator of forests, Mr. D. McIntosh, and an assistant manager, oil palm plantation, Mr. I. G. C. Squire, to Sierra Leone.

The Albert Medal of the Royal Society of Arts for the current year has been awarded by the Council, with the approval of the president, H.R.H. the Duke of Connaught, to Sir Ernest Rutherford, Cavendish professor of experimental physics in the University of Cambridge, "for his pioneer researches into the structure of matter." The Medal was founded in 1863 as a memorial to Prince Albert, for eighteen years president of the Society, and is awarded each year "for distinguished merit in promoting Arts, Manufactures, and Commerce."

King Edward's Hospital Fund for London has arranged, by courtesy of a number of firms, a series of visits to factories in and around London which are the sources of many of the amenities of modern life and will be of interest to scientific workers. The programme includes the following works: Osram (General Electric Co., Ltd.) Lamp Works, Brook Green, Hammersmith (June 27); The Gramophone Co., Ltd. ("His Master's Voice"), Hayes, Middlesex (July 4); Kodak, Ltd., Wealdstone, Middlesex (July 11); Messrs. Bryant and May, Ltd., Fairfield Road, Bow (July 18); United Glass Bottle Manufacturers, Ltd., Anchor and Hope Lane, Charlton (July 25); Messrs. J. Lyons and Co., Ltd., Ice and Confectionery Factories, Greenford, Middlesex (July 30 and 31). Full particulars of the visits can be obtained from the secretary of the Fund, 7 Walbrook, E.C.4.

The Liverpool meeting of the Institute of Metals, to be held on Sept. 4–7, is evidently proving attractive; already more than two hundred members—including many from overseas—have indicated their intention of taking part. The papers to be presented include a valuable series dealing with the die-casting of alloys, as well as the eighth report to the Corrosion Research Committee. A full discussion of corrosion problems will form a feature of the meeting, as is appropriate in a maritime centre such as Liverpool. On July 4 an election of members is taking place in connexion with the Liverpool meeting, full particulars of which can be obtained from Mr. G. Shaw Scott, Secretary, Institute of Metals, 14 Members' Mansions, Westminster, London, S.W.1.

The Swiss Society of Natural Science is holding its annual conference this year at Lausanne on Aug. 30–Sept. 2. The provisional programme which has been issued announces papers by Prof. E. Bosshard, of Zurich, on chemical industry, its past and future; Prof. C. Schröter, of Zurich, on a journey through Java in 1927; Prof. M. Askenasy, of Geneva, on the aims of research on tumours and the results already obtained; and Prof. A. Reymond, of Lausanne, on occult science in antiquity. The proceedings of the meeting will be organised in seventeen sections, covering all branches of science, pharmacy, engineering, the history of medicine and of science, etc. Communications for the sections should be notified to Prof. A. Maillefer, Musée de Botanique, Palais de Rumine, Lausanne, by June 30. Some beautiful and interesting excursions are promised. Full particulars of the meeting can be obtained from the president, Dr. J. Amann, 2 Avenue Rambert, Lausanne.

A recent *Daily Science News Bulletin* issued by Science Service, Washington, D.C., announces a gift by Mr. Jeremiah Milbank of 250,000 dollars for an international research upon infantile paralysis. Dr. William H. Park, of New York University, is chairman of the committee, and the universities of Chicago, Columbia, Harvard, New York, and Brussels, the Lister Institute of London, and the Metropolitan Life Insurance Company, will participate in the work.

Applications are invited for the following appointments, on or before the dates mentioned:—A full-time assistant-master for science and mathematics at the London County Council Beaufoy Institute, Prince's Road, Vauxhall, S.E.11—Education Officer (T. 1a), The County Hall, Westminster Bridge, S.E.1 (June 26). An assistant lecturer in physiology and an assistant lecturer in biochemistry at the University of Birmingham—The Secretary, The University, Edmund Street, Birmingham (June 28). A full-time teacher in the mechanical engineering department of Lincoln Technical College—The Principal, The Technical College, Lincoln (June 28). Two lecturers at the Municipal Technical College, Swansea, with qualifications in two of the following three subjects: chemistry, botany, pharmacy—Director of Education, Education Office, Dynevor Place, Swansea (June 28). A full-time assistant lecturer in engineering at the Technical College, Cardiff—The Principal, The Technical College, Cardiff (June 30). Principal of the Wigan and District Mining and Technical College—Registrar, Wigan and District Mining and Technical College, Wigan (June 30). An assistant master at the Rugby College of Technology and Arts, with good chemistry qualifications and subsidiary physics—The Organiser of Further Education in Rugby, 61 Clifton Road, Rugby (July 4). A lecturer in agricultural zoology at the University College of the South West of England, Exeter (for work jointly with the Seale Hayne Agricultural College, Newton Abbot)—The Registrar, University College, Exeter (July 4). An assistant lecturer in zoology at the University of Birmingham—The Secretary, The University, Edmund Street, Birmingham (July 5). A reader in materia medica and therapeutics at the University of Manchester—The Registrar, The University, Manchester (July 7). A technical officer at the Royal Aircraft Establishment, South Farnborough, for design and experimental work in connexion with electrical equipment for use on aircraft—Chief Superintendent (No. A 282), Royal Aircraft Establishment, South Farnborough, Hants (July 14). Candidates for not less than two vacancies for geologists on the Geological Survey of Great Britain—The Director, Geological Survey and Museum, 28 Jermyn Street, S.W.1 (July 14). A non-established draughtsman in the Ministry of Agriculture and Fisheries—The Secretary, Civil Service Commission, Burlington Gardens, W.1 (July 26). A senior lecturer in physics and applied mathematics at the Huguenot University College, Wellington, C.P., South Africa—The Registrar, Huguenot University College, Wellington, C.P., South Africa (Aug. 31). A professor of mathematics at the University College, Pietermaritzburg—The Registrar, Natal University College, Pietermaritzburg, Natal (Nov. 1). A zoological laboratory steward at University College, Hull—The Secretary, University College, Hull. A full-time science master at the Technical Institute, Tunbridge Wells—Dr. J. Lister, Technical Institute, Tunbridge Wells. Three junior assistants at the Directorate of Ballistics Research, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18. A capable research chemist or physicist in a research laboratory in London—Box No. 71, c/o NATURE Office, St. Martin's Street, W.C.2. A junior assistant at the Directorate of Metallurgical Research, Woolwich—The Chief Superintendent, Research Department, Woolwich, S.E.18.

Our Astronomical Column.

METEORS AND SKJELLERUP'S COMET.—Mr W. F. Denning writes: "The only nights favourable at Bristol for the observations of meteors, possibly connected with Skjellerup's comet, of last December, were June 10 and 11, which provided two excellent opportunities. The cometary orbit, however, approaches the earth's path to the nearest point on about June 7–8, so that this date had passed before the weather permitted suitable watching of the skies. Very few meteors were seen on June 10 and 11, and two only, out of about twelve observed, were directed from the region in which the cometary radiant was placed. There may have occurred a shower on preceding nights, but no information has come to hand with details of successful results, and I fear that none were obtained.

"Four fairly bright meteors were observed at Bristol, and as they may have been recorded elsewhere, I give their apparent paths :—

	G.M.T.	Mag.	From	To
June 10	11.5	1	313° + 69°	23° + 70°
„ „	12.5	Jupiter	325 + 56½	334 + 52
June 11	11.27	Jupiter	243 − 19	234 − 8
„ „	12.10	Jupiter	310 + 32½	308 + 31

The first two were observed by me; the others by an assistant. The radiants of the meteors were probably 251° − 25°, 310° + 62°, 251° − 25°, and 314° + 34°."

COLOUR PHOTOGRAPHY OF THE MOON.—Mr. F. J. Hargreaves, Director of the Photographic section of the B.A.A., was one of the first to obtain successful colour photographs of the moon; these were exhibited at a meeting of the B.A.A. some two years ago, and led to the conclusion that the colour of the greater part of the moon's surface resembles that of a weathered stone wall of a light brown or yellowish tint.

Mr. Hargreaves contributes an article on his photographic methods to the March number of the *Taylor-Hobson Outlook*, illustrated by two photographs; one is of the moon (not coloured) taken with a 6½-inch mirror and an equivalent focal length of 25 feet; the exposure was 2 seconds; a large amount of detail is visible both in the dark and brighter regions. The other is of the Andromeda nebula, exposure 1½ hours, focal length 20 inches; a good deal of detail is visible, the dark spaces between the whorls of the spiral being plainly discernible. It is noted that the picture of the farther edge of the nebula is some thirty thousand years older than that of the nearer edge.

These pictures are the more creditable in that the mounting of the equatorial is of the simplest character and almost entirely home-made. It will be remembered that the comet Grigg-Skjellerup at its return last year was first detected on Mr. Hargreaves's plates, although the huge instruments at the Yerkes and Bergedorf Observatories were already engaged in the search.

THE DISTANCES OF THE SPIRAL NEBULÆ.—An article by R. Hess in *Astr. Nach.*, 5561, brings out an interesting point regarding Dr. Hubble's estimates of the distances of the spirals. Hubble began by tabulating the apparent and absolute magnitudes of seven objects, including the Andromeda nebula, the two Magellanic clouds, and M 33. He thus deduced the average absolute magnitude of a spiral nebula as −15·0; he used −15·2 in deducing the distances of the fainter spirals from their apparent magnitudes. Mr. Hess points out, however, that in our star system there is a correlation between apparent and absolute magnitude; this feature also appears among the seven objects used for getting the scale; those with fainter apparent magnitude have also fainter absolute magnitude. Thus it is unsafe to use the value −15·2 derived from bright spirals as the correct mean to take for much fainter ones.

Mr. Hess admits that the material is insufficient to obtain the law of correlation, but he has made a preliminary attempt. He gives the following example of its application. Dr. Hubble estimated the distance of spirals of apparent magnitude 16·7 (which need an exposure of an hour with the Mt. Wilson 60-inch reflector) as 80 million light years. Hess's correlation law would reduce this to ten million light years, which would make the distribution of spirals in space some 500 times as dense as Hubble's value. No claim of accuracy is made for the correlation law deduced by Hess, but he seems to be correct in indicating the need for assuming such a law, which would lead to an appreciable diminution of Hubble's estimates for the fainter spirals.

BENGALI MARRIAGE AND COGNATE CUSTOMS.—Mr. M. M. Chatterji has published a number of notes on Bengali customs in the *Journal of the Asiatic Society of Bengal*, vol. 22, N.S., Pt. 6, which for the most part deal with rites and ceremonies connected with marriage. Prostitutes are devoted to their profession by a ceremonial or 'mock' marriage which is intended to preserve the religious purity of the system by an implied consent of the human or inanimate husband. The prostitute bears the mark of vermilion powder on her hair and the iron bangle on her left wrist which distinguish the married woman. The marriage may be with a degraded or pretended Brahman, with an idol, public or private, or with a long-lived shrub such as the tube-rose, of which the preservation becomes an anxious care. Should an idol which has been married be destroyed, as sometimes happens in the case of the private effigy, the surviving wife has to abandon all signs of wifehood. In the initiation into wifehood, on the appearance of the signs of puberty, the woman is segregated, not being allowed to see the sun or a male, in a cell or narrow room formed by a barricade in the corner of a room of two lines of bamboo branches on mud pedestals. She is under the supervision of a board of five women, of whom the chief must be a woman all of whose children are alive or, failing that, whose first-born child is alive. The girl's diet is carefully regulated, consisting mostly of uncooked vegetables and milk and its preparations. An important part of the observance is a bath on the fifth day in the unexcavated tank, which is not a tank but a platform of mud, which also appears in the ante-nuptial bath taken by both bride and bridegroom before marriage, when water is poured over the bathers. In the puberty custom, the girl's companions pelt one another with mud while the girl picks up clams which have been spread out on the bath and water poured over them. This may be regarded as indicating that originally this bath must have taken place in a stream or river.

HOURS OF WORK.—Report No. 47 of the Industrial Fatigue Research Board (London: H.M. Stationery Office), by Dr. Vernon and others, consists of two studies on hours of work, namely, the five-hour spell, and the two-shift system. It is found that the adoption of a rest pause within the 5-hour spell—with opportunity for refreshment—is desirable both for physiological and psychological reasons. The rest pause increases the efficiency of the workers, for, in various occupations the immediate effect of a rest pause was to increase the output. There is, however, a number of semi-continuous occupations where the rest pause is not practicable because the loss of time involved is greater than the nominal rest pause. It is suggested that it might be possible for different groups to take their rest successively. The two-shift system is the centre of much difference of opinion. Contradictory assertions are often made as to the effects of this system, assertions which it is difficult either to prove or disprove. This report is interesting for its negative character. Neither system seemed to show significant differences in any measurable standard, nor was there any difference in sickness. Where either system was in regular operation, workers seemed to adapt their habits and to be satisfied: a change over from one to the other was usually unpopular, and in some cases resulted in a high labour turn-over. The problems involved seemed to be rather of a social character and to be dependent on local conditions.

ANIMAL LIFE IN A PHILIPPINE HOUSE.—The various kinds of animal life that occur in a nipa dwelling-house in the Philippines form the subject of an interesting paper by Dr. F. X. Williams in the *Philippine Journal of Science*, vol. 35, January 1928 (pp. 53-118). During a residence of two and a half years, Dr. Williams has been able to record quite an extensive fauna sharing his dwellings in those islands. Scorpions, spiders, and centipedes are prevalent, and among the latter creatures a large species is recorded which was found in the nest of a sparrow, clinging around the bird's body with its head imbedded in the sparrow's side: the bird, it may be added, died from the attack. Termites are dealt with in some detail, and the author records the behaviour of the predaceous fly *Bengalia*, which he noted seizing these insects and carrying them near by to suck out their body-fluids. An unknown beetle larva living as an ectoparasite of a termite is figured. Wasps, bees, and ants are favourite groups with the author, who records a number of interesting observations on their economy. Among vertebrates, lizards are among the most constant representatives of a tropical house fauna. The so-called 'talking lizard' (*Gecko gecko*) is perhaps more often heard than seen, and is eager to devour such large insects as hawk moths and *Oryctes* beetles, or even small birds and bats. Among birds that live in houses of their own accord, the only truly domiciliary kind is the common sparrow (*Passer montanus*), while bats of several species are more frequent inhabitants.

BRITISH SPECIES OF PROTURA.—The Protura or Myrientomata are very minute, fragile wingless insects which remained unknown to science until the year 1907, when Silvestri erected a separate order for this reception. In the *Entomologist's Monthly Magazine* for May, Mr. H. Womersley describes three new British species of the genus *Acerentomon*, all from the southern counties of England. The descriptions are based upon single examples in each case, and although all three specimens were immature, the characters relied upon are stated to be constant throughout the different instars of any particular species, and are therefore to be considered specific. Mr. Womersley also provides a key to the British members of the order, and enumerates fourteen species up to date, of which eight belong to the genus *Acerentomon* Berl., three to *Acerentulus* Berl., one to *Parentomon* Wom., and two to *Eosentomon* Berl.

OXYGENATION IN RESEARCH.—L. R. Cleveland (*Science*, vol. 68, pp. 168-170; 1928), who by confining termites in oxygen at a pressure of 60 lb. per sq. in. for one hour has removed their protozoa without injuring the termites, suggests that a similar technique may be helpful in other investigations. He points out that it is an important and difficult problem to keep silkworms free from the protozoan *Nosema*, and that possibly by confining the eggs or cocoons of the silkworm in oxygen under pressure, this protozoan menace to the silk industry may be abolished. More than three hundred species of microsporidia, one or more species of the flagellate *Hexamitus*, and two genera of ciliates—*Ichthyophthirius* and *Chilodon*—are parasitic on fishes. It is known that *Hexamitus* can be killed by oxygenation and without the slightest injury to its hosts, and perhaps the other protozoan parasites of fishes as well as the trematode *Gyrodactylus* and the moulds (*Saprolegnia*) may be dealt with in the same way. By confining in oxygen under pressure insects concerned in the transmission of protozoa, it may be possible to obtain protozoa-free insects required for experimental work, and the method might be helpful in destroying the insects which infest grain and nuts. The fact that different protozoa react differently to oxygen, and that the death points are fairly separated, renders possible the removal of only some of the protozoa while leaving others, and hence observations on how the presence of one protozoan inhibits the multiplication of another. Dr. Cleveland further suggests that many of the examples of symbiosis should be re-investigated, *e.g.* insects with intestinal yeasts, or with intracellular yeasts and bacteria, to ascertain how, if at all, the micro-organisms aid their insect hosts or partners.

SEXUALITY IN THE MYCETOZOA.—The striking differences in structure exhibited by the various stages in the life-history of the slime-fungi have attracted the attention of many investigators, and although sexuality in the group was discovered by Jahn (1911) and recorded for several species, it has been left for Wilson and Cadman to work out a completed sequence of events and publish a detailed description of the whole process (*Trans. R. S. of Edin.*, vol. 55, part 3, No. 24). The complete life-history has been worked out for *Reticularia Lycoperdon* Bull., particular attention being paid to the accompanying cytological changes. This species differs from many others of the group in the absence of myxamœbæ and resting stages such as cysts or sclerotia in the life-history. Spore germination seems to depend on the osmotic pressure exerted by the surrounding liquid, and not on the presence of bacteria. The spores are uninucleate, and on germination give rise to small amœboid masses of protoplasm which pass into the flagellate form. On swarming, these cells withdraw their flagella, and then divide karyokinetically in a transverse plane. After a number of divisions the swarm cells become gametes, which fuse in pairs seemingly accidentally. Before the final fusion of the nuclei of two gametes, other swarm cells, from three to eight in number, are drawn into the fusion cell, the process being regarded by some authorities as 'ingestion,' by others as 'coalescence.' Wilson and Cadman consider the fact that the fusion cell is dominated by a diploid nucleus, and the entering swarm cells by haploid nuclei, constitutes a physiological difference between the two protoplasms sufficient to prevent their coalescing and become one. That this view may be the correct one is suggested by the fact that the nuclei of the entering swarm cells are digested in vacuoles and absorbed.

A BACTERIAL DISEASE OF COTTON.—The bacterial disease of cotton known as Angular Leaf Spot has recently assumed serious proportions in the Sudan. Hitherto, successful methods for its control have not been devised because the conditions for favouring or checking the disease were unknown. It could become prevalent under widely different climatic conditions, varying from desert to wet tropics, and further, its occurrence was independent of air temperature and soil acidity or alkalinity. R. E. Massey, however (*Annals of Botany*, 41, 497), has demonstrated a close correlation between soil temperature and the incidence of the disease. The experimental work was carried out on seedlings in boxes and also in the field, the temperature readings being taken at a uniform depth of 2 in., namely, that at which the seed is planted. Infection appears to be confined to a definite range of soil temperature. Whereas at 11°-20° C. it is slight, and not usually serious if conditions are favourable for the growth of the seedling, at 21°-26° C. infection is severe. At still higher temperatures, however, the intensity decreases, at 28° C. little or no infection being obtained, and at 30° C. the plant is generally immune. Preliminary experiments were also carried out with artificial inoculation, healthy seedlings being sprayed with water containing a suspension of the bacteria. If a cooling current of air was directed along the spray so that the soil and air temperatures were reduced from 34° to 22° C., marked infection was obtained. This furnished indirect support to Faulwetter's theory that splashing of raindrops was a means of transmission of the disease.

TRIASSIC FAUNA OF NORTH AMERICA.—In a monograph on the Upper Triassic marine invertebrate faunas of North America (*Prof. Paper*, 141, U.S. Geol. Surv.; 1927), J. Perrin Smith gives another instalment of his long-continued researches on the marine Trias. 314 species are described and illustrated by 121 plates. A summary of the geographical relationship of the faunas of the Triassic zones is given, and it is shown that at some periods the American Sea was connected with the Arctic and Oriental, at other times with the Mediterranean Sea. Some of the faunas have a wide distribution; that of the lower Noric coral zone extends from the Mediterranean region to California, and from thence to Alaska and the Himalayas. In all these regions it is characterised by the abundance of reef-building corals related to modern forms, which flourish only where the temperature is not lower than 74° F., and it is probable that this temperature extended up to Alaska. The ammonites form a large part of the Triassic fauna, and according to the author belong to two main stocks only, both descended from Carboniferous goniatites; one from the Gephyroceratidæ, the other from the Gastrioceras branch of the Glyphioceratidæ. In the Upper Trias there are numerous ammonoids showing dwarfed, degenerate, or reversionary characters, suggestive of racial old age.

MAGNETIC DECLINATION TABLES FOR THE MINING INDUSTRY.—For some years past, in response to appeals from mine-surveyors, particulars of the magnetic declination during each week have been supplied to the *Colliery Guardian* for speedy publication. As the usefulness of the data became familiar to surveyors, the need for modifications of the original scheme, and of additions to it, began to be felt. During the past year or more the subject has been much discussed in mining societies and publications, and representative requests for changes in the data supplied have been formulated and communicated to the Government departments concerned. These are the Royal Observatory, Greenwich, which is responsible for what is now the only complete magnetic observatory in southern England, at Abinger; and the Meteorological Office, which is responsible for the magnetic observatory at Eskdalemuir, just north of the Scottish border. Both observatories now provide data for each hour (originally only averages over two hours were published), these being mean values over the interval from one exact Greenwich hour to the next. The declination is given to the nearest half-minute of arc. Moreover, an indication is given, by attached symbols or special type, of the occurrence of unusual variation, within three intervals of range, in the course of any hour. This makes it possible for a surveyor anywhere in England or southern Scotland to form a rather accurate estimate, on any not too disturbed day, of the correction to be applied to a magnetic bearing for the departure of the declination at that hour from the mean of the day or year. Further, arrangements have been made by which duplicates of the original magnetographs can be purchased from the observatories at a small cost, so that for any special purpose still more accurate knowledge of the changes of declination may be gained than is permitted by the hourly tabulations.

Muller Hot Cathode Tube.—The X-ray tubes made by Messrs. Muller of Hamburg can now be obtained in Great Britain from Messrs. Watson and Sons (Electro-Medical), Ltd., of Sunic House, 43 Parker Street, Kingsway, and are described in a small booklet published by that firm. In these tubes the electrons which constitute the cathode stream are generated by a filament heated by a separate current, as in the more familiar Coolidge tube. The Muller tubes have, however, several distinctive features. The residual gas is helium, which, it is claimed, reduces the chance of molecular collision and also allows of a pure electronic discharge at a higher pressure than is possible with air. In practice, it is found that the helium-filled tube seldom breaks down from perforation. Several of the tubes are constructed on the line-focus principle. The filament of the cathode is so placed that the electrons emitted are projected on to the anode in the form of a line instead of a spot. The anode is made with the surface of the target more nearly at right angles to the incident beam than is usual, so that the line-focus, viewed from the direction of the principal ray of the X-ray beam, appears as a spot. Since X-rays are emitted in uniform intensity over an angle of nearly 180°, this arrangement does not reduce the intensity of the radiation to any extent, whilst the heat of the discharge is distributed over a wider area. Such a line-focus tube can therefore carry a heavier current than the corresponding tube of the ordinary type, without risk of overloading. It is necessary to take particular care in the centring and aligning of tubes of this type, as a loss of detail is noticeable if the tube is rotated to any degree, a loss which may be accompanied by somewhat curious astigmatic effects.

Crystal Structures of Benzene Hexabromide and Hexachloride.—Hendricks and Bilicke (1926) showed that benzene hexabromide and hexachloride both have four molecules in the cubic unit of structure. The crystal structure of these compounds is further discussed in the *Journal of the American Chemical Society* for March by R. G. Dickinson and C. Bilicke, who have obtained new X-ray data. The centres of the four molecules in the unit are at points equivalent to either $(\frac{1}{4},\frac{1}{4},\frac{1}{4})$ or (0,0,0), and the six bromine atoms nearest to these points form a regular octahedron or a ring in which the atoms are not coplanar, respectively. Stereochemical considerations favour the latter configuration, since if the cyclohexane ring has its centre at (0,0,0), the halogen atoms fall very nearly in tetrahedral directions from the carbon atoms and at distances of 1.94 A. from them. The configuration of the hexachloride molecule is shown by the experimental data to resemble closely that of the hexabromide.

A Quantitative Study of the Photochemical Activation of Sterols.—Recent discoveries have shown that rickets can be cured by sterols which have previously been exposed to ultra-violet radiation. In the *Journal of the American Chemical Society* for March, R. J. Fosbinder, F. Daniels, and H. Steenbook describe an attempt to determine the amount of energy necessary to secure a definite deposition of calcium in the bones of a rachitic rat. Specially purified cholesterol was used and, after exposure in different parts of the spectrum, was tested physiologically. It was found that only wave-lengths shorter than 313 millimicrons were effective in the process of activation, and with the Hg line at 265 mμ. a minimum energy input of 234 ergs was required to give a positive test. The energy input required increased with the wave-length up to 2730 ergs at 302 mμ. Assuming the Einstein law and the complete utilisation of all the light absorbed for the production of vitamin D, the results indicate that $3{\cdot}2 \times 10^{13}$ molecules or 2×10^{-8} gm. of vitamin D is sufficient to initiate a cure of rickets. This result may be compared with that of Rosenheim and Webster, who found that 1×10^{-7} gm. of irradiated ergosterol was sufficient to give a positive test. In view of the minuteness of these quantities, it seems impossible to relate the gross chemical or physical properties of the irradiated material with its antirachitic action.

The Rotating Loop Wireless Beacon.—The sixth special report of the Radio Research Board, by R. L. Smith-Rose and S. R. Chapman (London: H.M. Stationery Office, 1928. 2*s.* 3*d.* net), describes experiments carried out on a rotating loop beacon transmitter at Fort Monckton, near Gosport. The object of the investigation was to study the performance of the beacon when transmitting over land and sea, and in particular to ascertain the trustworthiness for navigation purposes of radio bearings taken under many different conditions. The experiments were made on board ship at many different distances from the beacon. The inaccuracies were found to be of the same order as those obtained in radio direction finding under the most favourable conditions. Up to distances of 50 miles, both by day and night the readings were sufficiently accurate for navigation purposes. Even at 50 miles the inaccuracy of the great bulk of the observed bearings was less than two degrees. When, however, the waves passed over land, appreciable errors occurred, and so it seems desirable that at least during the night time the path of the transmission should be entirely over the sea. The great advantage of the beacon system is that for reception only an ordinary radio receiving set is required. It is probable, therefore, that the beacon system will prove of great value in marine navigation. Experiments were also made with a closed loop instead of an open aerial, in order to compare the results obtained. The experiments prove that when an aerial is available it is always better to use it. Attempts were also made to improve the sharpness of the signal 'minima' by surrounding the whole of the rotating portion of the beacon by an open wire screen. A slight improvement in the sharpness of the minima was obtained, but it was largely masked by errors due probably to local conditions at Fort Monckton. The screen had certainly no detrimental effect on the radiation. It seems, therefore, that it would be possible to protect a rotating beacon from lightning by enclosing it within a symmetrical screen of vertical wires.

Coal Carbonisation Tests.—In amplification of the paragraph on the test of the 'Crozier' retort for low temperature carbonisation in our issue of June 9, p. 921, it may be said that the intermittent operation during the trial was enforced by the lack of electric power supply at Wembley. Although the retort is unsuitable for dealing with caking material, it is designed to deal with shales and lignites, and is claimed to be suitable for some British coals which are not now being carbonised.

Anthropological Research in Australia.

IT was announced in NATURE of Nov. 6, 1926, that the Rockefeller Foundation had made a grant of funds to the Australian National Research Council for anthropological research in Australia and the Pacific. With the help of these funds several important researches have now been carried out.

A systematic attempt is being made to collect as much information as possible about the surviving aborigines of Australia before it is too late. Mr. Wm. Lloyd Warner (University of California) has spent several months amongst the hitherto unknown natives of the north-eastern corner of Arnheim Land, where he has discovered an interesting form of social organisation and a highly elaborate system of totemism. He has now returned to the same region for a second season's work. Miss Ursula McConnel (University of Queensland) has spent some months making investigations amongst the Wikmankan tribe of the Archer River, Gulf of Carpentaria, and she will be continuing her work amongst the same people this year. Dr. A. P. Elkin (Universities of Sydney and London) is studying the natives of the Kimberley District of Western Australia. He has already obtained interesting and important results. His work will be continued for about eighteen months in all. Mr. C. W. M. Hart (University of Sydney) will be at work during 1928 amongst the natives of Melville and Bathurst Islands, North Australia. Mr. Donald F. Thomson (Universities of Melbourne and Sydney) is to spend twelve months amongst the natives of the eastern side of the Cape York Peninsula.

Outside Australia the chief problem that has been taken up has been the investigation of the Polynesian colonies in Melanesia. Mr. H. W. Hogbin (University of Sydney) has paid a short visit to Rennell Island and is now engaged in a systematic study of the people of Ontong Java or Luanuia, an outlying atoll of the Solomon Island group. The inhabitants are Polynesian in language, but have a very distinctive culture of their own, the affinities of which it is not yet possible to determine. Since the group was taken up by Messrs. Lever Bros., the population has decreased with extraordinary rapidity. Of an estimated population of five thousand in 1907, there only survive five hundred and sixty-eight, so that the present study of them is only just in time. Dr. Raymond Firth (Universities of New Zealand and London) left early in May for a year's field work in the outlying island of Tikopia—another of the Polynesian-speaking peoples of Melanesia.

The study of the native peoples of New Guinea is already being carried out by the Government anthropologists of the Territory of Papua and the Mandated Territory of New Guinea, but it is intended to supplement their work with that of special investigators. Mr. R. F. Fortune (Universities of New Zealand and Cambridge) is at present investigating the natives of the D'Entrecasteaux Archipelago.

In all the above-mentioned researches the aim is to study as completely as possible the language and customs of the people investigated. The Australian National Research Council has also provided for certain researches of more limited scope. The University of Adelaide has established a board for anthropological research and has carried out investigations in physical anthropology of the aborigines of South Australia and a study of the aboriginal music of the Arunta tribe. The Department of Physiology of the University of Sydney has initiated a series of investigations, still in progress, which have for their purpose the comparison of the physiology of the Australian aborignes with that of white people in Australia and in Europe. These investigations promise to give interesting results.

Optical Instruments for Research Laboratories and Works.

IT is not given to all men to be able to invent a proverb, but whereas it has been truly said that 'necessity is the mother of invention,' it has been the good fortune of Messrs. Adam Hilger, Ltd., to make invention the mother of necessity. There can be few persons responsible for the equipment of a physical or spectroscopic laboratory who will not realise the necessity of some of the beautiful instruments which have originated in the Hilger workshops.

The last fifteen to twenty years has seen an immense expansion in the range of products of this firm, disregarding the abnormal period of the War, and this growth of activity is reflected in the catalogue recently published.[1] In the early days, however, when the main products were confined to spectroscopic apparatus and optical work, the firm had the wisdom to build on a sound foundation of high quality work, and this reputation of thoroughness and consistency is still deservedly held at the present time. Hilger instruments have been concerned in many of the most important of modern researches, and the firm is entitled to an honourable place in the company of science, for it is true that the design and evolution of an instrument is a matter which often calls for the solution of problems quite as difficult as those in which the use of the finished instrument is employed.

The flattery of imitation cannot make the instrument maker vain; it calls not only for fresh invention but also for a continual improvement of his wares if he is to keep his lead. Of the various instruments wholly or largely originated by Messrs. Hilger, amongst which may be mentioned the group of wave-length spectrometers, the different spectrographs, the 'Twyman' interferometers, and instruments for spectrophotometry, ultra-violet refractometry, and the like, it is of the greatest interest to study the development of some of the leading types. The wave-length spectrometer has not only been greatly improved in convenience and optical performance, particularly in regard to stray light, but also the fundamental ideas in the design have been carried out in monochromators and various specialised forms of spectroscope, and the instruments have been adapted for spectrum photography and physical spectrophotometry.

In the class of spectrographs the new all-metal 'quartz' spectrographs will attract attention. They embody an optical system in which the number of component lenses has been reduced by the employment of aspherical surfaces, and it is claimed that a considerable improvement in the richness of spectrum detail has resulted, together with a possible increase in the range from 2000 A. in the ultra-violet to about 10,000 A. in the infra-red. It has been the general experience that quartz systems made from carefully selected material yield a degree of definition practically unattainable by systems made of glass, so that the performance expected of this instrument will certainly be of a very high order; it should be of great use in trying atmospheric conditions.

The spectrograph of standardised design with interchangeable optical systems is another new venture which should interest those who have no space for a multiplicity of instruments for different purposes, and the possibility of varying the optical and dispersion systems ought to be of the greatest interest to teachers.

---

[1] "A General Catalogue of the Manufactures of Adam Hilger, Ltd." Pp. 8+D22+E36+F36+H22+K2+L7+M28+N14+iv. (London: Adam Hilger, Ltd., 1928.)

Those interested in many recent advances in vacuum spectroscopy, X-ray work, physical photometry, and the like, will find new material of interest. Speaking generally, one great means of securing information about natural objects has been the production of visible pictures due to ordinary light; in this matter the limit of our resources has already been reached in regard to such possibilities as of resolution in microscopy, but when the range of radiation which we can employ for investigation directly or indirectly is extended far beyond the visible limit, our resources are indefinitely increased, and though the difficulties are great they will not be found to be insuperable. Such advances, then, are of fundamental importance.

The extension of so-called 'industrial research' has called for new instrumental developments. The 'Nutting' type of spectrophotometer can now be obtained in the form of a specialised industrial instrument complete in itself; the possibility of maintaining such an equipment in permanent adjustment should be valuable in a laboratory where absorption measurements are becoming of increasing importance in optical methods of control in manufacture. The optical system of the instrument is modified in the latest type by the introduction of a polarising prism into both of the separated beams.

There is still room for a satisfactory spectrophotometer which will produce a matching field of uniform colour without undue loss of light.

Amongst other newcomers to the catalogue we note the 'Mutochrome' and the 'Coverimeter,' names which those unfamiliar with the instruments should find intriguing enough. In the description of the Houston apparatus for investigating colour vision, we are told that a diagram can be produced to describe the colour vision of a subject which states results in 'an absolute manner.' There are not many matters in which Messrs. Hilger need be disillusioned, but this is one of them.

It might almost be considered that such an instrument as a measuring microscope had reached finality in design, but in recent years the present writer has been pointing out in lectures and in a book certain simple principles which should receive attention, although they had evidently been overlooked in many such instruments. It is gratifying to find that these principles have received full attention in a new photo-measuring micrometer of a very attractive design.

The fact that one or more Twyman interferometers will be found in almost every workshop in Messrs. Hilger's factory is a sufficient comment on the value and utility of these instruments. In the production of accurate optical parts for such instruments as these interferometers and the various other forms of interferometer of the Fabry-Perot and Michelson types, optical workmanship must touch the high-water mark of skill.

Work of the types which have been hinted at above means careful individual work. Especially in bringing out a new design for the use of workers in some branch of research, the maker is faced with problems which require time and patience for their solution; perhaps the first models may not meet all practical requirements; development work is essential, and yet in a way it is a 'liability'; it is like the injection of cold feed water into the boiler. The expense of development work must be borne by the better established branches of a business.

Yet there are ways in which such firms as Messrs. Hilger might perhaps make progress. Not for all are the marvels of precision, the charm of all possible refinements of workmanship, materials, and finish. How many of us have not learnt much of our optics with apparatus of the simplest description? On page D.10 we find a student's wave-length spectrometer of a simple type. Is it not possible that with care in design and with suitable choice of materials, a much wider range of apparatus could be made for students' use, which might not satisfy the requirements of research but would prove a godsend to teaching laboratories?

As the makers themselves state, this catalogue contains such instruments as are of most interest to chemists and physicists. The information is clear, precise, and usually sufficient; optical diagrams are given in many instances, and short bibliographies are often included in the descriptions. Special publications deal with particular groups of instruments of more restricted interest. Messrs. Hilger are to be congratulated on this catalogue. L. C. M.

The Etiolation of Shoots for Cuttings.*

A RECENT paper by Dr. Edith Smith upon the vegetative propagation of Clematis (*Trans. Roy. Soc. Edinburgh*, 55, Part 3, 643-664; 1928) again directs attention to the question of the etiolation of shoots used for cuttings. Dr. Smith finds it necessary to modify an earlier statement to the effect that clematis cuttings do not root at the node under ordinary conditions, as in fact many commercial houses still employ nodal cuttings with this plant. Normally, however, cuttings made an inch below a node root more readily. It was found, though, that after previous etiolation the stem rooted readily at the node. In an earlier paper from the Edinburgh Botanic Garden, Reed has described the ready rooting of cuttings of camphor after previous etiolation (*Trans. and Proc. Bot. Soc. Edin.*, 28, 184-188; 1922-23). Knight and Witt have also rooted shoots of apple and plum more successfully after previous etiolation, and pointed out that in the etiolated shoots the roots did not emerge through the callus as in the normal case, but arose higher up the cutting and emerged through the cortex (*Journal of Pomology*, 6, 47-60; 1927).

Priestley has described the ready rooting of etiolated shoots of broadbean and pea and correlated this with the development of an endodermis in these shoots upon etiolation (Master's Lectures, *Jour. Roy. Hort. Soc.*, 51, January 1926). In etiolated apple shoots, however, he found no endodermis, and Knight, Reed, and Smith also do not find an endodermis developed in their etiolation experiments. Smith suggests that etiolation acts in two ways, first by exciting meristematic activity, and secondly by 'softening' the hard tissues of the fibres and the pith.

Probably modern experimental work upon propagation will find this a profitable line of investigation. It is by no means a new one. Goude recently described in the *Gardeners' Chronicle* (Jan. 14, 1928) the method used at the Danish Experiment Station at Blangsted for the successful rooting of scion varieties of apples. The one-year maiden trees are laid down and the lateral shoots earthed up; as these shoots then develop under etiolated conditions a ring of wire is bound tightly around them. Roots later develop above the ring. The same method for preliminary treatment of shoots before they were removed as cuttings was described admirably by Duhamel in "Physique des Arbres" in 1763.

University and Educational Intelligence.

CAMBRIDGE.—Mr. C. Tate Regan, director of the Natural History Museum, and Dr. R. J. Tillyard, chief entomologist to the Commonwealth of Australia, have been elected to honorary fellowships at Queens' College.

Prof. J. B. Buxton has been re-elected into the professorship of animal pathology. Mr. T. G. Room, St. John's College, and Mr. S. W. P. Steer, Christ's College, have been appointed university lecturers in mathematics.

Mr. W. Dawson, Gonville and Caius College, has been appointed to represent the University at the centenary of the College of Forestry, Stockholm, next October.

Mr. C. Forster Cooper has been elected fellow of Trinity Hall; Dr. D. R. Hartree, Christ's College, has been appointed University demonstrator in physics; Dr. F. C. Phillips, Corpus Christi College, has been appointed University demonstrator in mineralogy.

The Tyson Medal in astronomy has been awarded to J. C. P. Miller, Trinity College, and the Mayhew Prize in applied mathematics to M. J. Dean, Trinity College. The Rex Moir Prize in engineering, the John Bernard Seely Prize in aeronautics, and the Ricardo Prize in thermodynamics have all been awarded to H. L. Haslegrave, Trinity Hall.

OXFORD.—In default of other candidates, Viscount Grey of Fallodon, Hon. D.C.L., has been elected Chancellor of the University as from June 16.

The report recently issued of the Delegates of the University Museum directs attention to the completion, during the past year, of the Sir William Dunn School of Pathology, and the new laboratory for teaching and research in biochemistry. Separate reports are included of seventeen scientific departments, in which are given lists of accessions to the various museum collections, and of researches and publications by members of the staff and other workers in each department. The accessions are especially numerous in the collections of the Hope professor of zoology and of the keeper of the Pitt-Rivers Museum.

A proposal has lately been started for the establishment of a club for workers in the departments of the Museum and allied institutions. It is felt that much advantage would result from the provision of more opportunities for intercourse among such workers. The accommodation aimed at is naturally of a kind which it is not within the province of existing college common-rooms to supply.

ON Thursday, June 14, the Duke of Connaught made his first visitation to University College, Southampton, and opened the George Moore Botanical Laboratories. The new buildings have been made possible by a bequest under the will of the late Mr. George Moore, of Southampton, and have been designed by the staff of the College, and particularly Prof. S. Mangham, professor of botany, and Mr. E. E. Mann, lecturer in civil and mechanical engineering. The dimensions of the building are 120 ft. × 30 ft., and it runs east and west, the north side being glazed so far as possible to afford facilities for microscope work. There are two floors. The ground floor provides thirteen rooms, including a theatre, two lecture rooms, library, two laboratories for physiology, and a photographic dark room. The upper floor has seven rooms, including a large elementary laboratory, pathological laboratory, laboratory for advanced work in systematic and structural botany and plant biochemistry, an exhibit room, and the usual preparation rooms. Plant houses, partly glazed with Vita glass, have been built along the south front and western end, and the surrounding grounds will be developed as a botanical garden. In drawing up the plans of the building, full provision has been made for increased accommodation for research work. The Principal of the College stated in his report that the cost of the new building and its equipment was only about £5000. In his address, the Duke of Connaught congratulated the College authorities on their careful management of the College funds, and expressed the hope that further benefactions would be forthcoming to enable the College to develop and to claim full university status.

ABOUT four years ago, Christ's Hospital, Horsham, started training a few of its older boys in practical farming, with the view of their migrating to the Colonies. The scheme is financed by the income of a legacy of about £5000 bequeathed by an old scholar of Christ's Hospital for that purpose. It is now proposed to develop the science teaching at Christ's Hospital by taking in biology, mycology, entomology, and kindred subjects, to help boys to qualify themselves for scientific posts under the Colonial Office. The present accommodation for science teaching at Christ's Hospital is not adequate to modern requirement, and in making the necessary extensions the opportunity is being taken to provide for biological work. The cost of the extensions will exceed £30,000, and since it was felt that the scheme for biological training is of significance far beyond the school itself, an appeal was launched on speech day last year by the then Lord Mayor, Sir Rowland Blades. The Corporation of the City of London responded with a gift of £1050, and other city companies brought the sum up to £6000. The Prince of Wales, who is president of Christ's Hospital, has now given £500. This, with subscriptions from governors and ex-scholars, brings the fund to about £14,200. Extensive additions for science teaching and for practical domestic work, costing about £20,000, are also contemplated at the girls' school of Christ's Hospital at Hertford. The funds at present available will only permit of the commencement of work at the girls' school. We hope that the initiation of the important scheme for biological training at the boys' school will not be long deferred for lack of funds.

THE Educational Colonies and Self-supporting Schools Associations of Great Britain and India are appealing for support in an attempt to embody their ideals in a pioneer colony. The Associations aim at such a reform of existing educational systems as will ensure for each child a thorough training, manual, physical, and scholastic, and maintenance when necessary, to be paid for during or at the completion of the training by a short period of employment that would be profitable both economically and educationally. The plan for the pioneer colony is one which has formed the subject of prolonged inquiry by the "Poverty Problem Study" department of the University of Calcutta and of numerous addresses and brochures by Captain J. W. Petavel, R.E. (retd.), Prof. J. W. Scott, of University College, Cardiff, and others. It combines the principles of the Swiss labour colony of Witzwil with those of the garden city movement and the co-operative movement, and is based largely on the beneficial effects on children of open-air life in rural surroundings with plenty of manual labour under skilful direction, at manifestly productive and therefore interesting tasks. It is described at length in "The Plan of the Educational Colonies Associations" (pp. 288, price 1*s*. 6*d*.). The honorary secretary of the Association in Great Britain is Mr. J. B. Pennington, c/o East India Association, 3 Victoria Street, London, S.W.1.

Calendar of Customs and Festivals.

June 24.

ST. JOHN THE BAPTIST. MIDSUMMER DAY.—A peculiar method of marriage divination recorded for England, in a locality not specified, was that an unmarried woman fasting should set out a table on the eve of St. John with bread, cheese, and ale, and then sit down as if to eat, leaving the street door open. Her future husband would then enter, bow to her, fill a glass of ale, and retire, leaving it on the table.

The sowing of hemp seed to secure the appearance of the lover, which was employed on the eve of St. Agnes, was also used at midsummer. Both processes point to the belief in the activities of spirits at this time, while the former recalls some of the north country wake ceremonies. Similarly, it was possible to foretell death by watching in the churchyard to see at midnight the spirits of those who were to die within the next twelve months. In Wales, if a St. John's wort were named for each person in the house and hung up, the first to wither would indicate who would be the first to die.

Certain herbs, if gathered on midsummer eve, had magical properties, or their magical properties were enhanced; for example, fernseed, which conferred invisibility, the rose, St. John's wort, vervain, trefoil, rue, mugwort, etc. They gave protection against disease or against spirits and witches. Orpine was set in clay on a slate or potsherd, and was called the 'midsummer man.' As the stalk was found next morning to set to right or left, it showed whether the lover would be true or false, a custom suggestive of phallic significance. Many of the customs which are superficially purely divinatory have certainly originated in practices intended to secure the fertility of those taking part. For example, in Greece there was formerly practised a method of divining the name of the future husband with the assistance of apples dropped in a vessel of water fetched by a boy from a spring on St. John's eve.

A closely related custom of Macedonia is called ὁ κλήδονας or κλήδονα, names of which the meaning is connected with 'omen,' but by the peasants, by an association of sound and from a certain feature in the observance, is connected with 'lock.' It, even more than the bonfire, is the most important observance of the feast of St. John. On the eve, plants are marked by the women for gathering next morning, and a brass vessel is prepared with flowers into which each casts a trinket. This is locked with a padlock after it has been filled with water by a boy after due observances at each of three fountains. The vessels are carried in procession through the village on the following day, each being guarded by young men with wooden swords. When the vessel is opened on the following evening, extempore verses prognosticate the fortune of the owners as each trinket is taken out. The frequently ribald character of these verses and the water ceremonial unmistakably point to a fertility rite, while a recent writer has pointed out the significant resemblance of the details to those of Rumanian marriage customs (Beza, "Paganism in Roumanian Folk-lore," p. 54 *sqq.*).

MIDSUMMER FIRES.—The most significant and important observance at midsummer is the survival of the fire festival. The practice of lighting fires on midsummer eve is of wide distribution and great antiquity. As on May Day and other occasions, when similar ceremonial fires are lighted, the people both jump through them themselves and send their cattle through them. King Manasseh, it is recorded in the Old Testament, caused his children to pass through fires in the Valley of Hinnom, and Ovid ("Fasti," iv. 655) refers to the custom of leaping through the fire. Medieval writers speak of the rites of St. John's eve among the Teutonic and Scandinavian peoples, and ascribe to them a pagan origin and a connexion with the sun.

The lighting of midsummer fires, and the practices associated with them more or less common to all, are recorded of the peoples of eastern Europe, of every part of Germany, and Spain, Italy, and Sicily. In France, where in particular pagan customs have lingered side by side with the observances of the Christian Church, they are recorded from many localities, and in Brittany these fires are lit regularly as an accompaniment of the *pardons* which take place around about midsummer. Often the parish priest goes in procession with the crucifix and lights the bonfire with his own hands; otherwise it is usual for them to be lighted after the recital of prayers by an old man. In Upper Brittany the fires were built around a pole which was surmounted by a nosegay or garland supplied by a man named Jean or a woman named Jeanne. Flowers from these garlands were charms against disease, and brands from the fire were a protection against lightning and conflagrations. In some localities in Great Britain the records show that the bonfire was similarly built round a pole surmounted by a garland.

In both Great Britain and Ireland the midsummer fires continued down to recent times. The references of medieval writers show that the fire ritual consisted of three elements—the rolling down a hill of a wheel swathed in straw, to which a light was set; a procession with burning brands around the fields; and the bonfire itself. In the vale of Glamorgan, within living memory, if the wheel burned well until it reached the bottom it was held to foretell a planteous harvest. In one record quoted by Frazer ("The Golden Bough," x. 103), the wheel was mounted on a pole projecting some three feet on each side, by which it was guided by young men. The aim was to roll the wheel, while it still blazed, into the waters of the Moselle, so as to secure an abundant vintage.

Further examples of the fire festivals in which these elements of the ritual appear have been collected by Frazer in "The Golden Bough," vol. x. From these instances, and more particularly from the form of the belief in the magical efficacy and purificatory powers of the midsummer fires which appears in Morocco, it would seem that the ceremonial is directed towards securing the prosperity of the crops and stock, by protecting them against the evil influences potent at this period. This seems more probable than that it is a survival of sun worship, as was suggested to the older writers by the presence of the wheel, or than that it is an act of worship of Baal, as was indicated by the interpretation of Beltane as Baal or Bel's fire.

June 29.

ST. PETER'S DAY.—Similar observances to those of St. John's eve took place on the eve of St. Peter. In Scotland fires were lighted on the hill-tops, and processions with torches took place. According to an ancient record, the boatmen of Gisborough, in Yorkshire, used to keep festival on this day, decking their boats, painting their masts, and "sprinkling their prows with good liquor." In Wales girls tied a small key on each wrist, and when in bed repeated the sixteenth and seventeenth chapters of Ruth nine times. The future husband would appear to them in a dream, and then the keys fell from their wrists.

Societies and Academies.

LONDON.

Royal Society, June 14.—**A. V. Hill**: (1) Myothermic apparatus. Improvements have made it possible to measure with relative accuracy, in the sartorius of the frog or any similar muscle, not only the heat suddenly produced by a single stimulus, but also that liberated over long intervals at rest or in recovery, or as the result of prolonged discontinuous stimulation. A Zernicke moving-coil galvanometer (Kipp) has been employed. The total heat has been measured from the area of the deflexion–time curve. The temperature of the muscle chamber has been maintained constant within 0·001° C. An 'all-metal' thermopile has been devised which responds quickly and is very completely insulated. A Ringer's solution containing phosphate (7 to 15 mgm. per cent) has led to improved performance in the isolated muscles employed.

(2) The rôle of oxidation in maintaining the dynamic equilibrium of the muscle cell. The resting heat-rate in oxygen of frogs' sartorius muscles agrees with existing determinations of the rate of oxygen consumption. The minimum resting heat-rate in the absence of oxygen is sufficiently accounted for by lactic acid formation. Stimulation produces an immediate increase in the anaerobic resting heat-rate. The total heat in eight hours may be as great as 5 calories per gram of muscle: the maximum rate may be as high as 1·4 calories per gram per hour. Resting anaerobic survival without stimulation leads gradually to the same high heat-rate. The effect of anaerobic stimulation in increasing the resting heat-rate can be reversed, partially or completely, by recovery in oxygen. The possibility of oxidation leads to the inhibition of reactions previously occurring. It is considered that the degenerative changes set up by anaerobic stimulation, or survival, proceed at a rate determined at any moment by the degree of oxygen want. Oxidation at rest is concerned with upholding the integrity of boundaries, or membranes, which are essential if the organised system is not to become a chaos of biochemical processes.

(3) The absolute value of the isometric heat coefficient *Tl/H* in a muscle twitch and the effect of stimulation and fatigue. Direct observations of *T* and *H* give a mean value of the isometric heat coefficient $Tl/H = 6{\cdot}16$, in close agreement with the value calculated from the lactic acid data of Meyerhof. Previous anaerobic activity, liberating a large fraction of the whole energy available, has little or no effect on the isometric heat coefficient. The effect, if any, is in the direction of a slight reduction; in extreme fatigue, however, the reduction is large. The results, therefore, of chemical studies of muscle (which have necessarily employed a large number of twitches) are applicable directly to a case of a single twitch.

(4) The absence of delayed anaerobic heat in a series of muscle twitches. In a series of muscle twitches, in the absence of oxygen, there is little or no heat production except during the contractions themselves: the 'total' heat is equal to the 'initial' heat. Hence the lactic acid formation—which must be accompanied by heat liberation—occurs entirely during contraction. The contrary conclusion of Embden, Lehnartz, and Hentschel, the experimental base of whose work has been criticised by Meyerhof and Schulz, rests on imperfect reasoning.

(5) The recovery heat-production in oxygen after a series of muscle twitches. The ratio (total heat in oxygen)/(total heat in nitrogen) for the case of a series of twitches, reckoning heat per unit of mechanical response developed, has a mean value of 2·07. This allows us to calculate the 'oxidative quotient for lactic acid,' and the result, 4·81, agrees well with the mean value, 4·7, of Meyerhoff and Schulz, deduced from experiments involving lactic acid and oxygen measurements. The 'isometric heat coefficient' *Tl/H* is the same in oxygen and in nitrogen, confirming the conclusion of Weizsacker and others that the initial heat is entirely non-oxidative in nature.

A. V. Hill and **W. Hartree**: (1) The anaerobic delayed heat-production after a tetanus. The supposed long-continued anaerobic delayed heat-production after a tetanus is due to a misinterpretation of the permanent increment in resting heat-rate produced by anaerobic stimulation. Its earlier part is a genuine occurrence, but it is complete within a minute or two. It is very variable in amount, ranging from 5 to 46 per cent of the initial heat. It is probably due to the over-stimulation of some of the fibres of the muscle producing a delayed formation of lactic acid. There is no sign of an endothermic process occurring at any stage in, or after, contraction. A statement by Furusawa and Hartree that in purified nitrogen a muscle becomes gradually inexcitable, as a nerve is known to do, was not confirmed.

(2) Factors determining the maximum work and the mechanical efficiency of muscle. The 'efficiency' of a frog's sartorius muscle has been measured. Its maximum value, as the mean of 56 observations on 21 different animals, is 26 per cent, with an average deviation from the mean of only 2 per cent. This refers to the initial (anaerobic) process only: for the complete cycle (including oxidative recovery) the maximum efficiency is only 12½ per cent. In man the efficiency of muscular movement may be twice as great. In the frog the very low value is due to the extremely expensive nature of the process required per second to maintain a contraction. Contractions of short duration, therefore, are necessary and movement must be rapid. In rapid shortening, however, muscle 'viscosity' plays a very large part in reducing the work done—74 per cent of the mechanical energy of the initial process is degraded into heat. In man the maintenance of a contraction is far less expensive. Consequently, the most efficient contractions are of considerable duration (1·3 seconds) and viscous resistance absorbs a far smaller proportion of the mechanical energy.

C. H. Best and **Ruth Partridge**: The equation of motion of a runner exerting a maximal effort. Experiments in which external resistances of varying magnitude have been applied to a runner show that the maximum speed of the subject is decreased by the amount calculated from the equation of Furusawa, Hill, and Parkinson. This is a satisfactory demonstration that the internal resistance of the muscles is real, in the sense that it has identically the same effect as an external added resistance.

S. Dickinson: Dynamics of bicycle pedalling. The maximum speed of pedalling a bicycle ergometer has been determined as a function of the load applied to the wheel. The relation between maximum speed and load is linear, speed decreasing as load increases, according to equation $P = P_0 (1 - k/t)$, where P is force exerted on pedal crank, P_0, is 'theoretical maximum force' attained only at zero speed, k a 'viscosity' factor, the 'theoretical minimum time,' and t actual time of a single leg movement. The value of k was much the same in all subjects; P_0, the 'strength' factor, varies widely. Bicycle pedalling, like other movements involving external resistance, shows an optimum speed, at which mechanical efficiency is highest.

C. A. Seyler: The Dictyoxylon cortex of Lycopodiales as a constituent of coal. By the metallographic method of polishing and etching, the characters of secondary xylem in transverse, radial, and tangential sections of coal can often be observed. A band of clarain in the Deep Soft seam of the Middle Coal Measures at Grassmoor Colliery, Derbyshire, has been investigated. The band has the structure of a broken network of sclerotic fibres, enclosing in its meshes a thin-walled tissue, and has macroscopic and microscopic characters of a heterogeneous Dictyoxylon periderm.

B. Sahni: On *Clepsydropsis australis*, a Zygopterid tree fern with a *Tempskya*-like false stem, from the Carboniferous Rocks of Australia. Several large specimens of this plant, recently discovered in rocks of the Kuttung Series (Carboniferous) of New South Wales, are described. These specimens reveal an extraordinary type of stem organisation not previously observed in any palæozoic plant. The trunk must have stood upright and attained a considerable height, with a heavy crown of foliage at the top; it was a 'false stem' composed of numerous relatively weak, but erect, repeatedly forked leaf-bearing axes, which were embedded in a dense matrix of adventitious roots and aphlebiæ.

W. O. James: Experimental researches on vegetable assimilation and respiration (19). Carbon dioxide was supplied to *Fontinalis antipyretica*, in solutions with and without bicarbonates. The effect of moving both kinds of solution at different rates past the plant was also observed. Only with relatively rapid movement of the solutions was the assimilation rate independent of the presence of bicarbonate. The results are discussed in relation to the aqueous diffusion of carbon dioxide and its effect on the photosynthetic process.

A. W. Greenwood: Studies on the relation of gonadic structure to plumage characterisation in the domestic fowl (4). In four cases the successful implantation of testicular material from the hen-feathered strain of Campines into castrated Brown Leghorn males produced the normal male head furnishings and behaviour, but did not lead to change in plumage character. These results support Roxas' conclusion that 'hen-feathering' of male in hen-feathered breeds is due to endocrine difference between the two testes. Successful implantation of testis from a Leghorn male into a castrated hen-feathered Campine did not result in change in plumage as would be expected on the basis of the above hypothesis. The failure may have been due to insufficient amount of testis, since it was incapable of inducing normal development of head furnishings.

T. P. Hilditch; Relationships between chemical composition of vegetable seed-fats and their botanical origin. In any one of the four orders, *Palmæ*, *Cruciferæ*, *Umbelliferæ*, and *Myristaceæ*, the composition of the fatty acids of the seed-fats is of the same general type, but each order is marked by definite and specific characteristics in the composition of the fatty acids. Thus the *Palmæ* seed-fats almost always contain 46 to 50 per cent of combined lauric acid, with minor amounts of caprylic, capric, myristic, and palmitic acids and relatively small proportions of oleic acid; in the *Myristaceæ* seed-fats myristic acid predominates; in Cruciferous seeds there is usually 40 to 50 per cent of combined erucic acid, the remainder consisting of oleic and linoleic acids in varying proportions; and finally, Umbelliferous seeds appear to be characterised by the presence of an isomeric form of oleic acid, petroselinic acid (20 to 75 per cent), not yet observed in seed-fats of any other order, except the closely related *Araliaceæ*.

PARIS.

Academy of Sciences, May 21.—**Emile Borel**: The calculus of probabilities and arithmetic.—**Maurice Hamy**: A comparator, suitable for the measurement of filiform spectra, intended for the determination of the radial velocities of stars. The method is based on the direct comparison of a solar and a stellar spectrogram, both obtained with the same spectrograph and containing the same comparison lines.—**Pierre Termier** and **Eugène Maury**: New geological observations in eastern Corsica: attempt at a tectonic synthesis.—**Louis Roy**: The equations of small movements of elastic surfaces.—**W. A. Tartakowsky**: The determination of the whole of the numbers representable by a positive quadratic form, with more than four variables.—**P. Vincensini**: Certain congruences of normals.—**Calugaréano**: A class of equations of the second order integrable with the aid of polygene functions.—**Vladimir Bernstein**: Some relations between the growth of a holomorph function in a demi-plane and its growth in a series of isolated points.—**Miécislas Biernacki**: The lines of Julia of integral functions.—**J. Crowden and M. G. Pearson: The Effect of Morphia on the Adrenaline Content of the Suprarenal Glands.—E. C. Eaves: The Pituitary and Nervous System in (*a*) Infantilism with Diabetes Insipidus, (*b*) Post Encephalitis Diabetes Insipidus.—May Mellanby and C. Lee Pattison: The Healing of Dental Caries.—N. G. Green and E. Mellanby: Vitamin A as an Anti-Infective Agent.—E. Mellanby, H. M. Surie, and D. C. Harrison: The Antirachitic Action of Ergot.

MONDAY, June 25.

Institution of Mechanical Engineers (at Southampton) (continued on June 26, 27, 28 and 29).

TUESDAY, June 26.

Royal Dublin Society (in the Science Room, Ball's Bridge), at 4.15.—Report of the Irish Radium Committee for the year 1927.—C. Boyle, M. Murphy, and H. A. Cummins: "Blossom Wilt" of Apple Trees and "Wither Tip" of Plum Trees, with Special Reference to two Biological Forms of *Monilia cinerea* Bon.—T. Dillon and H. F. Lavelle: A Suggested Method for the Utilisation of Seaweed.—A. G. G. Leonard and P. F. Whelan: Spectrographic Analyses of Irish Ring-money and of a Metallic Alloy found in Commercial Calcium Carbide.—L. B. Smyth: *[illegible]*, a New Carboniferous Coral.—L. P. W. Renouf: A Preliminary Account of Lough Hyne, Co. Cork.

Institution of Electrical Engineers (Summer Meeting at Scottish Centre) (continued on June 27, 28, 29 and 30).

WEDNESDAY, June 27.

Royal Society of Arts, at 4.—Annual General Meeting.

British Astronomical Association (at Sion College, Victoria Embankment).

British Psychological Society (Medical Section).—Mrs. Isaacs and Drs. Hadfield and Potts: Symposium on Mental Hygiene of Pre-School Age.

THURSDAY, June 28.

Society of Glass Technology (at the Applied Science Department of the University, St. George's Square, Sheffield), at 11.15.—General Discussion on Lessons from the Tour in Germany.—A. Cousen, H. W. Howes, and F. Winks: The Control and Distribution of Temperature in Lehrs.

Royal Society, at 4.30.—Prof. J. C. McLennan: The Bakerian Lecture on The Aurora and its Spectrum.—*To be read in title only*:—H. Jones: Photographic Study of Detonation in Solid Explosives.—Prof. E. T. Whittaker: On the Potential of the Electromagnetic Phenomena in a Gravitational Field.—B. Topley and J. Hume: The Kinetics of the Decomposition of Calcium Carbonate Hexahydrate.—L. W. Nordheim: On the Kinetic Method in the New Statistics and its Application in the Electron Theory of Conductivity.—P. K. Kichlu: First Spark Spectrum of Krypton.—Prof. R. W. Wood and V. Voss: The Fluorescence of Mercury Vapour.—E. Rudberg: The Velocity Distribution of Photoelectrons by Soft X-Rays.—L. M. Mathews: The Absorption Spectrum of Cæsium.—D. Jack: The Band Spectrum of Water Vapour. III.—F. W. P. Götz and Dr. G. M. B. Dobson: Observations on the Height of the Ozone in the Upper Atmosphere.—Prof. T. M. Lowry and M. S. Vernon: An Improved Method of Ultra-Violet Polarimetry. Anomalous Rotatory Dispersion of Sodium Tartrate.

Royal Society of Medicine (Urology Section), at 8.30.—Prof. Jurasz: Movable Kidney.

FRIDAY, June 29.

Royal Society of Medicine (Urology Section), 11 to 12.—Short Demonstration of Special Instruments.

SATURDAY, June 30.

Genetical Society (at the John Innes Horticultural Institution, Merton, S.W.19), at 1.—Annual Meeting.

Royal Society of Medicine (Disease in Children Section) (at Leicester).

FRIDAY, July 6.

Geologists' Association (in the Architectural Theatre, University College, Gower Street), at 7.30.—F. Gossling: The Geology of the Country around Reigate.—H. A. Hayward: The Geology of the Lower Greensand around Dorking, Surrey.

CONGRESSES.

July 9-14.

Seventh International Congress of Photography, 1928 (at the Imperial College of Science and Technology, South Kensington).—Dr. A. Steigmann: Theory of Photographic Sensitivity.—Dr. Lüppo-Cramer: The Herschel Effect as a Regression Phenomenon.—L. A. Jones and V. C. Hall: On the Relation between the Time and Intensity in Photographic Exposure.—Dr. S. E. Sheppard and A. P. H. Trivelli: A Comparison of some Developers for Sensitometric Standards.—Dr. S. E. Sheppard and Crouch: A Machine for the Automatic Development of Sensitometric Strips.—L. A. Jones: Systematic Nomenclature in Photographic Sensitometry.—L. A. Jones and Russell: The Expression of Plate Speed in Terms of Minimum Useful Gradient.—O. Sandvik: On the Measurement of Resolving Power of Photographic Materials.—L. A. Jones and Chambers: High-Intensity Time-Scale Sensitometer.—Dr. E. P. Wightman and Quirk: Intensification of the Photographic Latent Image.—Dr. A. Steigmann: Silver Iodide in the Full-Ammonia Emulsion.—Prof. Dr. Emil Baur: Sensitisation and Desensitisation.—Prof. Dr. A. Lottermoser: Observations and Measurements on the Light-Sensitivity of Silver Halide Sols.—Prof. Dr. Fritz Weigert: On the Light-Sensitivity of Photographic Layers.—T. Thorne Baker and Balmain: The Effect of Temperature on the Sensitivity of Selected Photographic Emulsions and the Influence of Wave-length on such Temperature Effect.—O. Bloch: The Interaction of the Silver Halides in Emulsion Form.—Dr. F. C. Toy, and others: On Turbidity.—Prof. Dr. J. Eggert: On Secondary Processes in the Exposure of Silver Halides.—Prof. Dr. R. Luther: Sensitometric Studies.—Dr. F. M. Hamer: A Chemical Study of Desensitisers. Part I. An Account of the known Desensitisers.—Dr. D. A. Spencer: The Ferro-Prussiate Process; The Ferro-Gallic Process; The Diazo-Type Process; A New Application of the Ferro-Gelatine Process; Printing in Colours with Diazo Compounds.—H. W. Lee: The Modern Super-Speed Lens.—S. Jaffenalo: The Stereoscopic Effect of High-Aperture, Long-Focus Objectives.—N. Fleming: The Photography of Sound Waves.—Dr. Anderson: The Testing of Photographic Shutters; Lens Interferometry.—Prof. Hartridge: The Focal Plane Shutter.—Capt. C. J. P. Cave: The Photography of Inaccessible Interior Architectural Details with a Spot-Light.—G. Aubourne Clarke: The Photography of Clouds.—Prof. E. G. Coker: Photography as an Aid to the Study of Mechanical Stresses.—O. G. S. Crawford: Archæological Photography from the Air.—Capt. M. Hotine: On Photographic Surveying.—Prof. Namias: On Positives by Reversal.—A. R. Hinks: The Work of the Wild Phototheodolite in the Shaksgam.—W. M. H. Greaves: Astronomical Spectrophotometry.—Dr. E. Viterbi: The Fine-grained Emulsion and its Application to Spectrography.—Mr. Elwell: Paper on and Demonstration of Talking Film.—A. J. Bull: Tone Rendering by Half-Tone Processes.—H. M. Cartwright: (1) The Progress of Photogravure Etching; (2) A Method of Colour Correction.—A. A. K. Tallent: Latest Applications of Pyro-Tanning Processes.—E. L. Turner: Modern Photo-Engraving Screens.—William Gamble: The Present Position and Future Possibilities of Photo-Engraving.—H. N. Durham: Mercury Printing Processes.—F. J. Tritton: The Uses of Colour Photography in the Printing Trade.—Prof. Dr. E. Lehmann: On his Two-Colour Process.—Dr. R. von Arx: Dye-transfer Process from Dye-Mordant Images.—F. G. Tutton: The Value of the Chromoscope in Commercial Colour Photography.—Commander H. E. Rendall: A Paper on Tri-colour

Cameras.—Dr. R. A. Houston: A Paper on the Colour Mechanism of the Eye.—Julius Rheinberg: Demonstration of Micro-Spectra Method of Colour Photography.—F. C. Tilney: Pictorial Photography: the Relation of Technical Advance.—H. Garnet and G. H. Oakden: The Original Binocular Stereoscopic Camera of John Benjamin Dancer.—Dr E. Kuchinka: W. Fr. Voigtlander's Eight-inch Double-Objective, and other Large Objectives.

JULY 16–20.

BRITISH EMPIRE CANCER CAMPAIGN (at the Royal Society of Medicine).

Monday, July 16.

Reception of Overseas Delegates at Buckingham Palace by H.M. the King.

2 to 5.—Registration of Delegates at the Royal Society of Medicine.

9.30.—Reception of Delegates and Ladies by Sir John and Lady Bland-Sutton, 47 Brook Street, W.

Tuesday, July 17.

10 (Royal Society of Medicine, Barnes Hall).—Discussions on The Relative Values of Surgery and Radiation in the Treatment of Cancer of the Cervix Uteri, Rectum, Breast and Buccal Cavity. Opened by Prof. Regaud.—Cancer of the Cervix. Opened by Dr. M. Donaldson.—Cancer of the Rectum. Opened by Sir Charles Gordon-Watson.

10 (College of Nursing).—The Etiology of Cancer. Opened by Prof. J. Ewing.

2.30 (at Middlesex Hospital).—Bland-Sutton Institute of Pathology.—(1) Demonstration of unusual Tumours. (2) Relation of malignancy to histological appearances in Cancer of the Breast. (3) Studies of the Rous Sarcoma:—(*a*) Immunity. (*b*) Factors which influence the infectivity of the Rous tumour. (*c*) Initial stages of the tumour produced by cell free filtrates. (*d*) Influence of physical and chemical agents. (4) Some experiments on lead therapy in Cancer. (5) The application of the Cinematograph to the study of tissue culture. Courtauld Institute of Bio-Chemistry.—(*a*) Demonstration of the metabolism of tumours following Prof. Warburg's views. (*b*) A trial of some unsuccessful methods for the sero-diagnosis of Cancer. (*c*) Routine observations performed on patients undergoing radical operations for Cancer. Barnato-Joel Laboratories.—Demonstrations will be given, mainly of a radiological character. These will include:—Effects of X-rays upon Tumour Growth. Effects of Radium rays upon Tumour and Normal Tissues. Experiments upon resistance in animals to human growth. Experiments upon the physiological action of X-rays. (In collaboration with the Physiology Department.) Operating Theatres.—Radical amputation of Breast by Diathermy, by W. Sampson Handley (and demonstration of cases in the Wards). Operations for Buccal and Abdominal Cancer by Gordon Taylor. Wertheim's hysterectomy, by Comyns Berkeley and Victor Bonney. Operations for Pharyngeal or Laryngeal Cancer by Somerville Hastings.

2.30 (at Radium Institute).—Demonstrations by Dr. Philip Gosse, Dr. Roy Ward. Radium and Radium Applicators. Radon "Seeds." Various types of seed introducers. Cases that have been treated with seeds. X-ray photographs, showing seeds in tumours. Operations on patients, introducing seeds. Demonstration of specimens in the Pathological Laboratory. Demonstration of the preparation and filling of Radon Seeds.—(At Royal College of Surgeons.) Lecture and Demonstrations by Dr. Murray.

Wednesday, July 18.

9.30 (Royal Society of Medicine, in the West Hall).—Discussion on The Classification and Treatment of Bone Sarcoma. Opened by Prof. Ewing. Special Demonstration on Bone Sarcoma.

9.30 (Royal Society of Medicine, Barnes Hall).—Discussion on Some Present Day Medical Aspects of Cancer.—Sir Thomas Horder: A Consideration of Cancer Cachexia.—Dr. Robert Hutchison: The Alleged Increased Frequency of Primary Carcinoma of the Lung.

9.30 (Royal Society of Medicine, Committee Room).—Discussion on Biological Effects of Radium and X-rays, with special reference to the Factors of Wave-length, Intensity of Radiation and Duration of Exposure. Opened by Prof. Regaud, Prof. Holthusen, Dr. D. Quick, Dr. Canti, Dr. Finzi, Prof. Lahm.

9.30 (College of Nursing).—Discussion on Occupational Cancer. Pathology, Statistics and Public Health. Opened by Prof. A. Leitch, Dr. T. H. C. Stevenson, Dr. J. C. Bridge, and Dr. S. A. Henry.

2.30 (at St. Bartholomew's Hospital).—Clinical Demonstrations:—Operations.—Sir Charles Gordon-Watson: Insertion of Radium for Carcinoma of the Rectum.—Dr. Barris: Insertion of Radium by Vaginal Route for Carcinoma of the Cervix Uteri.—Dr. Donaldson: Insertion of Radium by Abdominal Route for Carcinoma of the Cervix Uteri.—Mr. Keynes: Insertion of Radium for Carcinoma of the Breast.—Demonstration of Cases.—Prof. Gask: Cases of Carcinoma of the Tongue and other cases treated by Radium.—Sir Charles Gordon-Watson: Cases of Carcinoma of the Rectum treated by Radium.—Mr. Harmer and Mr. Rose: Cases of Malignant Disease of the Larynx treated by Radium and X-rays.—Dr. Barris and Dr. Donaldson: Gynæcological Cases treated by Radium and X-rays.—Pathological Demonstrations:—T. P. Dunhill: Carcinoma of the Thyroid—Macroscopic and Microscopic.—Dr. E. A. Carmichael: The Relationship of Cerebral Gliomata to Embryonic Glial Tissue.—Dr. Andrewes, Miss Fell: Tissue Culture in its relation to Malignant Disease.—Dr. Canti, Dr. Spear and Miss Cox: Effects of Irradiation on Tissue Culture.—Miss Strangeways: Comparative Demonstration of Leucocytes and Fibroblasts of the Rat cultivated in vitro.—Dr. Canti: Histological Demonstration of Carcinoma of the Cervix before and after Treatment by Radium.—Dr. Shore: Demonstration of Museum Specimens.—Prof. Hopwood, Dr. Levitt: Demonstration of Apparatus in connexion with Deep X-ray Therapy and Radium Therapy.

5—Tea in Library.—Dr. Canti: Cinematograph Demonstration of living tissues cultivated in vitro, and the action of Radium upon them.

2.30 (at St. Mark's Hospital).—J. P. Lockhart-Mummery, Sir Charles Gordon-Watson, and L. E. C. Norbury: Operations for Cancer of the Rectum (Perineal Excision) and Resection of the Colon. Demonstration of patients illustrating 5 to 10 year cures after Perineal Excision, and Demonstration of the Cancer follow-up System. Demonstration of Diagnosis by Barium, Enemata and X-rays, and by Sigmoidoscopy.—Dr. Cuthbert Dukes: Demonstration in the Cancer Research Department:—(1) Series of specimens showing early stages in the development of Cancer of the Large Intestine. (2) Specimens showing the intramural and extra-rectal spread of Cancer of the Rectum. (3) Specimens illustrating multiple tumours, obstructive tumours and unusual types of malignant tumours of the bowel.

Thursday, July 19.

9.30 (Royal Society of Medicine, Barnes Hall).—Discussions on The Relative Values of Surgery and Radiation in the Treatment of Cancer of the Cervix Uteri, Rectum, Breast and Buccal Cavity, contd.):—Cancer of the Breast. Opened by Prof. Burton Lee.—Cancer of the Buccal Cavity. Opened by Dr. Douglas Quick.—Evaluation of Statistics relating to Effectiveness of Treatment. Opened by Dr. Janet E. Lane-Claypon.

9.30 (College of Nursing).—Discussion on Methods of Treatment by Chemo-therapy, with Special Reference to Lead. Opened by Prof. Blair Bell.

2.30 (at the Cancer Hospital):—

A.—Surgical.

2.30–5.—Operations. Two Theatres. Demonstration of Cases of Cancer of the Buccal Cavity treated by Radium.

B.—Pathological.

(i) Experimental:—(1) Demonstration of animal tumours produced by various carcinogenic agents. (2) Demonstration of carcinogenic agents (shale oil, paraffins, acetylene tar, etc.). (3) Specimens of mule spinner's Cancer. (4) Betel-nut-chewer's Cancer. (5) Specimens of experimentally produced Cancer of gall bladder in animals. (6) Injected specimens showing vascular supply of tumours. (7) Spontaneous rat tumours. (8) Graphs showing incidence of tar tumours and effect of dilution of tar. (9) Charts of blood changes (due to X-rays) and microscopical specimens illustrating such changes in human cases and in the rabbit.

(ii) Clinical:—(1) Sero-diagnosis of tumours by a flocculation method. (2) Specimens of Cancer of Rectum of various types removed by the abdominal-perineal method. (3) Specimens of rare human tumours. (4) Demonstration of histological sections of kidneys from cases treated by colloidal lead.

C.—Radiology.

Deep therapy apparatus with special patient's turn-table. Paintings of cases of malignant disease treated by X-rays and patients showing the results of treatment. Demonstration of special skiagrams of tumours. Ionisation apparatus for the measurement of X-ray doses. Recording spectrophotometer for X-ray and Ultra-violet light spectra. X-ray distribution in irradiated media.

2.30 (at Westminster Hospital).—Stanford Cade and Arthur Evans: (*a*) Clinical demonstration of cases of Cancer of the Tongue and Mouth treated by Radium. (*b*) A case of lingual Cancer will be treated by Radium, to demonstrate the technique. Tudor Edwards—(*a*) Will demonstrate the transpleural approach of the thoracic part of the oesophagus and introduce Radium into the wall of the oesophagus.—(*b*) If available a malignant tumour of the lung will be excised.—Dr. Braxton Hicks and Dr. Hocking—(*a*) Will show specimen of (1) Chloromata. (2) Lung tumours. (3) Myxosarcoma and primary Cancer of the liver. (*b*) Demonstrate the manufacture of Uranium and give an account of its clinical uses in cases of Cancer.—Demonstration in X-Ray Department by Dr Caldwell, Dr. Allchin, Dr. Kerley.

2.30 (at St. Mark's Hospital).—Repetition of Programme for July 18.

2.30 (at the Lister Institute).—Demonstration by Dr. Thomas Lumsden, assisted by Miss A. C. Kohn-Speyer. (1) Culture of Normal and Malignant cells in pure serum. (2) The Effects of anti-Cancer sera on such cultures, showing the existence of specifically anti-malignant-cell bodies. (3) Treatment of various rat and mouse tumours by injection of antisera into the tumours. Subsequent immunity. (4) Cure of small "metastases" by local vaccine treatment of a co-existing large implanted tumour. (5) Lantern slides illustrating vaccine treatment of implanted tumours and the mechanism of regression. (6) Demonstration of a new Sarcoma of the rat which grows progressively in 100 per cent of rats inoculated and never regresses.

Friday, July 20.

9.30 (Royal Society of Medicine, Barnes Hall).—Discussion on The Early Recognition and Treatment of Cancer of the Stomach. Opened by Sir Berkeley Moynihan.

9.30 (Royal Society of Medicine, West Hall).—Discussion on Diagnostic Methods in Relation to Cancer. Opened by Sir Thomas Horder.

9.30 (Royal Society of Medicine, Committee Room).—Discussion on The Effects of Radium and X-rays on the Blood Vascular and Lymphatic Systems, with Special Reference to Malignant Growths. Opened by Dr. F. Carter Wood, Dr. A. Lacassagne, Prof. Holfelder.

9.30 (College of Nursing).—Discussions on Geographical and Racial Prevalence of Cancer. Opened by Prof. Major Greenwood.—Public Action in Regard to Cancer. Opened by Sir George Buchanan.

Farm Laboratories of the National Institute for Medical Research (Medical Research Council), Mill Hill, N.W.7.—Demonstrations:—By Dr. W. E. Gye: (1) Improved methods of extracting infective material from tumours. (2) The effects of tumour ferments, probably oxidases, in abolishing tumour inducing power; and methods of counteracting the action of these ferments. (3) Destruction of infective power by means of antiseptics, and conditions which influence the result.—By J. E. Barnard: (4) Microscopic demonstration of extracts of tumours. (5) Exhibition of microscopic methods for the study of filter-passing viruses. (6) Demonstration of ultra-filtration methods.

2.30 (at Guy's Hospital).

SATURDAY, JUNE 30, 1928.

The Application of Scientific Agriculture.

THE title of the annual journal of the Agricultural Education Association, *Agricultural Progress* (London: Ernest Benn, Ltd. 5s.), is ambitious. As an expression of the aims of this useful Association, the designation of its journal is beyond reproach, especially as modified by the expression of modesty implied in the Virgilian couplet (*pater ipse colendi . . . Haud facilem esse viam voluit . . .*) which completes the title-page. But the words inevitably suggest reflections as to the extent to which agricultural education has, so far, been effective in leading to progress in a material sense.

Academically, no one ventures to question the achievements of agricultural science. In the last hundred years the additions to knowledge have been very great, but in the material consequences—the increased production of human food—doubts must arise. Rothamsted itself, by the lips of its director, has been heard modestly to suggest that many of its discoveries have gone to confirm the wisdom of the ages. Even the most progressive country in the world, we are told, feeds itself, in the main, by the exploitation of the fertility locked up in its 'virgin prairies' rather than on the fruits of new knowledge.

Measured in profits, there has been really only one 100 per cent addition to traditional practice in tillage of the soil in the last century, and that is the discovery of chemical fertilisers—that substances extraneous to the soil of definite composition can be used to increase its production. Following this epoch-making discovery there have been many others of supreme scientific importance—the new biological activity of the soil may be instanced—but not one of them has had a material outcome comparable with the first mentioned; for they have all been of the same order of magnitude as the seasonal fluctuations by which *pater ipse* has willed that the husbandman's way should be made difficult.

It is, however, only fair to admit that a particular tiller of the soil, fortified at all points with scientific knowledge and endowed with capital sufficient to tide over hard times, such as the present, has it in his power, by adopting *all* the minor advances which his knowledge suggests, to maintain his average level of profits. Thus he may add one 10 per cent by making use of the improved wheats and barleys with which the scientific plant-breeder has presented him; and another 10 per cent by feeding his animals according to scientific principles, and so on. But even the members of the Agricultural Education Association must admit that such men are rare.

The obvious reply is, of course, that the educational standard of husbandmen in general is not high enough. But is not the difficulty really psychological? The adoption of the teachings of education in the everyday affairs of life is dependent on a will to progress, a desire for efficiency. As the late head of the Educational Department of the Ministry of Agriculture once pointed out (to American students of all people!), the pursuit of efficiency is philosophically not always desirable. A marsh starred with Grass of Parnassus is more productive of peace of mind than its efficient substitute a water-cress bed! Rural life is undoubtedly productive of a certain passivity—contentment with things as they are. It is perhaps irreverent to attempt the improvement of Nature's plants. A factory is always crying for improvement, but the lily does not suggest a painter!

Be that as it may, the fact remains that scientific agriculture has not furnished an incitement to the rural worker, unless, possibly, in one direction: the improvement of the animal has always attracted the British farmer, and that as a rule is the chief delight in farming. The animal has proved more plastic than the plant or soil, and it is somewhat unfortunate that the science of animal improvement has scarcely emerged from obscurity. Nevertheless, progress on the practical side is continuous. Such recent triumphs as the 300-egg hen and the 3000-gallon cow offer the husbandman greater rewards than even the largest gift of the chemist, fertilisers from the air, and irradiated foodstuffs.

Physico-Chemical Embryology.

Les bases physiologiques de la fécondation et de la parthénogénèse. Par Albert Dalcq. (*Les problèmes biologiques*, Tome 2.) Pp. viii+274. (Paris: Les Presses universitaires de France, 1928.) 45 francs.

AMONG all the departments of biology, the study of the developing embryo has probably felt least that powerful tendency towards physico-chemical explanations which has transformed so completely other biological fields. It is possible that this impression may be partly mistaken and due to the fact that no one has yet brought together into a fruitful correlation all the isolated and scattered researches on the chemical phenomena taking place in ontogeny. However that may be, the subject of fertilisation and the earliest happenings in the egg-cell has, as is generally known, given rise to a great many investigations which have been carried on with physico-chemical methods and a full appreciation of the importance of the quantitative. Fertilisation, moreover, forms a convenient subject for a review, in that its boundaries are fairly clear-cut and that for practical purposes it can be discussed in separation from the complicated events which follow it.

It is now thirteen years since Prof. F. R. Lillie published his little book on fertilisation, and the amount of activity which biologists have devoted to fertilisation since that time has made a new survey of the subject very desirable indeed. Such a survey was all the more necessary in that Lillie's book was written to a certain extent in the service of a particular theory, that of 'fertilisins,' a theory which is not now held in the unmodified form of that time. This survey has now been brought to a successful completion by Dr. Albert Dalcq, of the University of Brussels. Although those intimately acquainted with this field of work will not agree with him in all his individual judgments, they will certainly admit the success of his review as a whole, and most biologists can scarcely fail to find it a necessity for their shelf of monographs. The book is divided into seven chapters, which work backwards chronologically; thus the first deals with the physiology of cleavage and segmentation, the second with the time elapsing between the fertilisation act and the first cleavage, and the third chapter with the fertilisation process itself. The exposition is expanded at this point to include chapters on the agents of fertilisation and parthenogenesis, and the cytology of the 'activation' mechanism. The sixth chapter, on the physiological consequences of fertilisation, is practically an extension of the first one, but the seventh and last continues the time sequence by dealing with the period between full maturation and fertilisation. The book concludes with an admirably written summary of the present position.

Speaking generally, we may be said to know far more about fertilisation from the outside, as it were, than from the inside, for although a very great number of influences have been brought to bear on the egg-cell and the spermatozoon, the part played by actual physico-chemical analysis of the material itself has been much smaller. Almost all the factors in the environment of fertilisation which can be varied have been varied, and their effects noted minutely. The weakest part of our knowledge of the subject lies in the direct assessment of the physico-chemical changes going on inside the cell itself during these early hours of development. The strongest part of our knowledge is probably the straightforward cytology of the fertilisation process. All of these aspects are dealt with fully by Dalcq, who is particularly happy in his treatment of parthenogenetic agents, which he lists in convenient tables, and in his discussion of the various theories of cell-division.

A critical consideration of some of the details of his book, of course, brings to light various matters which could be improved in a second edition. No mention, for example, is made of the work of W. J. Crozier and his collaborators on the temperature characteristics of cell-division, although the time has surely now gone by when it can be regarded as useful to reproduce Loeb and Wasteneys' Q_{10} values without comment. Again, the discussion of the respiration of the egg-cell before and after fertilisation is confined unnecessarily to data on echinoderms, and such suggestive work as that of Parnas and Krasinska on one hand, and Bialascewicz and Bledovski on the other, is omitted. Thirdly, the investigations of various French workers, in which the 'energy of segmentation' was calculated from the energy required to stop it, are not treated in a very satisfactory manner. But it is unnecessary to catalogue such imperfections, which are inevitable in a book with any personal flavour at all, and will seem to biologists far more than compensated by the obvious value of the monograph as a whole. It may be noted in parenthesis that the proof-reading has not been too carefully done, so that the text and the bibliography are now and then at vexatious cross-purposes. There is no index.

The union of exact biochemical and biophysical work with the basis of cytological and morphological facts already known must inevitably lead to a new era in the study of the 'coming-into-being' of animals, and of this Dr. Dalcq's book on fertilisation provides a happy augury. J. N.

Timber Trees of Malay.

Malayan Forest Records. No. 3: *Commercial Timber Trees of the Malay Peninsula.* By F. W. Foxworthy. Pp. 195 + 140 plates. (Kuala Lumpur, F.M.S.: Forest Department, 1927.) 5 dollars; 12*s*.

THIS important and useful volume of the *Malayan Forest Records*, issued under the auspices of the Federated Malay States Government, has been prepared by Dr. F. W. Foxworthy, Forest Research Officer. The author states that the aims kept in view in its compilation are primarily those of the forest officer of the Malay States. A study of the volume has shown, however, that it is likely to have a wider range of utility, if alone for the very excellent series of photographs of the trees dealt with, with which the book is profusely illustrated. It is worth recording that, although the book is printed locally by a Singapore press, the plates are the work of Messrs. Lascelles and Co., Ltd., of London. Those who have had anything to do with the reproduction of good photographs to illustrate memoirs and so forth drawn up in many parts of the British Empire are well aware that it is very often difficult to obtain good results with the unavoidably inadequate local resources available. The action taken in this matter in the present volume is well worth following.

The timber trees of the Malay Peninsula are of many kinds and are very imperfectly known, says the author, and the need of a manual as an aid to the identification of the more important ones has been very much felt. He states that there are 2500 known species of trees in the Peninsula. "This is, perhaps, more than are recorded from all British India and Burma." This statement is not quite correct. In Gamble's "Manual of Indian Timbers" (2nd ed., 1922) the following is found: "In his introduction to the 'Flora of British India' Sir Joseph Hooker writes of the Indian region (including Ceylon) as 'perhaps the richest, and certainly the most varied, botanical area on the surface of the globe,' and true as this is of the flora in general, it is no less true for the woody species that constitute the forest vegetation." In a tabular statement appended to this remark, Gamble shows series, natural orders, number of genera, and number of species of the trees, shrubs and climbers of the Indian and Burma forests. The grand total comes to 4749, of which the trees number 2513, exclusive of introduced trees.

In discussing the lines on which his manual is drafted, Dr. Foxworthy states that such a manual should give, as simply as possible, the identification marks for each kind of tree and should also give a concise summary of what is known about each of the commercial trees. Work of this kind had been begun by the late Conservator of the States, A. M. Burn-Murdoch (who was previously in the Indian service). In 1911 and 1912 he published two parts of his "Trees and Timbers of the Malay Peninsula." The work came to an end by his death in 1915 and was discontinued. When the present author took up the work, it was reorganised so as to condense the material within one handy volume. It was therefore restricted to "those trees which are considered as present-day commercial timber trees with others which, not falling within that category, are so conspicuous in appearance as to commend attention in the forest."

After detailing the lines upon which the field work was carried out, in which he had the assistance of forest officers and others, Dr. Foxworthy gives some general statements on the geography, climate, and soils of the Peninsula, and then deals with the location, extent, natural conditions, and composition of the forests. The area occupied by the commercial forests is estimated to be about 30,000 square miles, although considerable parts of this tract have not yet been fully examined. There are also considerable areas which have been destroyed by the practice of shifting cultivation and are now only covered with inferior growth. As has been said, the species of trees are very numerous and it is not unusual to find single acres of forest which carry more than 100 species of trees.

The forests are roughly classified as littoral, lowland, and mountain or hill forests. The littoral forests are subdivided into the beach forests and the mangrove swamps, the latter forming an important source of firewood. The hill or mountain forests divide themselves into three types. The highest mountains are clothed with a very dense low-growing forest cover containing many species of poor quality, small trees with thick leathery leaves; the forest is at present of little value. Below this comes the mid-mountain forest with better commercial prospects, though at present it is only exploited in the neighbourhood of hill stations. In the mountainous country, high ridges stand out sharply and bear a dense cover of large trees on their crests, amongst which *Shorea Curtisii* is often abundant. The hill forests are roughly taken to be those above 2000 feet elevation.

The third division is the lowland forests. This type starts where the beach forest ends and runs up to the hill type, although, as is usual in such forests, the dividing line is not a sharp one. Briefly, the lowland forests are subdivided into swamp forests, forest which has been subjected to shifting cultivation and is now covered with a poor growth, and high forest. It is calculated that the second type—the aftermath of shifting cultivation—will require 250 years under natural conditions before it again becomes a valuable forest of commercial species. The high forest is what Schimper ("Plant Geography," Chaps. ii. and iv.) terms 'rain forest.' It contains a large number of species and includes most of the present-day commercial timber trees of the Peninsula.

"Our forests," says the author, "are most closely related to those of the Netherlands Indies, Borneo and the Philippines. Detailed studies in the two latter regions have shown that the forests have from 60 per cent. to 90 per cent. of their volume produced by trees of one family, the *Dipterocarpaceæ*. The indications are, from such studies as have been made in the Malay Peninsula, that our forests have about 60 per cent. of their volume of timber in this group."

Dr. Foxworthy has drawn up a key, which is mainly intended for use in the forest by forest officers; it lays most emphasis on those features which are most apparent in the field, more especially the bark, which forms the basis of the key. He has not arranged his material in botanical sequence since he says the book has no pretence at being a botanical flora; for the same reason his descriptions of trees are in simple language. All will not perhaps subscribe to Dr. Foxworthy's arguments or arrangement of his work. It is probable, however, that he will find the average forest officer and others working in the forests in agreement with him; and for the rest, time alone will prove whether the key fulfils the practical objects it aims at. This being said, the author may be congratulated on the compilation of a piece of work which should prove of great utility to all who work amongst or wish to become acquainted with the commercial trees of this region.

Prehistoric Research in France.

(1) *La Grotte de l'Observatoire à Monaco.* Par Marcellin Boule et L. de Villeneuve. (Archives de l'Institut de Paléontologie humaine, Mémoire 1.) Pp. 114+27 planches. 150 francs.

(2) *Les Poissons, les Batraciens et les Reptiles dans l'Art quaternaire.* Par Henri Breuil et R. de Saint-Périer. (Archives de l'Institut de Paléontologie humaine, Mémoire 2.) Pp. 170. 80 francs. (Paris: Masson et Cie, 1927.)

(1) "LA Grotte de l'Observatoire à Monaco" is the first of a series of memoirs to be issued by the Institute of Human Palæontology at Paris, founded some years ago by Prince Albert I. of Monaco.

The late Prince will long be remembered by prehistorians for the active interest he took in all kinds of prehistoric research and for the magnificent series of publications he inaugurated. Not least among these latter were numerous volumes dealing with the results of excavation in the caves near Mentone. The excavations were under the careful supervision of the Chanoine de Villeneuve, and it is largely due to his scientific precision and careful digging that so much valuable material was obtained.

After the work at Mentone was finished, attention was turned to another cave near Monaco, just below the Observatory and high up on the hillside overlooking the sea. For many years past excavation has been proceeding there, and the work in many ways has been one of peculiar difficulty. In the volume under review we have the results of these years of labour described for us by the Chanoine de Villeneuve and Prof. Marcellin Boule, who has undertaken the detailed study of the objects found, especially of the fauna.

The cave consists of a vestibule, descending rapidly at the back. A large number of archæological layers have been isolated, but these can be grouped into three series, separated by layers of stalagmite; at the bottom were found Lower Palæolithic, in the middle Mousterian, and at the top Aurignacian industries. An interesting find in one of the lower levels was a *coup de poing* made of limestone. This is the first one known in the Riviera district.

The fauna is as might be expected, but the presence of *Cuon alpinus* race *Europæa* is important, although it is not the first example to be found in the district, another having been discovered some years ago in a cave near Vence.

A chapter on the history of the excavations is first given. This is followed by an account of the individual layers and their contents, after which follows a careful description of the fauna and the tools found. The volume concludes with a large number of plates.

The only criticism that can be offered is that the description of the implements is perhaps rather inadequate, and the space allotted for the purpose insufficient. Especially is this the case when we consider the amount of space allowed for the description of the fauna. The plates are good, although perhaps not all quite up to the standard of what we have learned to expect from the Institute. All the same, the volume is a valuable addition to our knowledge of prehistoric times in the district, and Prof. Boule and his collaborator are indeed to be congratulated.

(2) The second of the memoirs published by the Institute deals with certain conventionalisations derived from naturalistic representations of fish, lizards, serpents, etc., that appear in Quaternary art. For many years past M. Breuil has been collecting material and forming series showing how the naturalistic representation of the animal becomes conventionalised. Starting with the original naturalistic representation, a number of diverging lines of development can be determined, there resulting finally totally different conventionalisations. These conventionalisations are of the nature of symbols, having apparently little connexion with the animal they represent; it is only by the finding of all the links in the chain that their meaning has been elucidated.

Collaboration with the Comte de Saint-Périer is indeed happy, and, as M. Breuil himself says, the descriptions are largely due to his colleague, to whom has been given his *dossier* of drawings and his general ideas on the subject. What that *dossier* of drawings is like the reviewer well knows. He spent much time in 1914 in wading through that enormous and precious mass of material.

An added interest is given to the work in that an attempt is made to correlate the various stages of conventionalisation with the actual age of the objects on which they are found. For this purpose the sixfold system of subdivision for the Magdalenian culture, long ago suggested by M. Breuil and now generally accepted in England, is adopted. The results are very interesting, as they show how the conventionalisation altered in the different industries belonging to these various subdivisions.

An important paragraph, which is not further elaborated, deals with the distribution of the industries of the various Magdalenian stages. It is interesting to note at what moments the Magdalenian culture spread its influence far and wide.

M. Breuil and the Comte de Saint-Périer are to be congratulated on their work and on the numerous well-chosen illustrations therein. It is to be hoped that the matter will not be allowed to remain where it is and that further volumes dealing with the conventionalisation of other animal forms, etc., will be issued within the next few years.

M. C. BURKITT.

The Minor Constituents of Coal-Tar.

The Higher Coal-Tar Hydrocarbons. By Dr. A. E. Everest. Pp. xiii + 334. (London: Longmans, Green and Co., Ltd., 1927.) 18s. net.

COAL-TAR products may be divided roughly into two groups, the major and minor constituents of tar, this division having relation to the percentage amounts in which these substances appear in the various fractions of tar distillation, but not necessarily to their intrinsic importance. Among the major constituents are the well-known benzene, naphthalene, and carbolic acid. Of the minor constituents, the most valuable, and historically the most interesting, is anthracene, the yield of which from average high temperature tar is about 0·4 to 0·8 per cent. Until recently anthracene was the only starting-point in the manufacture of anthraquinone colours, although now this important quinone is synthesised industrially from benzene and phthalic anhydride, the latter being derived from naphthalene.

Dr. Everest's book is devoted to a group of higher coal-tar hydrocarbons which are constituents of the less volatile fractions of coal-tar distillation and, like anthracene itself, they form only a very small proportion of the total distillate from tar, but owing to the large scale on which this distillation is conducted, the quantities of these hydrocarbons available would be considerable if they became of value for technical purposes. The subject matter of this book is arranged in three main chapters, dealing respectively with the acenaphthene, fluorene, and phenanthene groups. A concluding chapter is devoted to several hydrocarbons not immediately related to the three foregoing main sections.

Acenaphthene itself is a hydrocarbon which has already been utilised in colour-making. For this purpose it is first oxidised to its quinone, acenaphthenequinone, which is then condensed with hydroxythionaphthene (thioindoxyl) or its derivatives. The resulting colours are vat dyes of the Ciba scarlet series. More recently another oxidation product of acenaphthene, namely, naphthalic acid, has come into prominence as a starting-point in the production of complex vat dyes of the perylene series. The hydrocarbon, perylene, in the volume under review, is considered as a derivative of phenanthrene. It is figuring more and more in modern chemical literature, and is the subject of many current patent specifications.

Dr. Everest's treatise arrives at an opportune time, when fresh interest is being aroused in coal-tar products owing to the circumstance that the attention of chemical investigators is now directed to a new variety of tar produced during the low-temperature carbonisation of coal. This tar also contains its two groups of major and minor constituents, and among the latter are hydrocarbons either identical with or closely related to the hydrocarbons discussed in the present volume, which contains references to coloured hydrocarbons of unknown constitution, such as crackene and chrysogene. Recent investigations have revealed the presence of similar coloured substances in the less volatile fractions of low-temperature tar.

Many interesting research problems are presented by the hydrocarbon, fluorene, and its derivatives. This hydrocarbon has the remarkable property of forming a potassium derivative with heated caustic potash and a sodium derivative with warm sodamide. The latter reaction renders possible the isolation of fluorene on a large scale. The most readily prepared diamine of fluorene possesses certain analogies with benzidine and other colour-producing diamines, but although the disazo dyes from 2 : 7-diaminofluorene are direct dyeing cotton colours, they offer no special advantages over the commercial dyes made from benzidine and dianisidine. The long chapter on phenanthrene contains a comprehensive survey of the large amount of research which has been carried out on this hydrocarbon. Phenanthrene is still the forlorn hope of the colour-maker, although it is of great scientific interest owing to its relationship to the opium alkaloids, morphine, codeine, and thebaine, all of which contain a phenanthrene nucleus.

The phenanthrene structure has also been revealed in several more complex hydrocarbons. Among these are retene, obtained from wood tar, or by the action of sulphur on resin oils; chrysene and pyrene derived from high-temperature tars; and picene, a product of the distillation of lignite tar. All these substances are adequately discussed, and throughout the book there are copious references to original literature. The utility of the work as a reference book is further increased by the inclusion of complete author- and subject indexes. Within a handy compass, the book contains a considerable store of both scientific and industrial information, and is accordingly a useful addition to the technical literature of coal-tar products.

G. T. M.

Thermionics and Flames.

Handbuch der Radiologie. Herausgegeben von Prof. Dr. Erich Marx. Zweite Auflage. Vierter Band, Dritter Teil: *Glühelektroden,* von Prof. Owen W. Richardson, übersetzt und bearbeitet von Prof. Dr. A. Karolus; *Technische Anwendung der Glühelektroden,* von Prof. H. Rukop; *Flammenleitung,* von Prof. Erich Marx. Pp. xvi + 724. (Leipzig: Akademische Verlagsgesellschaft m.b.H., 1927.) 50 gold marks.

THE present rapid rate of progress in physics seems to make it inevitable that parts of a monograph should need revision even in the interval between preparation of the manuscript and publication of the book, whilst the task of bringing out new editions is at once the more necessary and the more difficult. The three sections of this volume of the "Handbuch der Radiologie" present as many different attempts to cope with the problem. "Glühelektroden" is essentially Prof. O. W. Richardson's "Emission of Electricity from Hot Bodies," with some additional references, and an appendix by E. Rupp, where the main results obtained in this field between 1921 and 1926 have been summarised. The decision to leave it in this form appears wise, since although there is no immediate prospect of radical alterations in the experimental basis of the subject, Prof. Sommerfeld's very recent application of the Fermi statistics to free electrons has at least shown that its theoretical basis is in too fluid a state to justify more drastic alterations yet.

The second section, Prof. Rukop's account of the technical applications of thermionic phenomena, is, on the contrary, entirely new. In its main features it constitutes another appendix to the preceding part, and deals with the two branches of thermionics which were deliberately omitted from the latter, namely, the construction of valves of various types, and their use as units of conducting networks. It will be of special interest to English readers from the fact that most of the references are to German patent specifications and literature, whilst two pictures of the Königswusterhausen and Langenberg transmitting stations will lend life to two voices which most of us will have heard but few can have seen. The hundred odd figures are good, and go far to contribute to the success of the writer in compressing his subject into as many pages.

The electrical properties of flames have again been treated by Prof. Marx, and his plan has been to retain the bulk of the older historical and descriptive work, but to give some considerable space to more modern theory. Prof. Marx himself has been largely responsible for the application of the Saha theory of thermal ionisation, and his account of it is thus particularly valuable and authoritative. One wishes that the phenomena of glow discharges were equally amenable to analysis. It is to be regretted that no reference has been made to the important researches of the last few years on cold flames, since the presence or absence of ionisation in these, and their peculiar spectroscopic properties, suggest strongly that they represent isolated processes which occur as intermediate reactions at higher temperatures.

Our Bookshelf.

Radio-Elements as Indicators: and other Selected Topics in Inorganic Chemistry. By Fritz Paneth. (The George Fisher Baker Non-resident Lectureship in Chemistry at Cornell University, Vol. 2.) Pp. vii + 164. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1928.) 12*s.* 6*d.* net.

Prof. Paneth's introductory lecture was partly of a historical character and partly critical of certain well-known claims of more recent years, being a discussion of "ancient and modern alchemy"; in it the author incidentally announced his inability to confirm Collie and Patterson's claim to the synthesis of helium and neon, but remarked that our cautious return to an earlier view of the feasibility of the transmutation of elements—"Alchymia scibilis est, non tamen adhuc scitur"—has greatly stimulated popular interest, unfortunately sometimes ignorant and credulous, in this branch of knowledge and speculation.

Nine following chapters are devoted to a consideration of the use of radio-elements as indicators, whereby, in view of the ease of detection of radioactivity and the known chemical identity of isotopic elements, it is possible to deduce or to follow the course of physical and chemical changes by an indirect process. Thus the method is applicable, for example, to a determination of the solubility of lead chromate, a known quantity of thorium-*B* being first added; to proof of electrolytic dissociation and of the interchange of ions; to a study of the phenomena of adsorption and colloid chemistry, and to technological, physical, and physiological problems. The discovery of the hydride of thorium-*C* was followed by the preparation of bismuth hydride from ordinary inactive bismuth, and lead hydride, first prepared by the radioactivity method, was later obtained from ordinary lead.

Four chapters which are devoted to the group of volatile hydrides are no less valuable than the preceding section. The remainder of the book, constituting a brief study of the natural system of the elements, does not invite particular comment. Name and subject indexes are provided.

A. A. E.

The Earth, the Sun, and the Moon. By Dr. George Forbes. Pp. 80. *The Stars.* By Dr. George Forbes. Pp. 79. (Benn's Sixpenny Library, No. 106 and No. 107.) (London: Ernest Benn, Ltd., 1927.) 6*d.* each.

The above little books by Dr. George Forbes may be described jointly. They are designed to awaken the interest and enthusiasm of beginners, and deal with the heavenly bodies in large measure from a poetical and romantic view-point. But they embody many of the latest results, including a brief description of Brown's lunar tables, and a note on Einstein's explanation of the motion of the perihelion of Mercury; the author seems to view the latter with disfavour as upsetting Newton's great law; but it seems more correct to view it as a slight amplification of the law, which Newton himself would have been glad to make if the evidence for it had then been available.

A few points call for comment: in the first book, on p. 59, it should be explained that the lunation is 2·2 days longer than the moon's period of revolution round the earth; the text suggests that they are identical. On p. 62, no extended regions of the moon approach the brilliance of snow as is stated in the text; even Aristarchus, the brightest point on the disc, has a lower albedo than this. In the book on the stars, on p. 60, the sun's motion is only two-thirds of the earth's orbital speed, instead of being "a little quicker"; on p. 68, it is an exaggeration to say that the pitch of a note from a locomotive whistle can be altered as much as an octave by the motion of a train. Even if the listener were in another train travelling in the reverse direction, the speed of each being 60 miles an hour, the change of pitch on passing would be less than this.

A. C. D. C.

Benedetto Croce: an Autobiography. Translated from the Italian by R. G. Collingwood. Pp. 116. (Oxford: Clarendon Press; London: Oxford University Press, 1927.) 5*s.* net.

ALTHOUGH the translation of this autobiography has only recently appeared, the work itself was completed during the War, and in fact before Italy was involved. The writer had reached his fiftieth year, and the value of the book is increased by a suitable prefatory note by J. A. Smith, summing up the importance of the influence of Croce and Gentile during the last twenty years.

The author's object in his work, which was not originally intended for publication, consists neither in confession, nor recollection, nor memoir. He seeks in plain terms to sketch a criticism and therefore a history of the contribution which he has made to the common stock of work done. It is natural that outward events enter into the narrative, which thereby gains in human interest, and one is conscious of the contrast between the political atmosphere of Rome and the academic quiet of Naples. His criticism of Marxism resulted in a deeper interest in philosophy, and in 1902 appeared the "Theory and History of Æsthetic." In the years of activity that followed, Croce found by experience the falsity of that pedagogic theory which restricts education to the first part of life. He also came to possess that toleration which reveres the efforts of past thinkers and recognises that no man can achieve finality in the search for truth.

H. D. A.

Frequency Curves and Correlation. By W. Palin Elderton. Second edition. Pp. viii + 239. (London: Charles and Edwin Layton, 1927.) 15*s.* net.

THIS work deals with the data used by the actuary, for whom it is primarily intended. Nevertheless, the account here given of curve fitting by the method of moments should prove extremely valuable to the non-actuarial reader, who is, however, recommended to begin by reading Appendix VII. An admirable discussion of fitting curves of Pearson's types is fully illustrated with numerical examples and diagrams. A valuable feature is a table of the various types, giving their equations, and a criterion for their applicability. The equations are also given with the origin at the mean, thus allowing a uniform procedure.

The treatment of 'goodness of fit' given in a later chapter could, with advantage, have been fuller. The matter of random sampling is treated in a somewhat summary fashion, the author advancing the opinion that a little thought and common sense are all that are required. The remainder of the book deals with various aspects of correlation. For the benefit of those who are more interested in this part of the subject an abridged course of reading is given in Appendix VIII. A table of the logarithmic gamma function is also given. No great mathematical attainments are demanded of the reader, and the book should continue to prove very useful.

Recent Advances in Ophthalmology. By Dr. W. Stewart Duke-Elder. (The Recent Advances Series.) Pp. xvi + 339 + 4 plates. (London: J. and A. Churchill, 1927.) 12*s.* 6*d.*

THE author of "Recent Advances in Ophthalmology" is careful to point out that this book is in no way to be considered a text-book. His object is to summarise the research work of recent years in association with the subject, to indicate the lines along which ophthalmology is at present developing, and to guide the student seeking what is of value in the accumulation of modern literature. This survey extends over a wide range, from physiological and embryological research to the neuro-psychological foundations of vision, and discusses methods of diagnosis and treatment and morbid processes. From the nature of the eye, it is inevitable that diagnostic methods should attract much attention; of these, the most important is biomicroscopy by means of the slit-lamp, the value and limitations of which are fully considered.

The chapter on neurology includes the observations of neurologists and ophthalmic surgeons on the visual paths and centres and their associated tracts in the nervous system. There is also a brief but well-reasoned section on the psychological aspects of vision and perception. The book is well illustrated and indexed and numerous references are given. Dr. Duke-Elder is to be congratulated on the way he has carried out his task.

Interpreters of Nature. Essays by Sir George Newman. Pp. 296. (London: Faber and Gwyer, Ltd., 1927.) 12*s.* 6*d.* net.

THESE essays, whether relating to explorers in science, great practitioners, or interpreters of human desires (as, for example, Keats), were well worth publication in collected form. They supply excellent reading. Especially interesting are those on the disciples of Boerhaave in Edinburgh, and William Osler as a physician of two continents. A more extended index would have been useful and convenient.

Letters to the Editor.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, nor to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Pressure of Calcium in the Sun's Atmosphere.

IN a recent interesting investigation, A. Unsöld has estimated the total number of atoms of various kinds in the solar atmosphere which give rise to Fraunhofer lines of the observed width and depth (*Zeits. für Phys.*, **46**, 765; 1928). The theoretical curves he has calculated reproduce with remarkable fidelity the contours of such lines as those of sodium, calcium, strontium, and barium. They give, it is true, too small values for the residual intensities in the centres of the lines, but in the wings, where the theory seems unquestionably trustworthy, they agree exceedingly well with observation. With the aid of the Saha theory of ionisation, Unsöld has deduced the total number of atoms of a given species per square centimetre column above the 'photosphere.' The results as regards the relative abundances of atoms of different kinds are in agreement with Miss Payne's estimates of *relative* abundances in stellar atmospheres, but Unsöld's method leads to an *absolute* determination. For example, for calcium he finds 2·3 × 10^{19} atoms per cm.^{2}.

CALCIUM ON THE SUN.

Nature of Equilibrium.	Level.	Partial Pressure of Calcium (atmos.).	Ca^{++}. (Fractions).	Ca^{+}. (Fractions).	Ca. (Fractions).
Chromospheric Equilibrium or Monochomatic Radioactive Equlibrium. (Strong selective radiation pressure.)	High Level Chromosphere	Small pressure gradient.	0	1·0	0
	⋮ (7000 km.) ⋮				
	Middle Chromosphere		0	×	×
	⋮ (7000 km.)		(Plane of demarcation)		
Local Thermodynamic Equilibrium. (Selective radiation pressure rapidly decreasing.) (Reversing Layer and Photospheric Layers.)	Base of Chromosphere	10^{-13}	1·0	10^{-3}	0
	⋮ (100 km.) ⋮				
	Level of maximum Ca^{+}	2×10^{-7}	10^{-3}	1·0	10^{-4}
	⋮ (30 km.) ⋮				
	Depth of complete opacity	5×10^{-5}	0	0·85	0·15
	⋮ Interior.		Ca rises to a maximum. Then Ca^{+}, Ca^{++}, Ca^{+++} . . . in turn.		

The question arises why this constant should have this particular value. Why should there be 2·3 × 10^{19} atoms of calcium per cm.^{2} present for absorption purposes in the solar atmosphere? As we penetrate the solar layers from outside, we shall go on encountering calcium atoms in various stages of ionisation, right into the far interior. How comes it that only the uppermost 2·3 × 10^{19} atoms per cm.^{2} render themselves apparent in the formation of absorption lines?

The answer must be that below the level corresponding to 2·3 × 10^{19} atoms per cm.^{2} complete opacity must have set in. Unsöld himself has calculated the *mean* pressure of these calcium atoms, assuming they extend through the complete chromospheric column of 14,000 km. thickness. He finds thus 1·1 × 10^{-8} atmos. But it appears to me, for reasons I have given elsewhere, that the greater part of this column of 14,000 km. is at a much lower pressure, in circumstances of what I have called 'chromospheric equilibrium,' the atoms being almost entirely supported by radiation pressure. This column thus includes only a minority of the calcium atoms, and the bulk of the atoms will accordingly be at a higher pressure, concentrated in a small thickness (some 100 km.) at the base of the column and comparatively unsupported by selective radiation pressure. It therefore seems to me more significant to calculate not the mean pressure but the pressure at the base of the column. For this purpose we may neglect radiation pressure and estimate the pressure by multiplying the value of solar gravity by the mass of calcium atoms per cm.^{2}. The result is a pressure of 4·1 × 10^{-5} atmos. This must accordingly be the pressure at which complete opacity sets in. A more refined calculation given in *Mon. Not. R.A.S.* (**88**, 200; 1928) gives 5 × 10^{-5} atmos.

I wish here to point out that this result is in very fair agreement with an estimate which I made in 1925 (*Mon. Not. R.A.S.*, **85**, 778) by an entirely different method. The method consisted in a crude modification of Kramers' theory of the absorption coefficient in the continuous spectrum formed by the ejection of photo-electrons. Assuming the sun was entirely composed of calcium atoms, I found that at the level from below which only one per cent of the continuous spectrum emerges, *i.e.* roughly at the level at which almost complete opacity is established, the total pressure (electrons plus ions) was 1·1 × 10^{-4} atmos. The corresponding pressure of calcium atoms (I assumed for simplicity complete first-stage ionisation down to this level) was accordingly 5·5 × 10^{-5} atmos. This is to be compared with the above values 4·1 × 10^{-5} atmos. and 5 × 10^{-5} atmos. derived by an entirely different path of reasoning direct from Unsöld's treatment of the observed line-widths of the *H* and *K* lines. The theory I was using is subject to criticism in details, but generally speaking the agreement of the two estimates strongly confirms the suggestion that photo-ejection of electrons is the dominant cause of the sun's continuous spectrum.

In the tentative picture of the sun's calcium atmosphere to which we are led by these and allied calculations, it appears that to a first approximation we may divide the chromospheric layer from the reversing layer and photospheric layers by a certain plane of demarcation. Above this plane the rarity of collisions permits monochromatic radiative equilibrium with strong selective radiation pressure. Below the plane collisions give rise to a state of local thermodynamic equilibrium in which selective radiation pressure decreases inwards exponentially with the optical thickness. In the upper region only those atoms are present which are capable of support by selective pressure. In the lower region the dissociative equilibrium of the different kinds of ions is determined by Saha's theory. The pressure at the interface will be very low, and even Ca^+ atoms will be in a minority compared with Ca^{++} atoms. As we descend, the proportion of Ca^+ atoms increases and rises to a maximum, thereafter decreasing and giving place to Ca atoms. Ultimately, increasing temperature causes ionisation of Ca atoms, and we pass in turn through maxima of Ca, Ca^+, Ca^{++}, etc., as first pointed by Pannekoek some years ago.

The accompanying rough table gives the scheme of pressures and stages of ionisation. Actually, of course, the two layers separated by the plane of demarcation in the scheme must merge into one another continuously, and the scheme does not pretend to treat the transition accurately.

E. A. MILNE.

The University, Manchester.

The Spectrum of the Hydrogen Molecule.

THE very accurate table of wave-lengths in the secondary spectrum of hydrogen which has recently been published by Gale, Monk, and Lee (*Astrophys. Jour.*, vol. 47, p. 90; 1928), has made possible a great advance in our knowledge of the structure in this spectrum. The very extensive series of band systems described in *Proc. Roy. Soc.* (A, vol. 113, p. 368; 1926) is fully confirmed, and the combinations are found to be exact to the accuracy of the new data. This is true in all essential details for the bands which involve the electron transitions 3⟶2 (α), 4⟶2 (β), and 5⟶2 (γ), but the weak bands involving the 6⟶2 (δ) and higher transitions will require some reconsideration.

As a result of a re-examination of the series of band systems towards the violet end of the spectrum, described in *Proc. Roy. Soc.* (A, vol. 115, p. 528; 1927), we have been led to the discovery of a very large number of bands which have the same final states as these. The bands as there described consisted of 6 progressions with a maximum of 4 members in each. We now have about 40 such progressions, several of them extending to 9 members. Many of the leading lines are very strong, and have been measured with the interferometer as standard lines by Gale, Monk, and Lee. As a result of this and of the large number of systems, we are able to determine the relevant data with very great precision. For example, we believe the following to be the final vibrational differences ($1''\longrightarrow0''$, $2''\longrightarrow1''$, etc.) of the lowest rotational levels of these systems: 1312·55 (4), 1276·60 (2), 1242·382, 1209·062, 1176·33 (3), 1144·00, 1112·08, and 1081·29. All these numbers are believed to be sure to within half a unit of the last digit but one. Where the last digit is enclosed in brackets it is less sure than in the other examples. In the one case in which there is a double check involving only standard lines, that is to say, in which all 4 lines have been measured with the interferometer, we find the practically identical values $1242{\cdot}381_1$ and $1242{\cdot}383_1$ cm.$^{-1}$.

The vibrational differences of the B states got by Dieke and Hopfield from measurements of the ultra-violet absorption bands of H_2 are 1313, 1276, 1247, and 1209 in succession. In spite of the apparent discrepancy at the third interval, we think that these B states must be the same as our final states, because the identity is now confirmed by the value of the moment of inertia. For a number of the bands we have been able to identify the $Q(m)$ lines up to $m=6$. This enables us to obtain the quantity α in $B_n''=B_0''-\alpha n''$. From the vibrational data, using Kratzer's formulæ, we then deduce $2B_0''=u\omega_0=31{\cdot}1$. This is about 12 per cent higher than the value got by Birge (NATURE, Jan. 28, 1928) from the ultra-violet data, and the agreement is as good as the method warrants.

Owing to the very large number of these progressions it will take some time to arrange them. The distribution of intensity among the bands presents different and interesting features in the various progressions, and the initial states evidently exhibit considerable variety. These bands, which extend from the ultra-violet right through the visible into the infra-red, account, together with the α, β, γ bands, for about half the total strength in the secondary hydrogen spectrum.

Many of these bands have an alternation in the intensity of the successive lines with a 3 to 1 ratio, such as was found to be characteristic of the strong bands of the α, β, γ series. These results now rest not only on the data of McLennan, Grayson-Smith, and Collins, but in the case of ${}_1A_2Q(m)$ they are confirmed by the intensity measures of Ornstein, Kapuscinski, and Eymers, and in the case of some of the α-bands by the intensity measures of Goos.

Yield Variability in *Hevea brasiliensis*.

THE most perplexing problem of the rubber-planting industry is the variable yield capacity of different *Hevea* trees. The yields of individual trees range from half a pound to 12 lb. a year, and rare trees are known that have given regularly 30 lb. and more per annum. It is the presence of so many poor yielders (unrecognisable before the tapping age) that keeps down production. Crops per acre on the average estate seldom exceed 350 lb., and numerous tests have shown that most of this rubber is obtained from some 25 per cent of the trees.

Investigations into the causes underlying yield variations have been in progress at the different rubber research stations for many years, and it was thought at one time that the number of rings of latex tubes in the cortex—a factor which is correlated in some measure with yield—would, on closer study, prove to be the determining factor.

With the object of throwing some light on this problem, I commenced in 1922 a detailed study of a group of 250 *Hevea* trees. Anatomical investigations of the cortices of these trees have been made regularly every year, and some of the trees have been studied exhaustively from root tip to leaf tip. Since 1925, when tapping commenced, the yields of all the trees have been measured after each tapping, and attempts have been made to correlate yields with the anatomical characters noted.

The decisive results obtained will be embodied in a forthcoming publication. Meantime it can be stated here that my investigations conclusively show that the number of latex rings is at no stage sufficiently closely related to yield to justify one in regarding this as the chief determining factor. In the early life of the plant, the number of rings present is no guide to the yield value of the tree, the correlation coefficient even so late as the fourth year being only about + 0·37.

With regard to the disposition of the various rings in the cortex, there appears to be nothing in the arrangements in the successive years from the third to the eighth which is likely to augment materially the value of the ring number factor as a dependable criterion of yield.

The inadequacy of the factor mentioned led me to investigate other characters, and in 1923 I discovered the existence of a relation between the bore of the latex tubes and yield. The great technical difficulties in the way of accurate measurement of average latex tube bore made progress in the study of this character extremely slow, but by the middle of last year I had definite evidence that the bore of the latex tube was the missing factor in the causation of yield variations. High yielders had, I found, large bored tubes, and poor yielders small bored tubes. Of particular importance was the discovery that trees in which the latex tubes have bores below a certain value never become high yielders.

Thanks to improvements made in technique, which enable measurements to be carried out with greater speed and accuracy, I have lately obtained complete confirmation of the previously discovered relation between latex tube bore and yield. Careful duplicated measurements of the latex tubes in the large group of trees mentioned have brought to light a striking correlation. Notwithstanding the disturbing effect of differences in the number of rings in the trees compared, the correlation coefficient of tube diameter with latex yield works out at the high figure of + 0·76 (P.E. ± 0·018). When the aberrations introduced by the variable number of latex rings are discounted by considering only the yield per ring, the correlation coefficient rises to + 0·83 (P.E. ± 0·014). (It may be mentioned here, for comparison, that the correlation coefficient of ring number with yield is only from + 0·3 to + 0·5 according to age of trees.)

It is interesting to find that latex yield increases much more rapidly than the square of the tube diameter. This is no doubt to be attributed to the disproportionate reduction in the internal resistances to flow which a slight increase in the bores of tubes of the order of latex tubes would bring about.

Other anatomical features, such as the density and disposition of the individual latex rings (the latter especially) are occasionally responsible for yield variations. If the disturbing influences of these two factors are taken into account, it will, I think, be evident that we now have, on the anatomical side at any rate, a fairly adequate explanation of the causes of yield variations in *Hevea brasiliensis*.

The practical value of the ascertained correlation between tube bore and yield is that it places at our service a character (defined early in the life of the tree) that can be used to distinguish potentially poor from potentially good yielders, for my observations show that for a rough initial classification, the latex ring factor can be ignored.

As to whether latex tube bore is a hereditary and constant character, there seems little doubt. Numerous one-year-old *Hevea* plants of vegetative origin have been found by me to have latex tubes of the same average bore as those of the 15- to 20-year-old trees from which the plants have been derived. Further confirmatory evidence has been provided by a recent examination of several hundred six-months-old nursery plants. In these, not only is a similar range of differences in latex tube bore observable, but roughly the same proportion of large, medium, and small bored plants occurs as among adult trees. It has, indeed, been found possible to classify *Hevea* plants by the new factor even at this early age, and although such a test bristles with difficulties, I am convinced that the detection of the 50 per cent odd plants found in every nursery that have latex tubes of too small a calibre to enable them to become good yielders can be made a practicable business. The elimination of such plants alone would be the means of doubling the productivity of future planted rubber areas.

It may perhaps be of general interest to botanists to know that I have also found a noteworthy correlation between the average cortex cell diameter and latex yield. This is only traceable in certain tissues, particularly the phloem parenchyma. Here also an agreement in cell size between *Hevea* trees and their budded offspring has been observed. Unfortunately, average cell size is, for many reasons, difficult to measure with certainty, and as a diagnostic character of yield capacity in *Hevea* (for which it was investigated) has too many pitfalls to be depended upon. However, the observation may not be without value also to those concerned with other branches of economic botany in which the vegetative organs are the source of the crop.

Diffraction of Cathode Rays by Mica.

A DIFFRACTION pattern was obtained by passing a cathode ray beam through a thin sheet of mica, with an apparatus similar to that used by G. P. Thomson in his interesting experiment on the diffraction of cathode rays by thin films of celluloid and some metals (*Proc. Roy. Soc.*, Ser. A, vol. 117, p. 600; 1928).

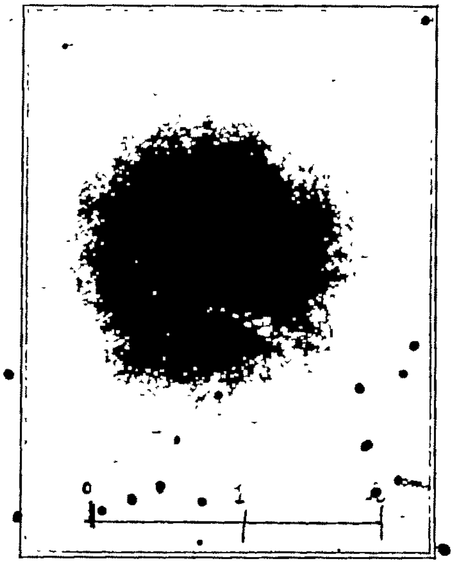

FIG. 1.

The pattern shows in some respect a resemblance to the Laue pattern of X-rays, but the most conspicuous feature of the former is quite different from that of the latter. In Fig. 1 is reproduced one of the photograms obtained, in which the distance between the crystal and the plate was 12 cm., and the voltage applied to the tube was about 50 kilovolts. As will be seen from the photogram, three sets of parallel bands intersecting each other at an angle of 60° form a net of triangular mesh, of which the net points are arranged into an array of spots. Some of the spots are remarkably intensified and somewhat elongated.

The distance between the parallel bands decreases as the applied voltage is increased. The distribution of the intensified spots is also changed with the applied voltage. When a magnetic field is applied in the path of the rays, the pattern as well as the central spot are shifted. From the magnetic deflexion it is found that the primary rays are more or less heterogeneous, while the transmitted rays seem to be fairly homogeneous. The formation of the net-like pattern may be accounted for as due to the diffraction of short waves by a two-dimensional lattice placed perpendicular to the incident beam, or, in other words, the diffraction of the 'de Broglie waves' by a single layer of net plane parallel to the cleavage face with atoms arranged in a triangular lattice.

This explanation seems to be justified, as the distance of the bands gives a right order of magnitude for the atomic distance. The appearance of the intense spots may be due to the effect of a three-dimensional lattice, and therefore they may correspond to the Laue spots. The elongation of the spots is perhaps due to the distortion of the specimen.

Further experiments are being made.

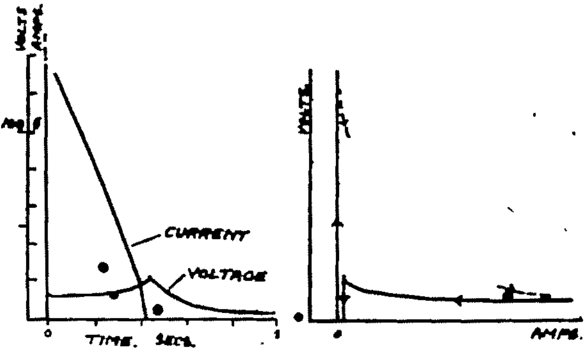
New Type of Discharge in Neon Tubes.

THE new type of discharge described in NATURE of May 19, p. 794, is evidently the same as that which I have produced when using a neon lamp as a safety device (*Proc. Leeds Phil. Soc.*, 1, 185; Nov. 1927). The method, although different, is similar in principle.

An ordinary 'Osglim' lamp, with the safety resistance removed from the cap, was connected across the coils of an electromagnet excited by 110 volts. This is not large enough to excite the neon lamp, but if the current is suddenly broken a high E.M.F. will, of course, result on account of the self-induction of the coils. The presence of the neon tube, however, limits the rise of voltage, since its resistance falls to a low value when excited in this manner.



(a) (b)

FIG. 1.

The behaviour of the neon tube under these conditions, which, as indicated by the nature of the discharge, was quite different from that when in normal use, was investigated in some detail. The results of these investigations agree in general with those already described in NATURE (loc. cit.), and an account of them is to appear in the next issue of the *Proceedings* referred to, but one or two points of interest may be mentioned here.

The 'Osglim' lamp used was of the 'letter' type, as the bee-hive pattern did not stand up to the discharge so well. With the aid of a cathode ray oscillograph, curves giving the relation between current and voltage, current and time, and voltage and time, were obtained and photographed. Several exposures were of course necessary, but with suitable precautions it was possible to repeat any particular curve as often as desired.

The variations of voltage and current with time in a typical case are conveniently shown together in Fig. 1 (*a*); and (*b*) indicates the nature of the current–voltage curve. It may be seen that on breaking the current in the inductive circuit across which the tube is connected, the voltage rises with great rapidity (to 300-400 volts) and drops almost immediately to a low value (about 11 volts in this instance). At the same time the current rises to more than 6 amp., and, as Fig. 1 (*b*) shows, attains its maximum as the voltage reaches its low value. The resistance of the tube at this stage is between 1 and 2 ohms.

The extinction voltage (which varies somewhat as the conditions are altered) is also seen to be quite different from that usually found when the ordinary pink glow is seen. It was thought at first that the second rise in potential (Fig. 1 (*a*)) synchronised with a second increase in brightness which is usually observed, but the current is always zero before the second peak is reached. Sometimes as many as three or four flashes were seen, and there were other divergences from what may be regarded as the normal behaviour under these particular conditions, but it is not possible to discuss them here.

The Corpus Luteum and the Cause of Birth.

RECENTLY, Dr. F. H. A. Marshall (*Biol. Rev.*, 2, 129; 1927) has examined the question of the relation of the corpus luteum to the causation of parturition. He has not reached any definite conclusion on the matter, but suggests that the stimulus for parturition may result from an ovarian-pituitary mechanism. Certain investigations which I have been carrying on for some time into the fœtal membranes and placentation of the marsupial *Bettongia cuniculus* have brought in their train observations which appear to show that the ovary has no influence whatever in causing parturition.

Bettongia cuniculus is a small diprotodont marsupial of the family Macropodidæ. A couple of hundred females of this animal have come into my hands in the last few years. *Bettongia* is polyœstrous, its breeding season lasting over seven or eight months of the year. Only one uterus is pregnant at a time, pregnancy being entirely unilateral. There is never more than one produced at a birth, there being only one ovum extruded from the ovary of one side. I have found no exceptions to these rules.

In the early stages of pregnancy the two uteri undergo identical changes, so that by external examination of the uteri alone it is impossible to say which of them is the pregnant one. The sterile uterus is therefore in a condition which is to be regarded as one of 'pseudo-pregnancy.'

It is now well established that uterine development, whether of pregnancy or pseudo-pregnancy, is a result of the stimulating influence of the secretion of the corpus luteum, and Hartmann (*Am. Jour. Phys.*, 71, 2, p. 436) has shown that the Marsupialia, as represented by the opossum, agree with the Monodelphia in this respect. In the case of *Bettongia*, the 'pseudo-pregnancy' of the sterile uterus must be induced by the corpus luteum of the contralateral ovary, seeing that there is no similar body in the ovary of its own side. This confirms, in the living normal marsupial, observations made by Hartmann (loc. cit. p. 441) on pregnant opossums from which the uterus of one side and the ovary of the other had been removed. This supports, too, Hartmann's contention that operative interference had nothing to do with his results. When the egg in the pregnant uterus has reached the stage where it possesses a well-formed primitive streak, involution of the sterile uterus begins to take place, while the other uterus undergoes the usual enlargement associated with normal development.

Seeing that a single corpus luteum, situated in one ovary, influences, up to this stage, the activities of both uteri, is it not reasonable to suppose that, at the time of involution of the sterile uterus, the secretory activity of the corpus luteum has begun to wane? As such seems to be the case, it is obvious that parturition could scarcely be caused by the action of the corpus luteum.

The only other way of accounting for the regressive changes in the sterile uterus is to suggest that they may be due to some inhibitory influence, but it does not seem that any such influence could exist without involving both uteri. T. THOMSON FLYNN.

Personal and Impersonal Styles in Scientific Communications.

DELIBERATELY encouraged by some editors, though not, I am assured, by the Editor of NATURE, a prejudice is growing against the use of the first person in scientific writings. If it were part of a more general prejudice against the increasing egotism of scientists (manifested, for example, in squabbles over priority and the assignment of credit), it would be admirable, though probably futile. But it is not; it is merely the stylistic fad of the moment, and is wholly contemptible. Truly, it is not well to be always saying 'I'; but there is no virtue, moral or literary, in the mechanical substitution of the third person for the first. The literary vice is not the repetition of pronouns or of any pronoun in particular; it is needless repetition in general; pronouns are mentioned specifically only because it is particularly tempting to repeat them too often. It is very much worse to repeat a cumbrous and artificial phrase than to repeat a pronoun; and when we find our pages, sedulously cleared of 'I's,' besprinkled with 'the present writer' and 'the author of the present paper,' it is surely time to protest against a Pharisaical misinterpretation of the Law.

Pedants are too often ingenious in excusing their sins; and somebody will probably discover literary sanction even for this last abomination, perhaps in the introductions to the Waverley novels. I would therefore insist that, even if Scott's circumstances had been normal, even if he had said 'the present' when he meant 'this,' Scott and his like, for all their excellencies, would still not be fit models for those whose first duty is to be brief and direct. If we must imitate anyone, let it be the masters of our craft; let us try to learn from Faraday, Rayleigh, Huxley, and many others how to say 'I' freely, naturally, with elegance and with dignity.

For there are real difficulties, peculiar to scientific writing, that it would be foolish to ignore. An analysis of about 200 of the worst flounderings in recent journals suggests that they arise in three ways. First, Prof. Smith wants to refer to his own earlier work, but does not like to say 'I found in 1924 . . .' Why should he not denote himself, as he would any other person, by his name, and say, 'Smith found . . .' Second, impersonal narrative becomes tedious; we want to vary 'The next experiment was . . .' with 'Then I tried . . .' Why should we not? The pronoun here is quite unobtrusive; for no emphasis can fall on it, as reading aloud will show. Last, we want to make a personal statement, distinguishing our opinion from facts or from the opinions of others. Here a moral issue is raised. If we are not prepared to make a personal statement in personal form, are we justified in making it at all? Can true modesty, or any other virtue, permit me to occupy valuable space in airing my views and yet forbid me to call them mine? NORMAN R. CAMPBELL.

The Arc Spectrum of Chlorine.

REGULARITIES in the arc spectrum of Cl were first discovered by Turner (*Phys. Rev.*, 27, 397; 1926), who found three pairs showing the difference 880 cm.$^{-1}$. A consistent extension of this work into the visible, and theoretical interpretation has, however, never been attempted, especially because the separation of the chlorine lines into arc and spark lines had not been possible. Thus the data given in Kayser's "Handbuch" contain lines of both types.

Recently Mr. K. Asagoe, of this laboratory, has been able to identify 23 arc lines in the region between 4700 A. and 4200 A. The method is similar to that used by Wood and Kimura (*Astrophys. Jour.*, 46, 181; 1917) in separating the arc and spark lines of iodine. An examination of these Cl lines shows that they form the combination $4s\,{}^{4,2}P - 4p\,{}^{4,2}(S, P, D)$. The frequency differences between the five lower levels are 530·4; 338·7; 1399·1; 640·8 cm.$^{-1}$. Attention has already been directed to the first of these by de Bruin (*Amsterdam Proc.*, 30, 19; 1927). But these are just the differences which one finds between Turner's lines in the far ultra-violet region. They must consequently be identified as ${}^2P(3p^5) - {}^{4,2}P(3p^4, 4s)$. In the following table the individual lines, their intensities and levels, are given:

1396·5	3	${}^2P_1 - {}^4P_2$	1351·7	3	${}^2P_2 - {}^2P_1$
1389·9	4	${}^2P_2 - {}^4P_3$	1347·2	5	${}^2P_2 - {}^2P_2$
1379·6	5	${}^2P_2 - {}^4P_2$	1335·8	2	${}^2P_1 - {}^2P_1$
1363·5	5	${}^2P_1 - {}^2P_2$			

All the lines found by Turner are thus accounted for. Although the terms arising from the configurations $(3p^5)$ and $(3p^4, 4s)$ are still approximately 'normal,' that is, the corresponding vector coupling is of Russell-Saunders type, the higher term group arising from $(3p^4, 4p)$, which the visible lines have as initial state, has a decidedly different character; this term group is—as one usually puts it—of 'higher rank.' The situation is quite similar to that in the arc spectrum of argon, where, according to the classification of Meissner (*Zeit f. Phys.*, 39, 172; 1926), the four $4s$ levels arise from a Russell-Saunders coupling, whereas the ten $4p$ levels which are grouped quite irregularly, are apparently due to some intermediate coupling (Goudsmit-Uhlenbeck). There is consequently a certain ambiguity in assigning l-values to the $(3p^4, 4p)$ group. However, the weakness of intercombinations leads to a distinction between doublet and quartet levels.

Corresponding results in bromine and iodine have been obtained, but the work is still in progress.

My thanks are due to Prof. M. Kimura, through whose kindness my stay in Kyoto has been possible.

The Influence of Gravitation on Electromagnetic Phenomena.[1]

By Prof. E. T. Whittaker, F.R.S.

In the Bakerian Lecture of 1850, Faraday described a series of experiments which he had made in searching for a connexion between gravity and electricity. "The long and constant persuasion," he said, "that all the forces of Nature are mutually dependent, having one common origin, or rather being different manifestations of one fundamental power, has made me often think upon the possibility of establishing, by experiment, a connexion between gravity and electricity, and so introducing the former into the group, the chain of which, including also magnetism, chemical force, and heat, binds so many and such varied exhibitions of force together by common relations."

The results of Faraday's experiments were negative; but, he said, "they do not shake my strong feeling of the existence of a relation between gravity and electricity, though they give no proof that such a relation exists." The proof was, indeed, not obtained until seventy years afterwards, when the measurements of photographic plates taken at the eclipse of May 1919 showed a deflexion of the rays of light from stars when the rays pass close to the gravitating mass of the sun.

The general theory of relativity, by which this deflexion was predicted, asserts that the presence of matter or energy in any region of space affects the metric in that region; as we may say, it causes a 'curvature' or 'distortion' of space, which not only determines all the gravitational effects in the region, but also has a remarkable influence on any electromagnetic phenomena which may be taking place there. This is the true solution of Faraday's problem.

It is important to notice that gravity and electricity have been brought into connexion in essentially the same way as light and electricity were brought into connexion by the Maxwellian electromagnetic theory of light, namely, by postulating that the same 'ether' transmits both kinds of actions. It is true that we do not speak much of the ether nowadays, and certainly do not regard it as a quasi-material medium filling all space; but when we endow space itself (or, in non-statical problems, space-time) with properties such as curvature, we are making it play the part of an ether. The principle that one and the same ether ought to serve for all purposes was enunciated by Faraday himself: "It is not at all unlikely," he said, "that if there be an ether, it should have other uses than simply the conveyance of radiations."

In what follows I shall make the simplifying assumption that the gravitational field is 'statical,' that is, such as would be produced by gravitating masses which are permanently at rest relative to each other, so that the curvature of space at any point does not vary with the time. In the distorted space of this fixed gravitational field, I suppose an electromagnetic field (either statical, or varying with the time) to exist; strictly speaking, the electromagnetic field has itself a gravitational effect, that is, it changes the metric everywhere; but this effect is, in general, small, and we shall treat the ideal case in which it is ignored, so we shall suppose the metric to be simply that of the gravitational field originally postulated.

The problem before us, therefore, is to study the existence and propagation of electromagnetic fields in a medium whose properties (that is, the distortions of space) vary from point to point, and this naturally suggests a comparison with the Maxwellian theory of electromagnetic fields in a medium the specific inductive capacity and magnetic permeability of which vary from point to point. Do the effects of the distortion of space resemble in any way the effects of a variable dielectric constant and permeability?

The answer is in the affirmative, though the resemblance is not quite perfect. In a gravitational field there are eight partial differential equations which have exactly the same form as the usual Maxwell's equations, but in place of the three simple linear equations which connect the components of the electric displacement of the Maxwellian theory with the components of the electric force, and the three equations which connect the components of the magnetic induction with the components of the magnetic force, we now have six linear equations which express six of the twelve components in terms of all the six others.

Thus, from the mathematical point of view, the problem is similar to that of the Maxwellian electromagnetic field in a medium the dielectric constant and magnetic permeability of which have a kind of six-fold æolotropy. A prophetic adumbration of all this is to be found in a remarkable sentence written by FitzGerald so long ago as 1894: "Gravity is probably due to a change of structure of the ether, produced by the presence of matter."

To learn what happens we must solve these equations, and, as a first and simplest case, let us suppose that the electromagnetic disturbance is a ray of light. In this case it is not necessary to obtain the complete solution of the partial differential equations, since we can make use of the theorem that "a ray of light is a null geodesic of space-time." Let us, then, suppose that the gravitational field is due to a single gravitating mass, which we may call the 'sun,' and let us find the null geodesics of this field, which will be the paths of rays of light in the field of a single gravitating centre. We find that a ray of light which comes from infinity and does not pass too near the 'sun' is simply deflected through a small angle, in the same way as the light from stars was actually found to be deflected in the eclipse photographs. But if it is aimed almost directly at the mass (which, it must be remembered, we are supposing to be collected in a point-centre), much more interesting things may happen. Thus if a certain constant depending on the initial conditions has a particular value, we obtain light-rays which are spirally asymptotic to a certain circle surrounding the 'sun'; one type of ray represents light which, coming from infinity towards the mass, is 'captured' by it, and never gets away again, but circles round it for ever; another type of ray, on the other hand, represents luminous energy which is, and always has been, imprisoned in the immediate neighbourhood of the mass.

---

[1] From a lecture delivered to the London Mathematical Society.

These phenomena cannot be observed in the case of our actual sun, because its mass is not sufficiently concentrated: the sun's bulk prevents the light rays from getting close enough to its centre; but it seems conceivable that, at the nucleus of an atom, we may have a concentration of mass into a space so small that the capture of light by an intense gravitational field may be realised.

To pursue this matter somewhat further, let us consider the field round a point-mass. If we draw round this mass a circle, the length of the perimeter of the circle may be denoted by $2\pi R$, a definition which determines the physical meaning of the quantity R. But the normal distance between two adjacent circles, of perimeters $2\pi R$ and $2\pi(R - \delta R)$, is *not* δR, but δR multiplied by a multiplier which increases indefinitely as R approaches a certain value a which depends on the sun's mass: that is to say, as we approach the circle of perimeter $2\pi a$ from outside, we find greater and greater difficulty in making any headway; we have to travel a very great distance in order to pass from one of these circles to another just inside it, the perimeter of which differs from it only very slightly, and we can never actually attain to the circle with perimeter $2\pi a$.

If, then, we consider a ray of light coming from infinity and travelling directly towards the point-mass, the velocity of the light will always be c; but when it begins to approach the circle of perimeter $2\pi a$, this velocity will only be sufficient to carry it onwards very slowly, if we measure its progress by the rate of diminution of perimeter of the circles it cuts through, and it can never, in any time however great, get nearer to the mass than the circle of perimeter $2\pi a$.

Thus, although the light is actually travelling for ever with its usual velocity, it remains permanently in the neighbourhood of the point-mass. The capture and imprisonment of radiation by the intense gravitational field surrounding a point-mass is a remarkable theoretical possibility, markedly different from anything in pre-relativity physics.

Let us now leave the consideration of light rays and pass on to other kinds of electromagnetic phenomena. The mathematical difficulties here are greater, since we now cannot avoid the partial differential equations; but they can be solved in many cases, provided that we take the simplest possible type of gravitational field, which may be arrived at in the following way. Consider the field due to a single gravitating centre, and, fixing our attention on the neighbourhood of a point O, suppose the gravitating centre to be removed to a very great distance from O, while its mass is increased, so that the attractive force at O (to use the language of the older physics) remains finite and equal to g; then we obtain what we may call a *quasi-uniform* gravitational field. In the neighbourhood of O it is essentially the 'uniform gravitational field' of the old physics.

Let us now consider the shape of the equipotential surfaces in a quasi-uniform gravitational field, due to a single electric charge at (say) the origin. We find that these equipotential surfaces are a family of coaxal spheres, having one limiting point at the origin. Thus the difference which a quasi-uniform gravitational field makes to the equipotential surfaces of a single electric charge is that, instead of being concentric spheres, they become coaxal spheres—they become more crowded together on one side of the charge, and less crowded on the other. The effect is exactly the same as if we supposed that, instead of having a gravitational distortion of space, we had the specific inductive capacity and magnetic permeability of the medium each varying as we move in the gravitational field, so that the medium is stratified at right angles to the direction of gravitation.

From these calculations we can deduce a physical result of some interest. Suppose we have an electric charge at rest at the origin, and suppose we have initially a quasi-uniform gravitational field in some particular direction, and that we then reverse this so as to have a quasi-uniform gravitational field in the opposite direction, and then reverse back to the original state of things, and so on. At each reversal the electric equipotential surfaces will change from being a family of coaxal spheres with their second limiting point in one direction, to a family of coaxal spheres having their second limiting point in the opposite direction. But this regular alternation of the electric field must set up radiation, just as the alternation of the electric field in a Hertzian oscillator does: and therefore an electron at rest in a varying gravitational field will, in general, emit radiation.

The knowledge that a motionless electron may radiate, while (as a natural consequence) an accelerated electron does not necessarily radiate, in a gravitational field, may prove useful in accounting for the behaviour of electrons in atoms.

Let us now pass on to the case when the gravitational field is that due to a single gravitating mass at a point, so that we have Schwarzschild's metric. The solution which represents the potential of a single electric charge, and therefore corresponds to the $1/R$ of the ordinary theory, has recently been discovered by Mr. Copson.[1]

The form of the equipotential surfaces is remarkable. Very near the electric charge they are, of course, practically spheres the centre of which is at the charge. But as we get farther from the charge and nearer to the gravitating mass, the equipotentials behave as if they were repelled by the mass, so that eventually they become concave to it (and therefore convex towards the charge!), the mass being in a cup-shaped depression in the equipotential surface. Eventually we reach an equipotential which consists of two closed surfaces touching each other, one (the smaller one) enclosing the gravitating mass but not enclosing the charge, while the other (the larger one) encloses this smaller surface and also encloses the charge. Beyond this, again, we have a series of simple closed surfaces, each of which encloses all the earlier members of the family.[3]

---

[1] *Proc. Roy. Soc.*, A, 118, 184; 1928.

The electric field is precisely the same as would be obtained, in the ordinary electrostatics, by supposing that the specific inductive capacity and magnetic permeability of the medium vary in a certain way with the distance from the gravitating mass.

Solutions of the fundamental equations have been found which represent more complex fields than those I have described; but they are perhaps not well suited for description in a lecture,[4] and I will therefore conclude with a remark about energy. In a *statical* gravitational field, electromagnetic energy is a scalar quantity, so we can calculate the 'total electromagnetic energy' contained in a specified region of three-dimensional space by integrating the amounts of energy contained in the sub-regions into which the region may be divided; and the conservation of electromagnetic energy holds. In *non-statical* gravitational fields these theorems are no longer true, since energy is not then a scalar quantity; the energy in one region is different in kind from the energy in another region, just as momenta in different directions are different in kind from each other.

Heirlooms of Industry in the Science Museum.[1]

By Col. Sir Henry G. Lyons, F.R.S.

THE idea of a general museum of science is only seventy-five years old, and was due to the Prince Consort, who, after the Great Exhibition of 1851, urged the formation of an institution which would extend the influence of science and art on productive industry. From this proposal arose the Science and Art Department with, as an essential part of it, the South Kensington Museum, the dual activities of which are now represented by the Science Museum and by the Victoria and Albert Museum respectively.

For a long time previous to this, scientific instruments, pieces of apparatus, mechanical devices, and such like had been preserved in many places, but a museum designed to illustrate the influence of science on technical development did not exist; even the Museum of the Conservatoire national des Arts et Métiers in Paris, which dates from the end of the eighteenth century, was, and still is, primarily the teaching collection of the Conservatoire. Recently technical museums having similar aims have been established at Munich in 1903, and at Vienna in 1919; others illustrating special industries are to be found in many cities.

While no one will dispute the utility of technical museums, it must be admitted that they fall far short of art museums in the attractiveness of the objects which they contain, and this fundamental difference affects every stage of museum arrangement. For the objects in a technical museum to be interesting, something of their history and their purpose, the part which they have played in the age-long development of the branch of industry to which they belong, must be known to the visitor, and to this end carefully edited labels are essential; important objects may be so displayed that the internal working parts can be seen, and their purpose understood; coloured diagrams and specially arranged illumination may be employed; models, etc., may be shown in motion; others may be so arranged that they can be set in motion by the visitor; all this being done with the object of supplying essential information in a form intelligible to the general visitor, with additional technical description for the specialist.

The dominating principle in such a museum must be to illustrate development. Everything, whether it be an industry, or a group of related objects, or a type of tool, is shown so as to emphasise the successive stages of development which have been traversed from early crude forms which sufficed in the days of hand labour through various grades of slow improvement to the rapid advances of modern times so effectively aided by steam and electricity. In some branches of human activity it is instructive to show a few examples from the times of the earliest civilisation, and from the handiwork of primitive races who exist to-day. In this way the story of time measurement, of various hand tools, and of land and water transport for example, can be illustrated far more effectively and attractively than if the exhibits were restricted to those dating from the last few centuries.

To take the case of an industry, aeronautics furnishes a convenient example of rapid development, for air transport has grown from its first experimental stages to an important branch of world communication within the lifetime of many of us. The series exhibited in the Science Museum begins with the first power-driven model aeroplane which John Stringfellow constructed in 1848, and which achieved a free flight of forty yards. Later on experiments in 'gliding flight' were of great importance in providing information on many points in aerodynamics, and Otto Lilienthal was its greatest exponent. One of his gliding machines of 1896 is exhibited. During the next seven years Prof. Samuel P. Langley, of the Smithsonian Institution at Washington, designed and constructed a man-carrying tandem monoplane, of which a model is on exhibition, but it failed to make a successful flight when tried in 1903.

Inspired by the experiments of Lilienthal in gliding flight, the brothers Wilbur and Orville Wright, of Dayton, Ohio, carried out a large number of gliding flights during several years after Lilienthal's death, and the success which they achieved encouraged them to construct their first power-driven aeroplane, with which they made their first successful flights on Dec. 17, 1903, the longest being one of fifty-nine seconds, when the distance covered was 852 feet. The aeroplane with which they made their flight is now on exhibition in the Museum, having been lent by Mr. Orville Wright. Another important example is Mr. A. V. Roe's light tractor triplane, which was built and flown by him in 1909, and is remarkable for low power of the engine, a 9 h.p. twin-cylinder J.A.P. engine. Another interesting type is the Antoinette model, of French design, which was flown across the English Channel by H. Latham in July 1909. Mr. S. Cody's machine, which he used in the military manœuvres of 1912, is also preserved in the Museum as an instructive type of pre-War aeroplane. This series is fittingly concluded by the Vickers-Vimy Rolls-Royce aeroplane on which Sir John Alcock and Sir Arthur Whitten Brown made the first direct trans-Atlantic flight in June 1919. The extraordinarily rapid development of this form of transport is strikingly demonstrated by the fortunate juxtaposition in the gallery of the Museum of the Wright Brothers' aeroplane, which flew 284 yards in 59 seconds in December 1903, and the Vickers-Vimy aeroplane, which covered 1890 miles in 15 hours 57 minutes in June 1919, only 15½ years later.

---

[1] Synopsis of a discourse delivered at the Royal Institution on Friday, April 20.

Road transport also provides a series in which the transition from early types to modern practice is strikingly shown—that of the bicycle. Starting from the hobby-horse of 1818, the first practical form of two-wheeled machine was the early bicycle invented by Kirkpatrick MacMillan, a blacksmith, of Dumfriesshire, in which he anticipated the rear-driving 'safety' bicycle of forty years later. Michaux's bicycle of 1865, one of the so-called 'boneshakers,' the Starley Spiderwheel Bicycle, and Lawson's bicyclette of 1879, bring us to the safety bicycles of to-day.

Just as in an industry, so with each tool or machine, the successive stages by which the early form has advanced through others of increased efficiency, or of greater convenience, bear witness to the inventiveness of successive generations, and, wherever possible, this is illustrated. Miners' lamps are represented by a long series, including every type of importance from Sir Humphry Davy's to the latest pattern of the modern lamp. In the same way a most instructive series of radio-valves, beginning with original valves of Prof. Fleming, and continuing through many modern types, illustrates the rapid advances made in a modern instrument of great economic importance.

In machine tools, the primitive form of lathe, in which the work is rotated by means of the forward and backward movement of a bow held in the right hand, was long in use and still exists in some countries, but it was replaced later by the spring beam, or pole drive, and this type is still used by the chair-makers of High Wycombe. About 1800, Henry Maudslay combined the slide rest and the use of a lead screw with change wheels for the production of screw threads, and the first workshop tool in which Maudslay embodied his invention is preserved in the Museum. A further advance is shown by Roberts's back-geared slide lathe of 1817, after which examples of the most modern types of workshop lathe complete the story.

The early history of the hammer is illustrated among the hand tools, where there is one of the diorite hammer stones which were used to hammer out the shafts of granite for the obelisks of ancient Egypt; but when greater power was needed mechanical devices were adopted. A lift hammer of 1556 is shown by a model, and lift and tilt hammers were still in use at the beginning of the nineteenth century; two hammers which were erected in Portsmouth Dockyard in 1804 by Simon Goodrich are shown by a model. In 1839, James Nasmyth invented his steam hammer, which is represented by a working model; and other models show the various improvements which were introduced at later dates. The great power presses of to-day are too large and heavy to be shown, but illuminated photographic transparencies are utilised to show the form and character of those used in modern practice.

The early forms of any machine or tool are now of the greatest interest to us as we compare them with later developments, but only in few cases have they been preserved. The first design is modified and improved; its importance is thereby diminished; and it is not until much later that its historical value is realised. By that time it has usually disappeared. Fortunately, a considerable number of such early types have been acquired from time to time for the nation, among which are:

Arkwright's original 'drawing frame' of 1780, in which the drawing of cotton is effected by successive pairs of rollers revolving at increased rates of speed.

Two of James Watt's double acting rotative beam engines of 1788 and 1797, of which the latter is shown in motion. Among locomotives, the original *Puffing Billy* of 1813 and the *Rocket* of 1829 are the most important of four which are shown.

In marine engineering, among many notable landmarks, are the engine of Bell's *Comet*; also the T.S. *Turbinia*, and the turbine engines with which she steamed thirty-five knots at Spithead in 1897.

The collection of ship models contains a number of early and important contemporary models which furnish details of hull construction and of rigging which are not otherwise obtainable; they include a model of Christopher Columbus's ship, the *Santa Maria*, which was presented by the Spanish Government; the *Prince*, which was built at Chatham by W. Pett in 1669; also a contemporary model of a 64-gun man-o'-war of 1805, which has supplied much information for the recent re-rigging of the *Victory* at Portsmouth. Another very instructive model is that of a yacht of 1660, built in the style of the Dutch vessels of that period.

The wholesale disappearance of the earliest forms of technical instruments, to which reference has already been made, has often deprived us of all but a single specimen of its type. An accurate copy is then the only way of representing it in a collection, and in recent years a number of reproductions of this kind have been acquired by the Museum. They include an astronomical instrument of Egypt (the 'merkhet') which was used for setting out lines, and for determining the time by observing the passage of selected stars over the meridian, and a shadow clock of the same country, both dating from about the eighth or tenth century B.C.; the 'groma,' as used by the Roman land surveyors, and also one of their 10-foot rods; two telescopes made by Galileo, which are now preserved at Florence; Newton's reflecting telescope, made by himself, and now in the possession of the Royal Society; and a copy of a fourteenth century rain-gauge from Korea.

It only occasionally happens that the life-work of one of the great inventors of the past can be suitably shown in a museum, but in the case of James Watt, the attic workshop in which he worked during the last twenty years of his life has been reproduced, and in it are placed all the machines, tools, and other contents of the original room at Heathfield, near Birmingham.

Obituary.

PROF. OTTO NORDENSKJÖLD.

DR. OTTO NORDENSKJÖLD, professor of geography in the University of Göteborg, died on June 2, at the age of fifty-eight, as the result of a street accident sustained two days before. A nephew of the great Swedish explorer and scholar, Baron A. E. Nordenskiöld, his attention was turned to natural science at an early age, and as a student at the University of Upsala he specialised in geology. He was appointed lecturer on mineralogy at Upsala after taking his degree in 1894.

The spirit of Linnæus broods over his old university, and the young Otto Nordenskjöld felt the old urge which for nearly two hundred years has sent out Swedish naturalists as pioneer-explorers to all parts of the earth. In 1895 he organised his first expedition, when he led a party of Swedish men of science for a summer's work in Tierra del Fuego in order to compare the geological formations, the fauna and flora of that southern archipelago, with those of north-western Europe. The glacial deposits attracted his attention in particular, and after the return of his companions he proceeded to the little-known lake-district of southern Patagonia, where the Cordillera of the Andes is interpenetrated by the fjords of the Pacific and where a narrow zone of sharp transition separates the wooded slopes exposed to the wet west winds from the dry gravel plateaux of the pampas. The region, then unexplored and uninhabited, was of special interest at the time, because of the dispute between Chile and the Argentine Republic as to the delimitation of the boundary set out in the treaty as "the highest summits of the Cordillera forming the watershed," and Nordenskjöld's demonstration that the watershed showed no relation to the Cordillera foreshadowed the compromise which Sir Thomas Holdich's subsequent arbitration commission happily settled. In the summer of 1898, Nordenskjöld conducted a small scientific expedition to the Klondyke region of Canada, then at the height of the gold rush.

On returning from this expedition Nordenskjöld found the interest of European geographers concentrated on Antarctic research, to which his own attention had first been directed at the Sixth International Geographical Congress in 1895. The *Belgica* expedition had just returned from its experience of the first Antarctic night, the *Southern Cross* expedition under Borchgrevink was wintering for the first time on the Antarctic continent, and preparations for two great national expeditions, working on a common plan in different regions, were going forward rapidly in Great Britain and Germany. Nordenskjöld determined that Sweden should take its part in Antarctic research; he set himself to the tremendous task of raising funds by private and public appeals to the small circle of scientifically minded Swedes. In order to gain personal experience of polar conditions he went to East Greenland as a member of Amdrup's expedition of 1900. He succeeded in fitting out an expedition in time to take part in the simultaneous series of observations. He was fortunate in securing Capt. C. A. Larsen, a Norwegian who had already had experience in the Weddell Sea, to command his ship the *Antarctic*, and in enlisting a very able body of scientific assistants. Early in the Antarctic summer of 1901–2 he reached his base at the farthest accessible point in the Weddell Sea on the east coast of Graham Land, while the *Gauss* under Prof. E. von Drygalski (now the sole survivor of the Antarctic leaders who started their work with the present century) and the *Discovery* under Capt. Scott took up their stations at two far-distant points on the circumference of the continent. A year later the *Scotia* under Dr. W. S. Bruce completed the first of the great combined international efforts to study the physical conditions of Antarctica.

Nordenskjöld alone of the four decided to send his ship back after landing, in the expectation that she should return the following year to take him off. He passed the winter of 1902 at Snow Hill in 64° 27′ S., carrying on meteorological and magnetic observations, and on the approach of summer making large geological and zoological collections. He found the conditions adverse to any extended sledge journeys from his base, though he discovered King Oscar Land, and followed its coast to 66° S. On returning he eagerly awaited the return of the ship which never came. A second winter had to be spent in the hut, but the observations were continued steadily until in the summer of 1903–4 an Argentine vessel appeared to bring him back to civilisation. The *Antarctic* had found the ice conditions of the previous year so bad that a party was landed to attempt to reach Snow Hill by sledging over the coastal ice, while the vessel returned northward in the hope of getting in towards the land farther east. The Weddell Sea proved inexorable and the ship was crushed and sank. Larsen and his crew wintered in a hut, Gunnar Andersson and his land-party in another, and by the most dramatic coincidence in the history of exploration, both parties arrived at Snow Hill just in time to return as a united expedi- with Capt. Irizar in the *Uruguay*.

On his return to Europe, Nordenskjöld was appointed professor of geography in the University of Goteborg, where he continued to occupy himself in preparing the full report of the results of his expedition, the publication of which was facilitated by a grant from the Swedish government. The Antarctic gives no rest to a man who has once come within the field of its attraction, and Nordenskjöld, like Scott and Shackleton, set his heart on a second and greater effort to get at the baffling problems of south polar geography, glaciology, and geology. By 1913 he had worked out, in conjunction with Admiral Palander, a scheme for an Anglo-Swedish expedition, and obtained promises of support from his own government and from influential authorities in Great Britain. The outbreak of war in 1914 put an end to the preparations, and he never saw the Antarctic again. In 1909 he had visited West Greenland, and since the War he made frequent visits to Spitsbergen and Iceland, continuing his earlier studies in Arctic geology. In 1920 he revisited Patagonia with a party of Swedish geologists, following the discovery of remarkable fossil reptiles.

During his tenure of the professorship at Göteborg, Nordenskjöld had always inspired his students with the spirit of research and maintained the high traditions of Swedish explorers and students of Nature. He was modest and unobtrusive in his manner, but insistent and persevering in the promotion of exploration and research. As a leader he was less a commander than a trusted comrade and a constant friend. An enthusiast in the search for knowledge, he was indifferent to the spectacular publicity which gratifies small-minded ambition. He always maintained the happiest relations with the geographers and polar explorers of other countries, and he will be greatly missed by many friends in all parts of the world, whose sympathy goes out to his widow and children. HUGH ROBERT MILL.

DR. J. A. THOMSON.

DR. JAMES ALLAN THOMSON, who passed away on May 6, was at the time of his death director of the Dominion Museum in Wellington, New Zealand, and also president of the New Zealand Institute. Notwithstanding ill-health, he had a very distinguished career. He was the first New Zealand Rhodes Scholar, and went to St. John's College, Oxford, in 1906, where he was awarded the Burdett-Coutts Scholarship, and later he was appointed to a lectureship in geology at St. John's.

Leaving Oxford in 1908, Thomson worked on the geology of the Western Australian goldfields, and published several papers relating to them. He was chosen senior geologist for the second Scott Expedition in 1910, and went to Sydney to work with Sir Edgeworth David with the view of preparing himself for his work. Unfortunately, at this point in his career, the first signs of the disease to which he ultimately succumbed began to show, and, greatly to his own disappointment, and that of others, he was not allowed to go with the expedition.

Returning to New Zealand, Thomson joined the Geological Survey as palæontologist, a position which he held until 1914, when he was appointed to succeed the late Mr. A. A. Hamilton as director of the Dominion Museum, and in spite of failing health he continued to occupy this position until the end. Though repeatedly forced to lay aside his work and battle with disease, his scientific activities never ceased for long and his interest in scientific matters was never dulled. He published many papers on geological subjects, and during the last six years of his life he was busily occupied on a monograph on the brachiopods, a work which he lived just long enough to finish and to see in print.

For his geological work, Thomson was awarded the Hutton Medal of the New Zealand Institute, and last January was elected president of the Institute; he was also one of its original fellows. His death removes a scientific worker of the highest ideals and a man of exceptionally attractive personality; in the face of much physical weakness he maintained an unconquerable cheerfulness. He died of tuberculosis at the early age of forty-seven years. C. C. F.

PROF. JOHANNES GADAMER, Director of the Pharmaceutical-Chemical Institute in the University of Marburg, died on April 15 at the age of sixty-one years. A native of Waldenburg, in Silesia, he was appointed professor of pharmaceutical chemistry at the University of Breslau in 1902, and in 1919 he succeeded the late Prof. Ernst Schmidt at Marburg. Gadamer worked upon many alkaloids and glucosides. He also edited the *Archiv der Pharmazie* and published a "Lehrbuch der chemischen Toxikologie." After the death of Prof. E. Schmidt, Gadamer undertook the completion of his book, "Ausführliches Lehrbuch der pharmazeutischen Chemie."

PROF. G. SCHULTZ, Director of the Chemical Technical Laboratory in the Technische Hochschule at Munich, died at the end of April, aged seventy-six years. A native of Finkenstein, in West Prussia, Schultz spent several years in the Berlin laboratories of the aniline dye factories, becoming later factory director at Basel. In 1896 he was appointed to the chair of chemical technology in Munich. He was the author of well-known standard works, including "Die Chemie des Steinkohlenteers" and "Farbstofftabellen."

News and Views.

APART from the 'news value' of the woman passenger, the latest Atlantic flight is mainly of technical interest. The *Friendship* is a Fokker F VII float monoplane with high-set, deep-section wing, driven by three Wright-Whirlwind engines of 150 kw. each. Taking the empty machine as 3·3 tonnes, crew, etc., as 300 kgm., fuel and oil as 3 tonnes, the total starting weight would be about 6·6 tonnes. The route chosen was a small circle from Newfoundland to Valentia, but in the prevailing fog the seaplane alighted 600 km. farther on, near Llanelly, on the south coast of Wales. A geographical distance of 3300 km. was covered in 21 hours at an air speed of 130 km. per hour, with a following wind of 30 km. per hour according to estimates. Navigation was almost entirely by compass and dead reckoning, and the accuracy with which the course was maintained indicates a fortunate absence of serious changes in the magnitude of the cross wind. The flight may be compared with the distance of 5200 km. from New York to Paris covered, solo, by Lindbergh in an aeroplane of one-third the size and power. The performance, measured in ton-miles in proportion to the total weight, is heavily in favour of the smaller aircraft.

RENEWED efforts to reach General Nobile and his companions have met with success. On June 20, Major Maddelena, in an Italian aeroplane, flew over General Nobile's camp on the pack-ice to the north of North East Land. He found it impossible to land, but dropped supplies of food, clothing, guns, and ammunition. General Nobile's party totals seven, including Prof. Behounek. On June 23, a Swedish machine succeeded in landing by General Nobile's camp. General Nobile himself was picked up and brought to Whale Island, and thence to his base ship the *Citta di Milano* on the following day. Swedish aeroplanes have been searching the coast for Prof. Malmgren and his two companions, who left the main camp and travelled westward to find help. Several steamers are at hand waiting in the hope of the ice opening, as is not improbable shortly, and Soviet ice-breakers are in Spitsbergen waters. These should be useful if loose pack or young ice bars the way, but it is unlikely that they could force a way through the heavy ice off North East Land. At the time of writing there is no news of the remainder of the *Italia's* crew who drifted away with the wrecked airship. Capt. R. Amundsen with Com. Guilbaud left Tromsö on June 18 in a French aeroplane to take part in the search. His plans were uncertain, and lack of news of his movements need not be taken to imply disaster. His aeroplane had a cruising radius of nearly 3000 miles, while the distance from Tromsö to General Nobile's camp is about 1000 miles. Norwegian and French warships have been sent north to help in the search.

PHYSICAL chemists of all shades of opinion will wish to associate themselves with the two hundred and more colleagues and students of Prof. Sydney Young, who, on June 15, offered, in an address, their congratulations on the occasion, a few months ago, of his seventieth birthday, their high appreciation of his services to the progress of physical chemistry, their regret on learning of his resignation from the chair of chemistry at Trinity College, Dublin, and their cordial good wishes for long and happy—in fact, active—leisure years. Prof. Sydney Young, whose name is associated in the minds of all chemists with investigations of fundamental importance on vapour pressures, boiling points, and specific volumes of liquids and mixtures of liquids, on the efficiency of apparatus for distillation, and on the quantitative aspect of fractional distillation, is a Lancashire man, his birthplace being Farnworth, near Widnes. In 1882 he was appointed lecturer and demonstrator at University College, Bristol, and occupied the chair of chemistry there from 1887 until 1903, when he became professor of chemistry at Trinity College, Dublin. Prof. Young was elected a fellow of the Royal Society in 1893; he was a member of the council of the Chemical Society from 1894 until 1898, and a vice-president from 1917 until 1920; from 1920 until 1925 he was a member of the Advisory Council of the Department of Scientific and Industrial Research, whilst he occupied the presidential chair of the Royal Irish Academy from 1921 until 1926. Two important books bear his name on the title-page: "Stoichiometry" (Sir William Ramsay's series of text-books of physical chemistry, 1907 and 1918) and "Fractional Distillation" (1903), revised and extended in scope, with the assistance of experts in various branches of manufacture, in 1922, under the title "Distillation Principles and Processes." Among Prof. Young's numerous original papers are some devoted to a study of the composition of petroleum.

SINCE the anthropoid ancestry of man became a subject of scientific discussion and table-talk, the interest aroused in the great apes, the nearest living relatives of humanity, has had an unfortunate repercussion upon the very creatures which a fellow-feeling should have spared and guarded. Only a few years ago a general outcry arose against the inordinate slaughter of gorillas in Africa, where large numbers were killed, sometimes for scientific purposes, more often in the name of sport! Now another of the great apes, the orang-utan, more restricted in distribution than its African relative, is threatened with rapid extermination in Sumatra, one of its two strongholds. The natives have discovered an easy method of catching orangs alive, and since there is a steady demand for living specimens for zoological gardens, they find the labour lucrative, and large numbers have been exported during recent months. In ordinary cases the market would become sated and decreasing demand would check the supply at its source, but there is a heavy mortality amongst captured orangs, so that one cannot look to economic laws to check the disastrous trade. In view of recent events, it would seem that nothing but drastic restriction of the capture and export of the orang can prevent its speedy extinction, and much support will be given to the Society for the Preservation of the Fauna of the Empire in its efforts to induce the Dutch Government to impose the necessary restrictions at the earliest possible moment.

THE annual report of the executive committee of the British Science Guild, presented at the annual meeting on June 21, comments on a variety of important problems associated with applied science. Attention is directed to some anomalies in Patent law, in particular the insecurity of British as compared with German and American patents. This insecurity arises largely through the fact that invalid patents are freely granted in Great Britain. There are also 'paper' patents—obtained merely with the view of extracting undeserved royalties from manufacturers who shrink from patent litigation, the cost of which is frequently enormous. Another subject that receives attention in the report is the position of science teaching in the public elementary schools. At present the selection of subjects is left to the local education authorities. Instruction in elementary science may be inadequate or even omitted entirely. A letter has been circulated amongst leading local authorities asking for the names of elementary schools in which adequate teaching of elementary science is being carried on. This inquiry should elicit some useful information regarding the nature of courses and the methods of instruction followed. The position of the technical expert in the public service and in industry is now being studied by a special committee appointed by the Guild. Since the War, administrative and clerical branches of the public services have been reorganised and a material improvement in the prospects of officers in these classes has been effected. There has been no similar reorganisation of the technical and scientific branches; new measures are necessary to afford such professional officers a status corresponding to modern conditions.

THE report also presents a series of six memoranda of considerable interest, illustrating recent developments in the application of science—mainly in the fields of agriculture and food products. In connexion with animal nutrition, great importance attaches to recent investigations of the part played by vitamins. The discovery that ergosterol, when submitted to ultra-violet irradiation, acquires very powerful anti-rachitic properties, is an example. Attention is also being paid by the National Institute of Industrial Psychology to the problem of eliminating needless human effort and waste of time in agricultural processes. In such matters as the destruction of injurious fungi and insect pests and the elimination of animal diseases distinct advances have recently been made. Consideration of these problems leads to a reference to the recent Imperial Conference on Agricultural Research. At this conference several useful proposals were made, including the establishment of three new bureaux devoted respectively to soil science, animal nutrition and animal health, and the formation of 'correspondence centres' to act as clearing houses for information. Other notes deal with the Empire Timber Exhibition (held in London last year), the formation of Imperial Chemical Industries, Ltd., and "Scientific Method in Conference Procedure."

THE results of archæological investigation in Egypt during the past winter seem to be in a fair way to establish beyond question the early dating of the prehistoric cultures of the Fayum and at Badari, for which Sir Flinders Petrie has urged a Solutrean origin and a dating directly related to the occurrence of that period in the European area. The excavations which Miss Caton-Thompson has carried out under the auspices of the Royal Anthropological Institute in the Fayum were mainly directed towards finding material to date the culture as it is found in that area. Although the much-desired cemetery which might produce dateable relics did not come to light, one site afforded evidence which, while without prejudging its Badarian affinities, may be regarded as directly determining the relation of the Fayum culture to predynastic. A preliminary report of Miss Caton-Thompson's expedition is being published in the July issue of *Man*. Miss Caton-Thompson's report also clears up a situation of some ambiguity which has arisen from accounts of the discovery of an alabaster factory which did not make it clear that two different sites were involved. An exhibition of such material as has been allowed to leave Egypt will be held at the Royal Anthropological Institute on July 9-21; admission free to non-fellows on presentation of a visiting card.

WHILE Miss Caton-Thompson was excavating in the Fayum, Mr. Guy Brunton was engaged on a similar problem at Badari, continuing under the auspices of the British Museum the work begun by the British School in Egypt. Here the evidence was complicated by the occurrence of copper beads from settlements and cemeteries apparently of an earlier date than any previously known. These had produced objects similar to those from the Fayum, pottery-ware, some finer in ware and finish than any other known, a delicately worked flint dagger, and the oldest known stone vase. During the past season, on which Mr. Brunton has reported in the *Times* of May 26, further support of the view that the Badarians were older than the predynastic peoples has come to light in the discovery of the undisturbed graves of the latter superimposed on those of the Badarians. A second phase of Badarian culture has also been discovered with pottery of different forms and eye-paint palettes of alabaster instead of the usual slate.

A PAPER on talking and synchronised motion pictures, by W. H. Bristol, the president of a company well known for its recording instruments for industrial applications, is published in the *Journal of the Franklin Institute* for February. The de Forrest and Case-Fox systems, where the sound is photographed on the edge of the film, have already been successfully used in picture theatres for short sketches and news films. Complete talking motion picture dramas, however, have not yet been presented to the public. It seems probable that very shortly the author's method will enable this to be done commercially. Many so-called educational films are used primarily for indirect advertising, but there are some truly educational films the value of which will be considerably enhanced by synchronised sound. In the Bristol system the turntable for the phonograph and the projector for the film are kept exactly in step by two synchronous electric motors operated by alternating current. Each of them is capable of transmitting about a quarter of a horse power. The sound-reproducing system consists of three parts, the electrical 'pick-up,' an amplifier, and a loud speaker. The quality of the reproduction depends on each of these three elements. The electrical device converts the mechanical undulations of the phonograph recorder into corresponding electrical oscillations. A long horn and a special amplifier are used for theatres. When taking a picture it is of the greatest importance that no extraneous noises be recorded. Hence the camera is placed in a booth, the only sounds reaching it being those which are intended to be recorded. In perfecting the 'talking motion picture' two main difficulties had to be overcome. The first was to get a simultaneous record of the sound and motion, and the second was the loss resulting when a film was broken and a piece of it lost. In the latter event both the sound and photographic records were spoilt.

The government of Greenland has recently presented to the Department of Zoology of the British Museum (Natural History) a white whale or Beluga from Greenland, with the heads and flippers of three other individuals. This extremely valuable material was collected specially for the Museum by the Danish administration, preserved in salt, shipped to Copenhagen, and thence to London. On arrival in the Museum the whale was found to be in perfect condition. A plaster cast of the entire animal, a male measuring 12 feet 6 inches in length and weighing about 1 ton, has been made, and this will in due course be exhibited. Dissections of the whale are in progress, and the skeleton when cleaned will form an important addition to the collection. The Beluga is hunted in the Greenland seas for the sake of its blubber and for its remarkably tough hide, which is used in the manufacture of boot-laces. The Department has also received the skin and skull of a Swedish wolf in exchange from the Stockholm Museum; this animal is now nearly extinct in Sweden. Mr. D. Holderness, engineer to the Harbour Board, Auckland, New Zealand, has presented seven specimens of the Giant Ship Worm (*Kuphus arenarius*) from the Solomon Islands. They were obtained for the Museum by Capt. Burgess of the Mission steamer *Southern Cross*, after several years of search and inquiry among the natives, and are the first specimens of the soft parts of the animal that have been seen by any naturalist since the time of Rumphius, more than two centuries ago. The Mineral Collection of the Museum has recently acquired a set of minerals from the pegmatite quarries at Newry, Maine, U.S.A., which are now being worked for pollucite; this mineral contains 34 per cent of cæsium oxide and is the richest known source of this alkali metal, which now finds an application in the construction of thermionic valves.

An offer of considerable interest to anthropologists and statisticians is made by the Eugenics Research Association, which announces a competition with prizes of £200 and £40 for the best two essays by American authors on "A comparison of both the crude birth-rate per 1000 females 15 to 45 years of age and the 'vital index' (or 100 births/deaths ratio) of the Nordic and non-Nordic peoples in the Americas." Data are to be considered in different periods from 1850 to the present time or last available census. Nordic peoples are considered to be those whose ancestors came mainly from Nordic countries. Such countries are defined as including the Scandinavian countries south of lat. 63° N., the Netherlands, England, Scotland, North Ireland, and certain German States, non-Nordic being regarded as the rest of Europe, Asia, and Africa north of the Zambesi. Essays must reach the Association at Cold Spring Harbor by Feb. 1, 1929. Prizes of the same amount are offered to European authors for essays on the same subject and under similar conditions.

The Right Hon. Viscount Astor will deliver the inaugural address to the congress at Plymouth of the Royal Sanitary Institute on Monday, July 16. The popular lecture by Prof. W. E. Dixon on "Poisoning in Daily Life" will be delivered on July 20. The subjects for discussion cover a wide field, and include the tuberculosis problem, immunity in scarlet fever and measles, puerperal fever research and fœtal deaths and injuries, juvenile rheumatism, ultra-violet therapy treatment, health conditions in factories and industrial rheumatism, smoke abatement, refrigeration, contamination of foods exposed for sale, milk, refuse and sewage disposal, and water supply. More than eight hundred delegates have been appointed to take part in the congress by government departments in the British Empire and foreign countries. Visits to institutions dealing with child welfare work, and municipal undertakings of professional interest to medical men, engineers, and others, are being arranged, as well as excursions of more general interest. The Health Exhibition, which is an important part of the congress, will include exhibits on water softeners, refrigerators, electric appliances, soaps and disinfectants, sanitary appliances, etc., and will be opened by the Mayor of Plymouth on July 16.

A preliminary announcement has been issued giving information about the Fuel Conference, 1928, organised as a sectional meeting of the World Power Conference. It has the support of forty-five countries, many government departments, universities, societies, important industrial corporations in Great Britain, and will be held at the Imperial Institute, London, on Sept. 24–Oct. 6. Application for membership should be addressed to the Secretaries, Fuel Conference, 1928, World Power Conference, 36 Kingsway, London, W.C.2, the fee for membership being 30s., or 20s. for members of participating institutions and associations. The Conference will be divided into Sections A-X, covering every aspect of the fuel industries, and advance copies of the papers to be presented are to be available to members of the sections in which they are interested. Reduced fares will be available on the railways under conditions to be announced later. Messrs. T. Cook and Sons, Ltd., have been appointed official travel agents and will assist members in obtaining hotel accommodation. Arrangements are being made for official receptions, entertainments, and excursions.

The radio photogram service which has been conducted by the Marconi Company since May 1926 for the transmission of photographs, drawings, signatures, and facsimiles of all kinds by radio between London and New York, has now been extended so that photograms received in New York by radio may be transmitted to other important commercial centres in the United States of America. A photogram sent from London by radio addressed to these cities is transferred in New York to the telephone-wire picture service of the American Telegraph and Telephone Company. The cities included in the radio-and-wire photogram service are Boston, Cleveland, Atlanta, Chicago, St. Louis, Los Angeles, and San Francisco. The service between London and New York has been widely used since its inception for the transmission across the Atlantic of news pictures, facsimile signatures, and even Christmas cards.

It is announced in *Science* that the Willard Gibbs gold medal, given annually by the Chicago section of the American Chemical Society, has been awarded to Prof. William D. Harkins, of the University of Chicago. The medal is awarded for work in either pure or applied chemistry of wide importance.

An earthquake of moderate intensity was recorded at Kew Observatory on June 21 at 16 hr. 37 min. 58 sec. G.M.T. The epicentral distance is estimated to be 4600 miles, and the shock probably occurred near Alaska. A smaller disturbance was recorded earlier at 10 hr. 59 min. 54 sec. G.M.T.; the epicentre being nearly 10,000 miles away.

The Institution of Naval Architects has acquired the freehold of two houses in Adam Street, thus securing for the Institution a permanent home in the same neighbourhood as before. On and after July 1 the address of the Institution will be 2 Adam Street, Adelphi Terrace, London, W.C.2.

'Commemoration Day' was held at Livingstone College, Leyton, on June 15. Dr. Carmichael Low was in the chair and gave an address on the advances that have been made in tropical medicine during the last forty years. The Principal reported that 1020 students had passed through the College, and appealed for £400 to close the financial year without deficit on the year's working.

Referring to Sir Herbert Maxwell's letter in Nature of June 9, Miss E. Armitage, Dadnor, Ross, Herefordshire, writes recording two similar events of death due to voraciousness. In a pond in her garden, a dead perch was found with a smaller perch fixed firmly in its mouth, while on another occasion, and on the bank of the pond, a dead kingfisher was discovered with a perch fixed in its mouth.

The fourteenth lecture in the series arranged by the Institute of Physics on "Physics in Industry" will be given, with the co-operation of the seventh International Congress of Photography, by Dr. C. E. Kenneth Mees, Director of the Research Laboratory, Eastman Kodak Co., Rochester, N.Y., at 8 p.m. on July 12. Dr. Mees will take as his subject "Physics in Photography," and his lecture will be delivered at the Institution of Electrical Engineers.

The annual report of the School of Tropical Medicine, Institute of Hygiene, and Carmichael Hospital for Tropical Diseases, Calcutta, for 1927, has recently been issued. A memorable event during the year was the unveiling, by Lord Lytton, Governor of Bengal, of a "Gate of Remembrance," which commemorates the great discovery of the mosquito transmission of malaria by Surgeon-Major Ronald Ross, I.M.S., in 1898, in the presence of Sir Ronald Ross himself, who made a suitable reply. Teaching and research occupy the time of the staff of the school, and much valuable research work has emanated from it. The Director makes the interesting statement that "all our research workers agree that light teaching duties are useful rather than otherwise, as they compel the worker to keep in touch with the broader aspects of his subjects and to cultivate the art of lucid exposition."

The following books are announced for early publication by the Cambridge University Press: "Great Britain: Essays in Regional Geography," by twenty-six authors, with an introduction by Sir John Russell and edited by A. G. Ogilvie; "The Symmetrical Optical System," Dr. G. C. Steward ("Tracts in Mathematics and Mathematical Physics").

Applications are invited for the following appointments, on or before the dates mentioned:—A lecturer in physics at the Borough Road Training College, Isleworth—The Principal, Borough Road Training College, Isleworth (July 7). The headship of the geography department in the University of Leeds—The Registrar, The University, Leeds (July 8). Two junior assistants at the Fuel Research Station, East Greenwich, S.E.10—The Secretary, Department of Scientific and Industrial Research, 16 Old Queen Street, S.W.1 (July 9). A public analyst for the Administrative Counties of Cambridge, Huntingdon, and Isle of Ely, and for the Municipal Boroughs of Cambridge and King's Lynn—The Clerk to the Cambridgeshire County Council, The County Hall, Cambridge (July 11). A demonstrator in the physics laboratory of the Royal Naval Engineering College, Keyham (Plymouth)—The Secretary of the Admiralty (C.E. Branch), Whitehall, S.W.1 (July 12). A full-time lecturer in the mathematics and physics department of the Polytechnic, Regent Street—The Director of Education, The Polytechnic, 309 Regent Street, W.1 (July 13). A whole-time research student in the department of helminthology in the London School of Hygiene and Tropical Medicine—The Secretary, London School of Hygiene and Tropical Medicine, 23 Gordon Street, W.C.1 (July 14). An assistant on the higher technical staff of the science division in the Science Museum—The Director and Secretary, Science Museum, South Kensington, S.W.7 (July 16). An assistant lecturer and demonstrator in engineering in the University College of South Wales and Monmouthshire—The Registrar, University College, Cardiff (July 16). An assistant inspector under the Ministry of Agriculture and Fisheries in connexion with agricultural and horticultural education and research—The Secretary, Ministry of Agriculture and Fisheries, 10 Whitehall Place, S.W.1 (July 16). A reader in biology, a lecturer in physics, and a lecturer in chemistry in the University of Hong Kong —C.A. [N], The Secretary, Board of Education, Whitehall, S.W.1. Scottish candidates should apply to [N], The Secretary, Scottish Education Department, Whitehall, S.W.1 (July 30). Temporary assistant chemists in the Government Laboratory—The Government Chemist, Clement's Inn Passage, W.C.2 (Aug. 4). A professor of mathematics in the University of Melbourne—The Agent-General for Victoria, Victoria House, Melbourne Place, Strand, W.C.2 (Sept. 3). A full-time graduate assistant with works' experience to teach engineering subjects up to Higher National Certificate mechanical engineering standard at the Darlington Technical College—The Chief Education Officer, Education Office, Darlington. A full-time lecturer in mining subjects at the Mansfield Technical College—The Principal, Technical College, Mansfield. A lecturer in geography, botany, and zoology at the Bedford Training College—The Principal, Training College, 14 The Crescent, Bedford. A senior lecturer in the chemistry department of Battersea Polytechnic—The Principal, Battersea Polytechnic, Battersea, S.W.11. A head of the physics department of Huddersfield Technical College—The Director of Education, Education Offices, Peel Street, Huddersfield. A lecturer in the physics department of Woolwich Polytechnic—The Principal, Woolwich Polytechnic, Woolwich, S.E.18. An experienced graduate agriculturist, to initiate scientific pedigree breeding in selected indigenous breeds in Nigeria —The Private Secretary (Appointments), Colonial Office, 2 Richmond Terrace, Whitehall, S.W.1.

Our Astronomical Column.

CONJUNCTION OF MARS AND JUPITER.—Mars and Jupiter are now 'morning stars,' rising nearly half an hour after midnight and approaching each other to a very interesting and close conjunction on July 3 at about 9^h P.M. They are situated among the south-westerly stars of Aries and both are moving eastwards, but the greater speed of Mars enables this object to overtake Jupiter on the evening of July 3 about three hours before they come above the horizon on July 4 at about $0^h\ 22^m$ A.M. Mars will be 0·3° south at the time of conjunction, and when both planets become visible, Mars will be a little to the south-east of Jupiter and very much fainter. Its ruddy light will contrast strongly with the pale yellow tint of Jupiter. Mars will appear faint, being only of 0·8 mag., while Jupiter will be of 1·8 mag., but neither planet will be near maximum brilliancy, being at considerable distances from the earth. Diameter of Mars, 6·6″, Jupiter, 34·8″. Maximum diameters:

Mars, opposition Dec. 21, diameter, 16″·0.
Jupiter, opposition Oct. 29, diameter, 46·3″ (Polar).

THE FIXING OF EASTER.—The passage of the measure for a fixed Easter through the House of Commons advances the solution of this matter by an important stage. It was wisely decided that the measure should not come into operation until the assent of the leading religious bodies had been obtained; but the indication of the desire of the representatives of the British nation is likely to bring this assent nearer. The Bill adopts the same rule for finding Easter that was adopted by the League of Nations Committee; namely, the first Sunday after the second Saturday in April.

VARIATION IN THE EARTH'S ROTATION.—It seems only a short time since this idea was put forward with hesitation as a possible explanation of the mysterious fluctuations that are found unmistakably in the motion of the moon, and to a smaller extent in the more rapidly moving planets. Prof. de Sitter, the president of the International Astronomical Union, has included proposals on this subject in the agenda for the coming meeting of the Union at Leyden. He divides the action into two parts, and gives formulæ for each in terms of the time and its square. The first part is taken to be discontinuous, and subject to abrupt changes at irregular intervals, varying from twelve to ninety years; the other is tidal friction; he suspects that the coefficient of T^2 is not constant, giving 1742 and 1869 as the dates of changes of rate. These dates do not coincide with any in the former list. He proposes that corrections based on his formulæ should be applied to astronomical time as now observed, thus reducing it to 'Newtonian' or uniform time. It will probably be difficult to secure unanimity in this matter, but it promises to give rise to an interesting discussion.

ASTRONOMICAL DISCOVERY.—Mr. W. F. Denning contributes a paper with this title to the *Nineteenth Century and After* for June. He gives an interesting review of many of the advances in astronomical knowledge that have been accomplished in recent years; but as he has himself been a successful cometary discoverer, it is natural to dwell more particularly on this section of his article. He notes that the record perihelion distance of a comet, which had been held for two centuries by the comet of 1729, has been broken twice in succession by the discovery of comet Schajn-Comas Sola in 1925, and again by the discovery of comet Schwassmann-Wachmann in 1927. The latter has an orbit that lies entirely between those of Jupiter and Saturn, and that deviates so slightly from a circle that it may be possible to follow it round the whole course of its orbit. Allusion is also made to other additions to Jupiter's comet family, the latest being Reinmuth's comet discovered last January.

Mr. Denning notes that 115 comets were detected between 1900 and 1925, of which 70 were new comets. The rate of discovery of the latter is therefore three per annum, very close to the figure derived from the statistics of the nineteenth century. It may be noted (though not included in Mr. Denning's paper) that we have to deplore the death of the most active and successful comet hunter of recent years—Mr. William Reid—which occurred in Capetown on June 8.

Research Items.

CONCEPTIONS OF GOD IN WEST AFRICA.—In No. 2 of *Africa*, the journal of the International Institute of African Languages and Cultures, Prof. D. Westermann analyses the religious beliefs of West Africa. Three groups of beings are conceived as more or less imbued with personality and worthy of veneration: (1) individual tutelary spirits, (2) local deities, (3) the God of Heaven. The individual tutelary spirit enters a man at birth and determines his character and destiny, and protects, advises, and helps him. As the *okra* or spirit had been married in the spirit world before entering upon its human tenement, among the Ewe it is necessary that at marriage the spirit wife should be propitiated by placing in a small hut dedicated to her a small part of each present destined for the earthly betrothed or wife. Local deities are the chief object of worship. Most are the incorporation of natural objects or phenomena, mountains, rocks, springs, thunder, rarely animals. There are also gods of war, peace, of the year, harvest, etc. Idols are often set up in their honour at which they can be worshipped. As a rule a priest is set apart for each deity. He is often selected by the deity, *i.e.* a state of ecstasy is induced in him. The local deity receives its power from the God of Heaven, by whom the administration of a definite sphere of living beings is delegated to him. The God of Heaven is also connected with a natural body, namely, the visible heavens; but he is unique in that he is above everything and is everywhere. Everything owes its existence to him. He is the creator and the preserver of all that is in the world. His characteristic qualities are power, justice, and goodness; but his remoteness, his universality, and his goodness have made the conceptions of him vague and shadowy.

MAGIC AND TABOO IN BENGAL.—In the *Indian Antiquary* for June, Dr. Biren Bonnerjea notes examples of magic and taboo in Bengal as positive and negative elements in an identical attitude of mind towards physical and spiritual phenomena. The use of a clay image is prevalent both as a love charm, when the heart is pierced with a thorn-tipped arrow, and a means of injuring an enemy, when a knife or pin is stuck into the heart. Night blindness is cured by the internal use of a firefly, which is eaten inside a banana. A still-born child is buried inside the house instead of cremated, in order that the mother may bear another child. Examples of contagious magic are the concealment of the name by the use of nicknames, while a woman is known as the daughter, wife, or mother of such and such a person. The placenta is taken away in an earthenware pot in order that no animal may devour it; nor should it be destroyed before the *annaprâśan* ceremony, 'the taking of the rice,' which is the naming ceremony, otherwise the child will die. A charm to stop rain is for a child to burn a candle of cloth. Much virtue is attributed to abuse as a protective or propitiatory rite. Hence in the month of Bhâdra (July–August) practical jokes are played with the object of provoking abuse, as a protection against ill luck; and with the same object those who have inadvertently looked at the moon in this month, throw stones and brickbats into their neighbours' houses. Among the taboos, excessive praise must be avoided. The names of scavengers and water carriers are taboo, and euphemisms are employed, nor must the names of snakes, robbers, tigers, and so on, be used after nightfall. Food taboos include not merely beef to all Hindus, but also many vegetables such as onions, garlic, palms, and lentils.

A TRANSATLANTIC FLIGHT.—Records of the passage of birds across the Atlantic from east to west are much less frequent than those of the contrary journey, and the experience of human aviators also suggests that, in general, weather conditions do not favour the Europe to America crossing. The more to be wondered at is the extraordinary migration of lapwings—by no means strong fliers—recorded by H. F. Witherby (*British Birds*, vol. 22, 1928, p. 6). On Dec. 20 and 21, 1927, flocks of lapwings, one of which was estimated to number 500 individuals and another 1000, arrived in Newfoundland. The lapwing is not an American bird, but the source of the migration was definitely indicated by the presence on one of the birds of a *British Birds* ring, which showed that it was a native of Cumberland. It is certain, therefore, that large numbers of lapwings crossed the Atlantic from Britain to Newfoundland—a distance of about 2200 miles—in a single flight. The author shows that the weather conditions were extremely favourable for such a journey. A spell of frosty weather in Britain made it imperative for the birds to seek new feeding grounds; they moved westwards and became involved in a wind blowing almost due west at a velocity of about fifty-five miles an hour. This, added to the lapwing's normal speed of some forty-five miles an hour, would permit of the total journey being accomplished in about twenty-two hours. Lapwings have been recorded from America only on eight previous occasions, and these were generally solitary birds.

SOME TROPICAL CRUSTACEA.—In the *Bulletin of the Bingham Oceanographic Collection*, vol. 1, Art. 2, Mr. Lee Boone describes several rare and new Crustacea ("Scientific Results of the First Oceanographic Expedition of the *Pawnee*, 1925." Crustacea from Tropical East American Seas. 1927). This expedition was founded for the purpose of oceanographical research, undertaken and directed by Mr. Harry Payne Bingham in his yacht *Pawnee I.*, for exploration in the West Indian Caribbean regions, fishes being the chief object, but incidentally the crustaceans have proved of remarkable value. The range of depth explored was from littoral regions to nearly 500 fathoms, and it is the deep-sea forms which are of peculiar interest. In order to realise the richness of the crustacean fauna, one has only to glance at the records of the contents of two dredge hauls made consecutively north of Glover Reef, in which twenty species of deep-sea Crustacea were captured, nine of which (seven decapods and two isopods) are new and two rediscovered forms, a brachyuran and a macruran, not seen since the type specimens were captured by the *Blake*, besides other rare finds. Perhaps the most interesting of all is a new isopod named *Arcturus pawneeanus*, which was found intertwined in the branches of a comatulid, living as a semi-parasitic commensal. Its six posterior legs are hooked for clinging and are entwined round one of the radials, whilst three anterior pairs of legs are feathery and floating, thus bearing a striking resemblance to the host so that it is difficult to distinguish between them, the segmentation also closely resembling the pattern of the radial. An anamouran *Uroptychus rugosus* Milne Edwards, previously taken by the *Blake*, occurred symbiotically on the same crinoid intertwined in its arms, the legs resembling the cirrhi, the chelipeds resembling the radials, and the carapace being very like the central disc. Here again the commensal is difficult to distinguish from its host.

Yet another 'guest' inhabits the crinoid, a small stalked barnacle named by Boone *Scalpellum rodstromi*.

EFFECT OF POTASSIUM ON INVERTEBRATE MUSCLE.—In an article entitled "The Action of Potassium on Muscle-Preparations from Invertebrates (*Brit. Jour. Exp. Biology*, vol. 5, No. 3; 1928), Mr. George P. Wells makes an important contribution to the comparative study of various invertebrate muscles (*Aplysia, Helix, Maia*). Hitherto many contradictions have appeared in the action of potassium not only in different species but even in the same tissue from the same species in the hands of different workers. By studying very wide ranges of potassium concentration, the author has been successful in showing that these discrepancies originate chiefly in the great dependence of the action of potassium upon its concentration. There is, in fact, a remarkable similarity of behaviour in the invertebrate muscle studied and in vertebrate muscle. In all cases examined it was found that muscle is normally relaxed at a certain definite potassium concentration (which has a different absolute value in different species). At this concentration removal or addition of potassium causes contraction, the degree depending upon the concentration. Rubidium, cæsium, and also ammonium are shown to possess closely similar action to potassium; lithium has a different action. It is pointed out that the similarity of action of potassium and ammonium contradicts Zwaardemaker's hypothesis that the former acts by virtue of its radioactivity. A very plausible hypothesis of the action of potassium and its allies is put forward based on that of Mines. The very different physiological effects of potassium, rubidium, cæsium, and ammonium on one hand, and of lithium and sodium on the other, bear a very suggestive resemblance to the relative abilities of these ions to penetrate the highly impermeable membranes studied by Michaelis: the potassium group may well act by producing changes of potential difference across certain membranes in the cell which the sodium group is unable to effect.

ENCYSTMENT OF *PARAMECIUM*.—L. R. Cleveland (*Science*, vol. 66, p. 221; 1927) points out that *Paramecium* has not been definitely shown to encyst in Nature or in laboratory cultures, and that some investigators have doubted its ability to encyst. He therefore records his observations, though they are incomplete. Two or three cubic centimetres of a rich culture of *Paramecium* (species not determined) were injected into the recta of frogs, with the result that encystment of the *Paramecia* occurred in about two per cent of the frogs, namely, in three frogs. In one frog, examined five and a half hours after injection, only encysted *Paramecia* were present. Some of these were placed in depression slides and frequently observed; and on the fourth day fission was observed to be beginning, and on the fifth day two *Paramecia* were seen in the cyst and some of them excysted, especially when abundant tap-water was added to the preparations. A high percentage of the *Paramecia* were killed and disintegrated within one or two hours after injection into the frog's rectum. All attempts to bring about encystment in removed recta, or in rectal contents, failed.

LETHAL FACTORS IN A GRASS.—In a genetic study of the grass, *Lolium perenne*, Mr. T. J. Jenkin (*Jour. of Genetics*, vol. 19, No. 3) finds that many of the plants are highly self-sterile and that several types of chlorophyll-deficient seedlings occur, including complete albinos, variegated and various grades of green, as well as extreme dwarfs and a full green type which dies back for no apparent reason about the time the second leaf appears. Of these lethal types, yellow-tipped albino was the most studied. Selfing a vigorous green plant gave rise to normal green, non-surviving green, and this albino type. The latter may survive for several months, but they never become full green or strong plants. When the parent plant was crossed with unrelated green plants, lethals did not appear in F_1, but when the F_1 was back-crossed to the original parent, the offspring indicated that the latter was heterozygous for two lethal factors. Another plant was highly self-fertile, and produced green, variegated, and albino seedlings. Of these, 1770 were green. They were of two types, surviving and dying at the second-leaf stage, in the ratio 3 : 1. The non-surviving green was indistinguishable from that type derived from the other plant. But when these two plants were crossed they gave for the most part in F_2 and F_3 9 : 7 ratios. Hence the factor producing the non-surviving green type occupied a different position in the germplasm of the two species.

THE MORPHOLOGY OF BUD-SCALES.—The somewhat conventional treatment which the morphology of bud-scales receives in many botanical text-books gives an air of finality to the subject which it does not seem to possess. In a recent paper (*Biological Reviews*, vol. 3, No. 2), A. S. Foster makes a re-examination of the whole problem based on a very comprehensive survey of the most important literature on the subject. Morphological interpretations of the scales from the viewpoint of formal and idealistic morphology are considered, and their effects on recent theories indicated. The major emphasis, however, is placed upon the more dynamic aspects of the problem, and the nature of the bud-scale is examined in the light of developmental, experimental, anatomical, and causal investigations. The author thinks that Goebel's well-known interpretation of bud-scales as arrested growths of foliage leaf primordia fails to account satisfactorily for unsegmented bud-scales, and entirely leaves out of consideration the multipotent nature of foliar-*Anlagen*. More recent work, especially on the anatomy of cataphylls, suggests that structurally they are divergent foliar organs, which in many instances develop unlike the foliage leaves from the beginning, and any attempt to recover the formal elements of the foliage leaf in every bud-scale is considered futile. Attention is then directed to the fact that in spite of the numerous morphological and phylogenetic interpretations of cataphylls, some of which rest almost entirely on theoretical considerations, almost no information is available as to the mode of internal development in scales, and the physiological factors which in part determine their divergent growth. It is suggested that further experimental and developmental research will show the important relation of the nutrition and metabolism of the developing bud to the periodic alternation of scale leaves and foliage leaves; and then the problem of bud-scale morphology will properly become an important phase of the wider question of organ differentiation at the growing point. Foster's paper, to which is appended a bibliography of 196 references, is a mine of detailed information regarding the subject of bud-scales.

THE ROCKS OF AFRICA.—The attention of geologists and explorers is directed to the "Catalogue of the Rock Collections in the Mineral Department of the British Museum (Natural History)," by W. Campbell Smith, of which Part I., dealing with Africa, has just appeared (British Museum, 1928, Price 2*s*.). Other parts, dealing in turn with each of the continental and oceanic areas, will be issued in alphabetical order. The very carefully documented rock-specimens in the Mineral Department (numbering more than 50,000) form a most valuable reference collection for research and comparison, and it is of the greatest importance for the progress of petrology that workers in this branch of science should realise the wealth of material that is here available for their use. Moreover, the catalogue shows what regions of the world are at present poorly represented, and so encourage collectors of every description to fill up the gaps with contributions that will be especially welcome. The present part begins with an interesting historical introduction, and the rocks of Africa follow. Mr. Campbell Smith is to be congratulated on a compilation of the utmost value. Not only do the notes on each group of specimens indicate where, when, and by whom it was collected, but copious references to literature in which any of them have been described are added, together with a record of such analyses as have been made. Indexes follow of persons (donors, collectors, and authors); of localities; and of rock-names and geological formations. As it is issued, the growing catalogue will undoubtedly become for petrologists, and indeed for geologists in general, one of their most valued and stimulating books of reference.

Thermographs and Hygrographs.—We have received a copy of a recent catalogue issued by Messrs. Pastorelli and Rapkin, 46 Hatton Garden, London, E.C.1, showing Edney thermographs, hygrographs, and hair hygrometers. For amateur meteorologists, instrument No. 10, which records pressure, temperature, and humidity of the atmosphere on a single chart, will appeal on the grounds of economy and convenience. The price is sixteen guineas, which is far less than the combined prices of separate self-recording instruments for the three quantities measured. Fewer charts are required, and a smaller screen will house the single instrument. There is the added advantage that errors in the time scale due to swelling or contraction of the paper, or to gaining or losing of the clock, do not prevent simultaneity of occurrence of changes of the three quantities from being detected—an important point in studying 'fronts.' For official use these advantages may be counterbalanced to some extent by the drawback that in tabulating hourly values, time may be lost because three workers cannot use the same chart at the same time. No. 18 is a 'distance' recording hygrograph costing £24, designed for use in timber-drying kilns, etc. Such instruments—in which mercury in steel bulbs is used for the thermometers, with flexible steel capillary tubing connexions to a Bourdon tube and recording mechanism, enable the latter to be placed conveniently far from the kiln.

Research on Glass.—Vol. 10 of *Experimental Researches and Reports* has recently been published by the Department of Glass Technology of the University of Sheffield. It consists of a collection of papers published in other journals during 1927, giving an account of the work carried out in the Department. Some of this work is concerned with the properties of special glasses, but much of it is more technical in character. A useful contribution is entitled "Notes on Some Methods used in the Analysis of Glasses."

A Micro-calorimeter.—In the *Journal of the American Chemical Society* for April, S. Lipsett, F. Johnson, and O. Maass describe a calorimeter which can be employed for the determination of heats of solution using only 4 c.c. of solvent and has an approximate heat content of 1 calorie. This calorimeter was made from a platinum crucible, and is arranged so that it can be rotated about a horizontal axis. The solute is placed in an inner vessel and is brought into contact with the surrounding solvent by rotation of the calorimeter, which is jacketed and submerged in a water bath. The temperature is measured with a platinum resistance thermometer. A series of determinations of the heat of solution of sodium chloride at constant concentration gave results differing by less than 0·26 per cent from a mean value.

Apparatus for Artificial Sunlight.—Messrs. Watson and Sons (Electro-Medical), Ltd., of Sunic House, Kingsway, have published, under the title "Artificial Sunlight Apparatus," a catalogue of ultraviolet apparatus which includes some standard instruments of other leading makers in addition to their own. The instruments are classified under their different types, *i.e.* mercury arc, carbon arc, etc., and the list, though not large, is quite representative. The introduction to the publication deals briefly with the history of actinotherapy and with the physics of the absorption of radiation by matter. This latter section appears of somewhat doubtful value, for there is still a big gap between the knowledge of the reaction of the atom to radiation and the observed data of the biological effects on living tissue. The characteristics, advantages, and disadvantages of each type of lamp are dealt with in considerable detail, and summarised again at the beginning of the section dealing with that type. Such points as the cost of running, repairs, and the necessity for the use of goggles are treated very fully, and it is exactly this practical information which is required by the doctor who is compelled to select his apparatus from a catalogue. It should be noted that the cored carbons are here included under the section devoted to carbon arcs, though in many cases the radiation produced by the former is nearer to that of the typical metallic arc in quality.

Diesel-Electric Locomotives.—High-speed Diesel engines which run on crude residual oil are highly efficient from the commercial point of view and can now be made with a total weight of about 20 pounds per horse-power. In conjunction with a suitable direct current generator and two motors, they can be used advantageously in a locomotive for ordinary railway traction. In the *English Electric Journal* for April there is an interesting account of a Diesel-electric locomotive which has been made for the London, Midland and Scottish Railway. It will be used on the Manchester-Bury line. The power equipment consists of a 500-h.p. Beardmore engine coupled to a 340-kilowatt 600-volt generator. The generator supplies power to two traction motors, each of 280 h.p., mounted on one of the motor coach bogies. The engine has four running speeds, an 'idling' speed of 350 revolutions per minute, intermediate speeds of 600 and 750 r.p.m., and a full load speed of 900 r.p.m. The control is purely electric, the master controller being provided with 'dead-man's' handles. A battery of accumulators is provided for starting the engine. Self-propelled vehicles of this type do not affect the question of electrifying a railway system. If complete electrification of a system is commercially justifiable, it would probably be better and cheaper than using Diesel-electric units. But the latter units should prove very useful in those districts where the traffic density is not great enough to justify electrification. It provides a motive power considerably cheaper than that of steam-propelled vehicles.

Elections to the Royal Society.

At the weekly meeting of the Royal Society on Thursday, June 21, Lord Melchett of Landford (formerly Sir Alfred Mond) and Sir William S. McCormick were elected into the Society under the statutory provision whereby two persons may be recommended at stated intervals who either have rendered conspicuous service to the cause of science, or are such that their election would be of signal benefit to the Society. Lord Melchett, chairman of Imperial Chemical Industries, Ltd., was born at Farnworth, Lancashire, in 1868; he has brought a ripe experience and much earnest thought and judgment to the national and Imperial aspects of science and industry. His powers and his interests are in keeping with the family traditions. His father, Sir Ludwig Mond, was a chemist and inventor of high standing, and, moreover, a munificent benefactor to the Royal Society. Sir William McCormick, who was born at Dumfries in 1859, is administrative chairman of the Advisory Council on Scientific and Industrial Research, as well as chairman of the University Grants Committee.

The following were elected foreign members of the Society:

Prof. Albert T. J. Brachet, rector of the University of Brussels, who holds the chair of anatomy and embryology in the Faculty of Medicine in that University. He is already a *correspondant* of the Paris Academy of Sciences.

Prof. David Hilbert (born in 1862 at Königsberg) occupies the chair of mathematics in the University of Gottingen. He was educated there, and at Heidelberg, Leipzig, and Paris. Prof. Hilbert is the author of numerous memoirs and treatises in pure mathematics, published in continental journals.

Dr. Paul Langevin is professor of experimental physics at the École Normale Supérieure, Paris. He is the enunciator of a theory of diamagnetism and paramagnetism, familiarly referred to under his name. He is already a foreign member of the Reale Accademia Nazionale dei Lincei, Rome.

Dr. Richard Pfeiffer (who was born in 1858) is professor of hygiene and bacteriology in the University of Breslau; formerly he occupied a similar chair in the University of Königsberg. He is distinguished for his researches on the bacilli of cholera, typhus, and influenza, and on outstanding problems of protective inoculation.

Prof. Ludwig Prandtl (born in 1875 at Freising) holds the chair of applied physics, mechanics, and thermodynamics in the University of Gottingen. He received his technical training at various institutions in Munich, and filled important posts in that city. Before transferring (1907) to Gottingen, he was professor at the Technical High School, Hanover. He is a distinguished pioneer in the study of aerodynamics.

Prof. Richard Willstätter, of Munich, who was awarded the Nobel prize for chemistry in 1915, was born at Carlsruhe (Baden) in 1872. Entering the University of Munich, he studied under Adolf von Baeyer, and ultimately succeeded the master in the chair of chemistry. He is the author (with A. Stoll) of the classic treatise, "Untersuchungen über Chlorophyll: Methoden und Ergebnisse" (Berlin, 1913). We may recall that on July 2, 1927, Prof. Willstatter was included in the Scientific Worthies series of Nature.

Herring Investigations at Plymouth.

Mr. E. Ford has published a report on his herring investigations in the *Journal of the Marine Biological Association* (vol. 15, No. 1, Feb. 1928, pp. 267-319). The report is in four parts, dealing in turn with the methods used in the treatment of the data, the average number of vertebræ in the herrings of the English Channel and the south-east of Ireland, the Plymouth winter fishery of 1924–25 to 1926–27, and the growth of young herrings in the area under discussion.

The first part is important, for in it the author gives a concise account of his methods of age estimation and growth calculation from the scales of the herring. In making comparisons between two lots of fish by means of growth calculation, difficulty is often experienced by the fact that very often one cannot be certain whether or not the calculated lengths, l_1, say, are bimodal. It was found that a fish with a small l_1 had a larger second-year growth than a fish with a large l_1, a fish with a small l_1 grew more than one with a large l_1, and so on, and equations have been deduced from which the length of a fish in any given year can be calculated from its length in the previous year.

The usual method of examining herrings for their 'racial' characteristics is to ascertain the statistical difference between the means of variable characters of samples of fish from different areas, but often these differences are so great even on one ground that the definition of a 'race' is impossible. If this mixture occurs on spawning grounds—and there is no doubt that it does—what is the chance of racial characters being passed on to the next generation? Mr. Ford defines the present limits of 'race' investigation, and confines himself to the study of morphological characters of temporary populations, which, along with the study of age and growth from the scales, should at least help in the solution of the problem of migration.

In the Plymouth winter fishery the 1920 year-class constituted a large proportion of the samples for three seasons, but it is not to be assumed that the same fish returned to the spawning grounds each year, because this was a widely spread rich year-class, and the return of fish to a ground cannot be proved without detailed examination of growth and other characters each year. There are large variations in the length of fish of the same age in this area, and the author names the following as causes for this: (*a*) Some fish were spawned earlier than others; (*b*) some had experienced better conditions for growth than others. Added to these, however, is the effect of the mesh of commercial drift nets on the length of herrings in the samples. There is a difference in growth between the fish of the western end and those of the eastern end of the English Channel, the larger growth taking place in the more open waters of the west.

Observations on the growth of the young (whitebait) herrings taken in the rivers flowing into Plymouth Sound, show that there is a considerable variation in the length of the fish, but there seems to be a general agreement between the mean length of these herrings and the calculated length l_1 of the adult herrings of the Plymouth winter fishery.

Herring investigations in general present many obstacles to the observer, and in this paper the author has clearly defined the probabilities and difficulties of the work, while the concise accounts of his method of treatment of the data will no doubt be of great assistance to others engaged in marine biology.

Annual Congress of the South-Eastern Union of Scientific Societies.

THE thirty-third congress of the South-Eastern Union of Scientific Societies took place at Rochester on June 6–9, with Sir Martin Conway, M.P., in the presidential chair. The congress was well attended, and delegates were sent from most of the seventy-four societies comprised in the Union.

Sir Martin Conway's address was on "Mountain Exploration." The Matterhorn, Sir Martin said, was once thought to be the abode of evil spirits, and even now we find little chapels at the base of mountains, the object being to dam back the evil spirits from descending into the valleys. In the Andes of Bolivia the mountains were held to be the abode of gods. Indeed, almost all over the world the mountains were held to be the abode of either devils or gods. In the Chinese mind there is a great love for the mountains, and many poems have been dedicated to them; this affection is exceptional amongst the peoples of the world.

Sir Martin said that, geologically, mountains are quite modern, some of the youngest being found in the Himalayas, and the hundreds of peaks there have not yet been worn down as in the case of other ranges, as, for example, the Scottish mountains, where denudation has gone on for a much longer period. Mountains are continually being broken down by the forces of Nature, and at periods in geological history fresh mountains have been reared up from the crust, making up for the denudation of other ranges. In Great Britain, as in other countries, it was only during the course of the last century that people began to see beauty in great heights, and poetry and art have done much since to beget a love for mountain climbing.

Respecting the breaking down of mountains, Sir Martin said he has seen as many as eighteen avalanches in one hour in the Himalayas. In the same range there are great glaciers and great precipitation of snow. The South American Andes are in the main poorly supplied with snow, and the glaciers are as a rule eaten up by evaporation before they reach a low level. On the other hand, in Spitsbergen, although the highest of the mountains is but 7000 feet high, they are the grandest of all, as they are clothed with snow to their base.

In Dr. William Martin's address to the archæologists, he emphasised the necessity of organised work on proper lines, and showed how such work can be prevented from being but desultory and unscientific. He showed what powers exist under the Ancient Monuments Act to prevent destruction of objects of interest, and emphasised the fact that such powers are very limited, and that but little can be done where there is a determined effort to do away with monuments that are in the way of modern so-called improvement. In speaking of the archæological remains in the Medway Valley, Mr. A. E. Hurse stated that he considers that the ancient highway, sometimes known as the Pilgrims' Way, which may have really dated from neolithic times, crossed the Medway somewhere near Snodland. Another ancient highway, sometimes called the Old Road, is remarkable as being in the line of many megalithic remains, such as the circles at Addington, its dolmens, and Kits Coty House. The fact that neither road was much utilised to serve as parish boundaries seems to show that they were to a great extent lost before Saxon and Norman times, when boundaries began to be defined.

Mr. G. E. Hutchings in his paper on the vegetation of the district showed that the area comprises wide chalk areas and salt marshes, and forms an admirable one for the study of plant ecology; little work has yet been done in this direction. Papers of a botanical nature were read by Mr. C. E. Salmon, on fruits and seeds of allied plants, and by the Rev. L. Denton Sayers, on gall-formation in plants.

In the geological section Mr. H. B. Milner gave an illustrated paper on "Geology from the Air," and by the aid of numerous aerial photographs showed how the aeroplane can be utilised for geological study. During flights that he has made in Iraq and Palestine he has taken photographs which give an added interest to the geology of these districts. In thickly wooded country air pictures are particularly valuable, as they can form the basis of maps which can afterwards be more closely filled in by ordinary field work. 'Cut-offs' or ox-bow lakes can thus be identified which may be overlooked by ordinary means in such a country. The meanders of the Jordan were vividly portrayed in one of the pictures shown. English coast-line scenery takes on a new aspect from the air, whilst inaccessible regions in all mountainous parts of the earth can be studied in air pictures. Aerial geology is in its infancy, and much may be expected from it.

Dr. S. W. Wooldridge gave a characteristic paper on the geomorphology of the North Downs, and Mr. G. Dines a paper on the Bapchild palæolithic site. Prof. E. W. MacBride read a paper on the conditions of progressive evolution.

A public lecture was given by Mr. Aymer Vallance on old timber houses, introducing many pictures to illustrate the evolution of the half-timbered houses from what is considered the neolithic plan of drawing branches of trees so as to form an arched roof, to the curved 'ships' timbers' which in early houses supported the roof. Then followed the upright timbers to support a second floor, and finally the curved timbers were used only for walls of that floor, seen outside such a house as part of the half-timbering. The houses at first had a long room or hall where the household met for meals, and many of these were later cut up so as to form a number of rooms, or even separate cottages. When rooms were added on the upper floor the heads of the family would retire to one of these, which came to be known as the 'solar,' a name that gave rise to some discussion. It was suggested that the name arose from the room being in a position exposed to the sun, but it may have been the room where the family could be alone or *solus*.

In the Regional Survey Section, Mr. C. C. Fagg gave a history of the movement, in the development of which he has for many years taken an active part.

Many excursions were made during the congress, some of a strictly scientific nature, those devoted to archæology being well attended. Not the least interesting was that to Gads Hill Place, which was thrown open by the kindness of the occupiers, who showed the visitors many items of interest to lovers of Dickens. A reception by the Mayor in the Guildhall was followed by a lecture by Dr. Mortimer Wheeler on Roman Rochester. The remains of the old Roman walls, the Cathedral and the Castle, the House for Six Poor Travellers, and other places in the town, were visited under local guides during a comprehensive perambulation. At the delegates' meeting the honorary secretary announced that the congress for 1929 would be held at Brighton, under the presidency of Sir Arthur Keith.

University and Educational Intelligence.

BIRMINGHAM.—Considerable increases in the contributions of various authorities in the Midland district to the University of Birmingham have been announced recently. The County Council of Staffordshire has increased its grant from £1000 to £1250 per annum; Worcestershire C.C. from £750 to £1000; Warwickshire C.C. from £500 to £1000 (on the condition that two scholarships are provided); Smethwick from £250 to £350; Dudley from £100 to £200; West Bromwich £260 to £520; Shropshire C.C. £150 to £250. New grants have been made by Walsall (£250) and the City of Worcester (£250). The City of Birmingham has now decided to increase its contribution from £15,000 per annum to the proceeds of a penny rate (equivalent at the present time to about £26,000 per annum).

The degree Congregation which is to be held on June 30 is to be marked by the conferment of honorary degrees on distinguished members of the legal profession to signalise the inauguration of the Faculty of Law in the University.

CAMBRIDGE.—The George Henry Lewes studentship of the annual value of about £250 is being offered for research work. Candidates should send a statement of their qualifications, the subject of their proposed research, and the name of one referee, to Prof. Barcroft, Physiology School, Cambridge, by July 10.

LONDON.—Sir Gregory Foster, Provost of University College, has been elected Vice-Chancellor for 1928–29 in succession to Sir William Beveridge.

Prof. E. N. da Costa Andrade has been appointed as from Aug. 1 to the Quain chair of physics tenable at University College. Prof. Andrade was educated at St. Dunstan's College, University College, the University of Heidelberg, where he obtained the Ph.D. Degree in 1911 (*summa cum laude*), the Cavendish Laboratory (1911–12), and the University of Manchester (1913–14). Since 1920 he has been professor of physics at the Royal Military College, Woolwich. His published work includes: "The Structure of the Atom" (3rd edition, 1927); "Airs"; "The Atom"; "Engines"; and various papers on physical and mathematical subjects in *Proc. Roy. Soc.*, *Phil. Mag.*, *Annalen der Physik*, and other technical journals.

The following doctorates have been conferred: D.Sc. in Anatomy on Miss I. C. Mann (St. Mary's Hospital Medical School), for a thesis entitled "The Development of the Human Eye." D.Sc. in chemistry on Prof. E. C. Williams, until recently Ramsay professor of chemical engineering, for a thesis entitled "(1) The Use of Highly Porous Bodies in the Recovery of Benzole from Coal or Coke Oven Gas. (2) The Purification of Benzole by means other than Sulphuric Acid Washing." D.Sc. in Physiology on Dr. C. H. Best (University College and the National Institute for Medical Research), for a thesis entitled "The Effect of Insulin on the Dextrose Consumption of Perfused Skeletal Muscle." D.Sc. in mathematics on Mr. Charles Fox (University College), for a thesis entitled "I. Null Series and Integrals; II. Generalisation of the Fourier-Bessel Integral Transform."

The degree of M.Sc. in the principles, history, and method of science for internal and for external students will in future be termed the "M.Sc. Degree in History, Methods, and Principles of Science."

A University post-graduate travelling studentship has been awarded to Mr. H. I. Andrews. Mr. Andrews (Imperial College—City and Guilds (Engineering) College) proposes to undertake research work in locomotive engineering upon the locomotive test plant at the University of Illinois. A University post-graduate studentship in engineering has been awarded to Mr. D. M. Robinson (King's College), who was awarded in 1927 the Siemens' Prize in electrical engineering and a £50 research scholarship from the Institute of Electrical Engineers.

NEWCASTLE-UPON-TYNE.—The special committee appointed by the Council of Armstrong College has unanimously agreed to recommend the appointment of Sir Westcott Stile Abell as professor of naval architecture in succession to Dr. J. J. Welch, who retires on Sept. 30. Sir Westcott Abell was professor of naval architecture in the University of Liverpool from 1910 until 1914, and since then he has been Chief Ship Surveyor of Lloyd's Register of Shipping. Sir Westcott was president in 1924–25 of the Institution of Marine Engineers.

Mr. H. P. Mulholland, of Queens' College, Cambridge, has been appointed lecturer in mathematics as from Oct. 1.

OXFORD.—On June 18 the Halley Lecture was delivered by Dr. Harlow Shapley, Director of the Harvard College Observatory, on "A Search for the Centre of the Milky Way." Dr. Shapley, who illustrated his discourse by an ample supply of excellent lantern slides, succeeded in arousing and sustaining the interest of a large and appreciative audience. The lecture fell into three main divisions, namely, the search for the direction and distance of the centre; its surroundings; and the veil of cosmic material behind which it is hidden. Photographic views show that of equal areas of the heavens, one might contain 600 times as many stars as another. The stellar material may be either organised or nebular. Our galaxy has been shown to be a 'bun-shaped' system rotating round a centre. It is possible to see through the galaxy, and so to become aware of the existence of other 'supergalactic' systems. The dark obscuring veil is due to the presence of an enormous amount of meteoritic material. The dark structures observable in certain nebular regions are due not to gas, but to vast quantities of cosmic dust.

DR. JAMES DAVIDSON, chief assistant entomologist at Rothamsted Experimental Station, Harpenden, Herts, has been appointed head of the Department of Entomology at the Waite Agricultural Research Institute, University of Adelaide.

THE governing body of the Chelsea Polytechnic, London, S.W.3, has appointed Mr. F. J. Harlow, Principal of the Wigan and District Mining and Technical College, to be Principal of the Polytechnic in succession to Mr. Sidney Skinner, who retires on Aug. 31 next. Mr. Harlow will take up his duties at Chelsea on Sept. 1 next.

THE London School of Hygiene and Tropical Medicine has made arrangements for courses of lectures and practical demonstrations for the guidance of employees of business firms and other bodies who are about to proceed to tropical and sub-tropical countries or are home on leave. In addition to providing guidance for life in the tropics and personal hygiene, they will also include a short account of some of the more common diseases, with advice in regard to measures of protection against such diseases, and some guidance in simple methods of self-treatment. The first course of nine lectures is being given by Col. G. E. F. Stammers, on July 16–26, from 11.30 A.M. to 1 P.M. each day. A synopsis of the lectures can be obtained from the Secretary, London School of Hygiene and Tropical Medicine, 23 Endsleigh Gardens, Euston Road, W.C.1.

Calendar of Customs and Festivals.

Midsummer Processions and Fairs.—At about midsummer and the beginning of July, processions take place in many localities, sometimes as an observance of a forgotten local cult. More frequently, especially in connexion with fairs, they mark the close or beginning of an annual or semi-annual period. Such was the ceremony observed at Alnwick when, before the proclamation of the fair, representatives of the townships owing service to the Duke of Northumberland attended at Alnwick Castle. In London, up to Tudor times, the setting of the watch for the coming year was accompanied by processions on Midsummer Eve and St. Peter's night in which the Lord Mayor and Sheriffs took part, attended by cresset bearers, the city giants, minstrels, etc. A similar procession took place at Chester, where the pageant included a dragon, hobby horses, and other beasts of medieval fancy. At Burford a dragon was paraded around the town annually in memory, it was alleged, of a battle of Saxon times. The procession, which in the Isle of Man paid the rent of Mannan-beg-mac-y-heir, the eponymous deity of Manx mythology, by carrying green grass to the top of Barule, was rather in the nature of a first-fruit ceremony, of which similar traces remain in England in the dedication of cuttings of hay or rushes to the use of the church at midsummer.

June 30.

St. Paul the Apostle.—Traditional accounts of the martyrdom of St. Paul preserve some particulars which are of interest, especially in connexion with the preternatural origin of springs. On decapitation, the head of the martyr gave three leaps, and at each of these there sprang up a fountain where the head fell, "which fountains remain to this day and are reverenced with singular devotion by all Christian Catholics."

July.

Bouphonia.—'The Slaying of the Bull' in Athens took place at the end of June or beginning of July. Barley and wheat were laid on the altar of Zeus Polieus. Oxen were then driven round the altar, and the one which ate the corn was sacrificed after being wetted with water brought by maidens. The ox was felled with an axe and its throat cut with a knife, both men who performed these operations throwing away the weapon and flying immediately. The beast was then skinned. All present partook of its flesh, and the skin was stuffed and yoked to a plough.

A trial for the murder of the ox followed. After each one officiating in the sacrifice had been accused and passed on the blame to the next grade of operators, the murder was finally brought home to the axe and the knife, which were condemned to be cast into the sea. The sacrifice was a crime demanding the extreme penalty. Frazer suggests that the victim, by partaking of the corn, showed himself to be the corn spirit, an aspect of Dionysus personified in the bull. The wetting of the bull is a rain charm analogous to customs of the harvest in many countries.

July 2.

St. Otto. A.D. 1139.—In the course of his missionary journeys among the Slavs, St. Otto necessarily came into antagonism with pagan beliefs. At Stettin a sacred oak, at the foot of which was a spring, was allowed to remain standing at the entreaty of the people on the condition that they ceased to perform their superstitious practices there; but an attempt to cut down a sacred nut tree nearly led to the death of the saint at the hands of the owner in whose field it stood. A peculiar form of divination in war at Stettin is recorded. Nine arrows were laid on the ground and a sacred black horse was led up and down among them by its attendant priest. If the arrows remained undisturbed by the horse's hoofs the result of the war would be favourable.

July 2-4.

Processus and Martinian.—If it rains on July 2 heavy showers will follow and the corn be spoiled. Rain on the day of the translation of St. Martin (July 4) will be followed by rain for forty days.

July 3.

A solemn celebration in the church of St. Leu and St. Gilles, Paris, commemorated the miracle of the bleeding of a statue of the Virgin in *la rue aux Ours* when it was struck with a knife by a drunken soldier in the year 1513. The image was transported to Rome; but the memory of the event was perpetuated by an annual ceremony performed by the inhabitants of the street, who used to throw a figure of the soldier, fashioned in faggots, into the fire. An elaboration of the ceremony was checked by the magistrates in 1744, whereupon it took the form of a three days' parade of Paris before the destruction of the figure, which was now made of osier, clothed and armed with a knife.

July 6.

Old Midsummer Day.—This day was still reserved as the proper occasion for midsummer observances in remote localities in Britain so late as the early part of the nineteenth century.

At Puxton, Somersetshire, on the Saturday before Midsummer day O.S., used to take place the division of certain common lands for the ensuing twelve months. The rights were confined to certain estates and their tenants. They were summoned to the church for the ceremony of measuring the chain by the ringing of the bell. This chain was eighteen yards long, *i.e.* four yards short of the common chain. The party then repaired to the common. Twenty-four apples had been previously prepared with marks, each distinct and each having a distinctive name. As each acre was measured an apple was taken from the bag and a mark to correspond cut in the turf with a special knife kept for the purpose. A certain number of acres, called the 'outlet' or 'out-drift,' were set aside for expenses and let by an inch of candle, burnt in silence except for the bids.

July 7.

St. Thomas à Becket's Day.—In Cornwall a festival called 'Bodmin Riding' was kept up on the Sunday and Monday after St. Thomas à Becket's day. A company on horseback with musicians, and a puncheon of ale brewed for the purpose in the preceding October, rode around the town, the crier saluting each house and wishing the inhabitants 'a prosperous morning, long life, and a prosperous riding.' The riding tune was then played and the householder invited to drink the riding ale. On the next day a procession went to the Priory, where they received two garlands on staves and then proceeded to Town End, where the games, lasting two days, were formally opened. A mock trial was also held, presided over by a lord of misrule. Pretended offences, such as peculiarity or irregularity in dress, were punished by a "summons to Halgaver," a place of which the name "signifieth goat's moor . . . a little without the town and very full of quagmires."

Societies and Academies.

LONDON.

Royal Society, June 21.—**C. V. Boys**: Solid dipleidoscope prisms. Bloxam's hollow prism, known as Dent's dipleidoscope, is described. The instrument affords the best practical means of comparing the intensity of illumination of two images, and can be used to check the accuracy of Fresnel's equations for the intensity of light reflected from and traversing refracting surfaces. The solid dipleidoscope prism might be used with advantage to increase the precision of good astronomical instruments.

G. I. Taylor: The forces on a body placed in a curved or converging stream of fluid. The particular case of straight converging flow is of special interest in aeronautics; the resistance is $-(1+a)\ V\partial p/\partial x$, where V is the volume, $\partial p/\partial x$ the gradient of pressure in the fluid, and the 'virtual mass' of the body for accelerated motion in the direction of the stream is a times the mass of fluid displaced. The equations are applied to find the couples exerted on bodies of various shapes. The couple about the direction of the stream-lines is the most interesting, because in a uniform stream of perfect fluid this couple is zero, and even in a real fluid it is zero for all bodies which possess a plane of symmetry containing the direction of the stream. When the stream is curved or converging the asymmetry of the stream reacts with certain elements of asymmetry in the body, causing it to take up certain definite positions. Thus an elongated body with a curved centre line rotates in a curved stream until the plane of the centre line coincides with the plane of curvature of the stream-lines, but the direction of curvature of the body is opposite to that of the stream-lines.

G. I. Taylor: The energy of a body moving in an infinite fluid, with an application to airships. The energy in the fluid surrounding a body which moves without rotation in an infinite fluid depends only on the terms of the first degree in the spherical harmonic series for the velocity potential. Conversely, these terms are completely determined when the expression is known which represents the energy of the flow in terms of the components of velocity of the body. As an application of these results a simple formula is developed giving the virtual addition to mass associated with a body moving with a uniform acceleration through a fluid in terms of the equivalent distribution of sources and sinks which give rise to the same external flow.

S. S. Cook: Erosion by water-hammer. The pressure generated at the first moment of impingement of a column of water against a fixed surface is independent both of the length and of the sectional area of the column, and therefore it may be inferred that the same pressure will arise from the impact of a drop of water, being in this case, however, confined to the point of impingement. In the case of vacuous cavities collapsing in an incompressible fluid, the work done by the surrounding fluid closing in is converted into velocity energy, concentrated, when collapse is nearly complete, at the reduced surface of the cavity; and, if further collapse is prevented by the interposition of a fixed surface, high water-hammer pressure will be produced. The erosion of steam turbine blades is attributed to the impact of drops of water struck by the rotating blades, and it may be aggravated by irregularity of shape of the drops, causing a cavity to be entrapped at the surface of impact.

Sir Robert Robertson and J. J. Fox: Studies in the infra-red region of the spectrum. Part I.—Description of prism spectrometer and apparatus. A description is given of the prism spectrometer and apparatus used to explore the infra-red absorption spectrum of ammonia, phosphine, and arsine. Attention had to be paid to the necessity for keeping the source of energy constant, for calibrating mechanism for reading wave-lengths, for shielding the thermopile from variations of air pressure, for keeping close watch on the temperature of the prism, especially when made of rock-salt, on account of the high temperature coefficient of its index of refraction; for accurate alinement of observation tubes, and for obtaining a galvanometer of great sensitiveness and freedom from external perturbations.

Sir Robert Robertson, J. J. Fox, and E. S. Hiscocks: Studies in the infra-red region of the spectrum. Part 2.—Calibration of prism spectrometer; general procedure; preparation of pure ammonia, phosphine, and arsine. The 'wave-length drum' was first calibrated in terms of angle of rotation of the prism table. Large-scale dispersion curves were constructed from Paschen's determinations of refractive indices of the three dispersing media, rock-salt, quartz, fluorite. For the region of the spectrum $0\cdot5\mu$ to $16\cdot5\mu$, a curve showing the correction, in μ, to be applied to any place on the drum graduation was drawn, and for regions $0\cdot5\mu$ to $3\cdot5\mu$ and $0\cdot5\mu$ to $9\cdot5\mu$ curves were drawn connecting drum graduation and wave-length for quartz and fluorite prisms respectively. The gases were purified by fractional distillation.

Sir Robert Robertson and J. J. Fox: Studies in the infra-red region of the spectrum. Part 3.—Infra-red absorption spectra of ammonia, phosphine, and arsine. Tables and graphs are given of oscillation and rotation-oscillation bands, together with a general description of the bands observed. With the prism instrument used partial resolution was obtained beyond $2\cdot2\ \mu$ with quartz, $4\ \mu$ with fluorite, and $5\ \mu$ with rock-salt, and fine structure obtained beyond 3μ with quartz, 6μ with fluorite, and 8μ with rock-salt.

Sir Robert Robertson and J. J. Fox: Studies in the infra-red region of the spectrum. Part 4.—Discussion of absorption bands of ammonia, phosphine, and arsine. In certain sequences of bands the members preserve a constant ratio of wave-numbers to one another: $0\cdot68$ for PH_3/NH_3 and $0\cdot91$ for AsH_3/PH_3. Several harmonic sequences of oscillation bands are found in each gas, but a main sequence is common to all three gases, and a sequence common to ammonia and arsine alone. From the bands resolved, the fine structure has been evaluated, and wave-number differences obtained indicating rotation bands. Oscillation frequencies become slower in the order ammonia, phosphine, arsine, and wave-number differences in rotation bands show that the molecules rotate more slowly in the same order. Support for Hund's view that ammonia has a tetrahedral structure is adduced from bands observed for the three gases.

J. Hollingworth: The polarisation of radio waves. With the recently constructed apparatus the radio waves received can be split up into their physical components, which can thus be studied separately. In particular the form and extent of the abnormal polarisation of the wave returned from the upper layer can be defined quantitatively. Owing to the annual variations involved, observations must be continued for some time.

A. C. Menzies: The spark spectrum of copper. Instantaneous photographs of the copper spectrum in the Schumann region are obtained by fusing copper wires in a small chamber attached to a vacuum grating spectrograph. The method allows of the use of small capacity pumps, since a low pressure is only required preliminarily. Owing to the high velocity of light the evolution of gases in the fuse is too slow to cause appreciable absorption before the light has reached the plate. Also the lines are very sharp, since 'wandering' of the source is reduced. The spectrograms are not rich in lines, but this is not a disadvantage when one is seeking the lines due to low-level terms. The lowest term of the copper spark spectrum $1\,{}^1S_0$ has been identified with the term-value −21929·4, and is in accordance with the Heisenberg-Hund scheme.

W. H. Taylor and W. W. Jackson: The structure of cyanite, Al_2SiO_5. A qualitative investigation has been made. Data were obtained from X-ray rotation photographs taken under conditions such that an estimate of the density of the photographic image yields reliable information concerning the relative strengths of reflection by different crystal planes. The fundamental assumptions are that the oxygen atoms are arranged in cubic close packing, with the silicon and aluminium atoms distributed among the interstices so that they lie at the centres of groups of four and six oxygen atoms respectively. The main features of the structure are described,. Explanations are suggested of the highly perfect cleavage parallel to the *a*-face, and also of the striking difference in hardness exhibited in different directions on this face.

F. H. Constable: A new interference method of measuring the surface area of film catalysts. (1) The theory. The meaning to be assigned to the surface area of a catalyst is discussed. The area will necessarily vary with the means of measurement adopted. In view of the urgent need for a standard method of measuring the area of film catalysts, and the uncertainty attached to adsorption methods, a chemical method has been adopted. The surface is covered with a very thin film of a compound the specific volume of which is considerably greater than that of the metal. The thickness of the film is known from the colour, and the mass of the film is determined independently, hence the area is known. (2) Nickel: a method of preparation of the film, an apparatus for activation and study of the surface area. Metallic films made by the oleic acid method, applying the finely powdered oxide to china clay rods, failed to conduct electricity, so that it was necessary to introduce a new method. Graphite-coated china clay rods were used as the foundation for an electrolytic deposit. The small masses of nickel used could be measured by the quantity of electricity passed. The method of the paper above was used in a special apparatus of quartz. The maximum increase in area on activation was about five times, while reduction at 563° produced a surface only 1·3 times the support area.

S. J. Davies and C. M. White: An experimental study of the flow of water in pipes of rectangular section. A built-up pipe was used which permitted variation in the controlling dimension of the section, without change of the boundary surfaces. In all, 400 tests have been made on pipes, varying in section from 2·54 cm. broad by 0·0154 cm. deep to 2·54 cm. broad by 0·0681 cm. deep. A range of $\rho v d/\mu$ from 60 to 4600 has been investigated. Employing progressively shorter 'entrant lengths' gives evidence of a third or 'lower' critical point, in the neighbourhood of $\rho v d/\mu = 140$, below which eddies are not transmitted along a pipe. For turbulent flow the values of the resistance coefficient are the same as those obtained from tests of smooth circular pipes, provided that the comparison be made on the basis of the hydraulic mean depth. The latter is thus the controlling dimension in channels with a width-breadth ratio as great as 100 to 1, and hydraulic mean depth as small as 0·01 cm. (equivalent to a round pipe 0·04 cm. in diameter). Roughness, constituted by irregularities some 2 per cent of the distance between the surfaces, has no measurable effect upon the resistance to viscous flow or the turbulent resistance.

J. M. Walter and S. Barrat: The existence of volatile intermetallic compounds. The band spectra of the alkali metals and of their alloys with each other. The power of forming volatile binary compounds with each other is general among the alkali metals. Probably 1-5 per cent of the vapours of mixed alkali metals at their boiling point are in the form of these diatomic molecules. Each compound possesses a characteristic band spectrum. Many of the spectra show, in addition, a narrow region of continuous absorption, which, it is suggested, corresponds to the continuous absorption of the halogen molecules. The vapour density of potassium, redetermined by the Victor Meyer method, indicates that the proportion of the diatomic molecules cannot exceed 5 per cent in the vapour at 935° C.

G. Temple: The theory of Rayleigh's principle as applied to continuous systems. This paper deals primarily with continuous one-dimensional oscillating systems, such as a metal bar. If we consider the system to be vibrating in its gravest mode, we may use Picard's method to construct a sequence of functions which form successive approximations to the amplitude. Rayleigh's principle can be applied to each member of the sequence to yield an approximation to the fundamental frequency. The approximations thus obtained steadily decrease to the true value. An upper limit to the difference between the true fundamental frequency and any approximation belonging to the sequence is obtained. Rayleigh's principle is extended to the calculation of the frequency of the first overtone.

R. Schlapp: The Stark effect of the fine-structure of hydrogen. The influence of an electric field on the fine-structure of the energy levels of the hydrogen atom in the Stark effect is investigated by means of the wave-equations of Darwin and Dirac. In weak fields each level splits up into several, the electric separations being, in general, proportional to the field-strength. In the highest fine-structure level of any state, however, the separations are proportional to the square of the field. On Kramers' theory the separation due to a weak field is always proportional to the square of the field. In strong fields each of the Stark levels of the Schwarzschild-Epstein theory is found to have a modified fine-structure. The case of $H\alpha$ is worked out in detail.

Dudley M. Newitt: Gaseous combustion at high pressures (Part 10). The co-volume corrections, maximum temperatures, and dissociations of steam and carbon dioxide in explosions. After applying all necessary corrections, it is shown that in explosions of a theoretical hydrogen–air mixture the mean maximum temperature actually attained rises from about 2585° to between 2660° and 2718° (absolute) as the initial pressure is increased from 3 to 175 atmospheres, the degree of steam dissociation steadily diminishing from 2·2 to about 1 per cent. In a theoretical carbon monoxide–air mixture the mean maximum temperature actually attained gradually rises from 2385° up to between 2700° and 2760° (absolute) as the initial pressure is increased from 3 to 175 atmospheres, the degree of dissociation of carbon dioxide at the maximum temperature remaining fairly constant at 5 per cent throughout. In the explosion of a $2CO + O_2 + 4CO$ mixture where carbon dioxide dissociation at the maximum temperature is entirely suppressed, the mean maximum temperature gradually rises from 2710° up to between 3020° and 3100° (absolute), as the initial pressure is increased from 3 to 150 atmospheres.

Lord Rayleigh: Observations on the band spectra of mercury. A mercury band spectrum is described which is excited by fluorescence, with the continuous hydrogen spectrum as a source. This spectrum is remarkable as showing in emission the band 2540 near the resonance line 2537 without the resonance line itself. It is observed also that the continuous spectrum on the short wave side of the bands 2345, 2338, etc., extends as far as 2150 and thus much beyond the position of the forbidden line $1\,{}^1S_0$—$1\,{}^3P_2$, 2270, which was found under other conditions to limit this continuous spectrum. The series of bands 2345, 2338, etc., examined in emission with large resolving power, is free from the complications of a finer underlying structure which appear in absorption. The structure in the band 2482 to 2476, described by earlier writers as continuous, is enigmatic in terms of the quantum theory. The band does not appear in absorption.

L. P. Davies: The photo-electric properties of some metals in the soft X-ray region. A photo-electric detector is fitted with iron, cobalt, copper, and nickel photo-electric plates in turn, and these four metals also form the anti-cathode. The ratios of the soft X-ray efficiencies are not affected by changing the photo-electric plate, but their absolute values are. Approximately, iron and nickel are 10 per cent more efficient than cobalt and copper as soft X-ray emitters, and 20 per cent more efficient than cobalt and copper as photo-electric detectors.

C. F. Powell: Condensation phenomena at different temperatures. An apparatus is described whereby the supersaturation required to produce condensation on ions and on associated molecules in the presence of dust-free air, over a range of temperature from −25° to 50° C., has been measured. The effect of the air is of importance not only by determining the amount of water vapour condensed per unit volume for a given degree of supersaturation, but also by preventing the evaporation of water from the walls of the expansion chamber. Apart from the experimental difficulties to be met in working at higher temperatures, atmospheric temperature gives the best conditions for the cloud method of investigating atomic phenomena.

(*To be continued.*)

Physical Society, May 25.—W. H. Eccles and Miss W. A. Leyshon: Some new methods of linking mechanical and electrical vibrations. Methods whereby the frequency of an electric oscillatory circuit can be brought under the control of a tuning-fork are described. The electrical circuit may include a crystal contact, piezo-electric resonator, neon lamp, or pointolite lamp. The latitude of working conditions is narrow, but the difference in natural frequency between the fork and the controlled circuit may be very considerable.

DUBLIN.

Royal Dublin Society, May 22.—S. Leonard: The waste land of North County, Wicklow. A survey has been made to ascertain what areas of no agricultural value are suitable for afforestation. Owing to the need of shelter from the prevailing south-westerly winds, suitable areas are confined to the northern and eastern slopes of the hills. They amount to about 11 per cent of the waste land, or 6 per cent of the total surveyed.—H. Ryan and J. J. Lennon: The action of alcoholic hydrochloric acid on methyldiphenyltetrahydropyrone. It has been shown previously that γ-benzylidine-methylethylketone reacts with benzaldehyde to form isomethyldiphenylcyclopentenone. The latter body was converted by acid into methyldiphenycyclopentenone, and this in turn reacted with benzaldehyde forming benzylidine-methyldiphenylcyclopentenone. The same ultimate product can be got from α-benzylidine-methylethylketone, which in the presence of alkali is converted by benzaldehyde into methyldiphenyltetrahydropyrone. From the latter, by means of concentrated hydrochloric acid in absolute alcohol, the same methyl-diphenylcyclopentenone was obtained as that previously got from γ-benzylidine-methylethylketone. In this way the α- and γ-benzylidine-methylethylketones by interaction with two molecular amounts of benzaldehyde formed the same ultimate condensation.—H. Ryan and M. T. Casey: The action of aromatic amines on nitric esters. The reactions between primary aromatic amines and nitric esters appear to be indirectly hydrolytic; for example, aniline and butyl nitrate gave aniline nitrate and butyl-aniline. In the case of secondary and tertiary amines the action of nitric esters seems to be chiefly one of oxidation. A slight degree of nitration also occurs. The reactions between dimethyl-aniline and the nitric esters of the polyhydric alcohols were found to be much more rapid than in the case of monohydric alcohols. The relative rates of decomposition of various nitric esters in the presence of dimethylaniline were measured by the intensity of coloration produced after a given interval.—H. Ryan, J. Keane, and J. Dunne: The estimation of diphenylamine and diphenylnitrosamine in the presence of their derivatives. Another method has been suggested by Ryan and Dunne which consists in extracting the powder with alcohol and reducing the extractive in alcoholic solution with stannous chloride and hydrochloric acid. The alcohol is removed from the mixture, which is then distilled in a current of steam. The diphenylamine is extracted with chloroform and estimated volumetrically with bromide water. A modification to this method is recommended by Ryan and Keane by the use of a chloroform instead of an aqueous solution of bromine, in which case the degree of bromination is less dependent on light conditions.—N. Cullinane, J. Algar, and H. Ryan: A synthesis of lotoflavin (5-7-2′-4′-tetrahydroxyflavone) and of 7-2′-4′-6′-tetrahydroxyflavone. Phloracetophenone-4-6-dimethylether interacted with methyl 2-4-dimethoxybenzoate forming 2-hydroxy-4-6-2′-4′-tetramethoxybenzoylacetophenone. The latter body on warming with hydriodic acid gave 5-7-2′-4′-tetramethoxyflavone, from which by further action of hydriodic acid 5-7-2′-4′-tetrahydroxyflavone was obtained. This flavone is similar in properties to, and probably identical with, lotoflavin obtained from *Lotus arabicus* by Dunstan and Henry in 1901. By a similar method the isomeric 7-2′-4′-6′-tetramethoxy and tetrahydroxy flavones were obtained from phloracetophenonetrimethylether.—B. O'Donoghue, J. J. Drumm, and H. Ryan: The commercial utilisation of Java citronella oil. In an attempt to determine whether it would be possible to produce high-class perfumes from the crude Java citronella oil which is imported for use in household soaps, it was found that citronellal can be readily separated from the crude Java oil by means of sodium bisulphite, and from the residual oil the geranial can be obtained with the aid of its double compound with calcium chloride. No economical process for separating citronellol was devised, but this perfume can be readily got by electrolytic reduction of the citronellal separated from the oil.

PARIS.

Academy of Sciences, May 30.—**A. Lacroix**: A new region of intrusive nepheline rocks in Madagascar.—**Belzecki**: The equilibrium of elasticity of a rectangular prism.—**Albert Portevin**: The influence of various factors on the internal tensions in wire drawing.—**Paul Piou** and **A. P. Bérard**: The velocity of absorption of sulphur dioxide by magnesium hydroxide.

ROME.

Royal National Academy of the Lincei, Feb. 19.—**U. Cisotti**: The conception of constant tensors in Euclidean varieties.—**G. A. Crocco**: The weight of the aeronautic structure. The design of aeronautic structures is dominated by the criterion of minimum weight, and it becomes necessary to carry out a preliminary approximate calculation without defining exactly the design or developing all the calculations demanded by the science of construction. With the principal factors governing the weight of a structure as starting point, an approximate relationship is deduced which is valid for any structure statically defined, and is to be considered later in its application to aeronautic structures.—**A. Lo Surdo**: Characteristics of triodes with saturating grid tensions.—**F. Zambonini** and **A. Ferrari**: Investigations on lead phosphate and chlorophosphate (pyromorphite). The results of X-ray analysis by the rotating crystal method demonstrate the almost fundamental identity in crystalline structure of lead orthophosphate and pyromorphite, in contradiction to the formula proposed for the apatites by Abegg and Bodländer and by Werner, who regarded these minerals as halides of a complex cation. The mean value of the lattice constant, calculated from the position of the lines due to the radiation $K\alpha_1$, is 9·65 A. for lead orthophosphate and 9·91 A. for pyromorphite; the Debye method gives 9·67 A. and 10·135 A. respectively. From the mean values the densities are calculated to be 7·03 and 7·06, which are in good agreement with the experimental values.—**S. Minetti**: The necessary and sufficient conditions for an entire function to be of a certain genus and a certain order (3).—**A. Masotti**: The equivalence of tensors.—**L. Berwald**: A normal invariant form of the second variation.—**A. J. M'Connel**: The parallel transport of a vector along a finite circuit: Case of a Riemannian space (2). Results previously obtained are applied to the case of a Riemannian space.—**G. Ascoli**: Laplace's equation of hyperbolic space.—**Gina Burani**: Quadrics of Riemannian space of three dimensions. Slebodzinski has recently defined, as quadric of a Riemannian space V_3, a surface Q the lines of which are asymptotic to the geodetics of Q and consequently of V_3. It is now shown that, for quadrics so defined, Bonnet's theorem, according to which the quadrics (of S_3) are characterised by the property that along each line of curvature the principal relative radius of curvature is proportional to the cube of the other, is, in general, not valid.—**G. Palozzi**: The projective invariants of contact between oblique curves.—**G. Scorza-Dragoni**: The quasi-continuity of compound functions. If $f(y)$ is a continuous function in y, and $y(x)$ is a quasi-continuous function in x, the compound function $f(y(x))$ is also quasi-continuous, but if $y(x)$ satisfies a certain condition, the hypothesis of the continuity of $f(y)$ in this theorem may be replaced by that of its quasi-continuity.—**E. Bortolotti**: Local co-ordinates in the projective-differential geometry of a surface: the unit elements.—**P. Nalli**: Integral equation of the third species and applications to differential equations (2).—**C Cannata**: Contribution to the ballistic theory of variable stars (2). Consideration of the essential features of the ballistic theory of variable stars for elliptic orbits shows that only two cases present themselves, dt/dT either remaining positive for any value of E or changing its sign; constantly negative values are excluded. These results are applied to various examples of each of the two cases.—**E. Fermi**: Statistical deduction of certain properties of the atom. Application to the theory of the periodic system of the elements (2). It has been shown that mean results concerning the distribution of the electrons about the nucleus of a heavy atom may be obtained by assuming that the electrons form round the nucleus a kind of gaseous atmosphere, to the calculation of which statistical considerations may be applied. Given the pronounced density of this electron atmosphere, it will be in a condition of complete degeneration at ordinary temperatures. Application of the statistical method to the theory of the periodic system of the elements renders it possible to predict exactly the atomic numbers at which the various anomalies of the periodic system commence.—**G. Gentile**: Rutherford's theory of the satellites. Calculation by means of classical electrodynamics gives results which throw doubt on the stability of the nuclear systems described by Rutherford in his paper on the structure of the radioactive atom and origin of α-rays, since values are obtained for the mean life which are incompatible with experimental results.—**G. R. Levi** and **A. Celeri**: Pyrophoric lead. This substance has the same face-centred, cubic crystalline structure as ordinary lead and is composed of granules sufficiently large to give sharp, thin lines in photograms obtained by the Debye method. Pyrophoric lead, sometimes slightly contaminated by the oxide, may be prepared by heating the citrate, tartrate, or formate. When slowly oxidised, it yields the oxide directly, but its more or less profound oxidation is a function of the time and of the dimensions of the metallic granules and does not stop at any definite compound.

SYDNEY.

Linnean Society of New South Wales, Mar. 28 (Annual General Meeting).—**Late Prof. L. Harrison**: Host and parasite. For many groups of parasites, host and parasite have come down the ages together. Parasites in general live under conditions which afford little stimulus to evolutionary change, and so tend to differentiate at a slower rate than their hosts, suffering what has elsewhere been called a retarded evolution. The relation between host and parasite may serve several useful purposes: a phylogenetic relationship may be established, or a supposed relationship may be refuted; suggestion of convergent resemblance may be refuted; support may be forthcoming for the common origin of groups now occurring on separated land masses, and thus for the existence of former land connexions. Little use appears to have been made of the host-parasite relation until comparatively recent years, but the degree of unanimity reached by workers on different groups of parasites indicates that the host–parasite relation is a general principle and is capable of wide application. It is concluded that there is a general specificity underlying obligate host-parasite relations, however much this may be obscured, in some groups, by the interposition of other factors.—**Charles G. Oke**: Notes on Australian Coleoptera, with descriptions of new species, Part I. Notes on species belonging to the families Staphylinidæ, Pselaphidæ, Buprestidæ, Ptinidæ, Cerambycidæ and Chrysomelidæ. Five genera and forty-four species are described as new, fifteen species being noted as inquilines living with ants and one with termites.—W. F. Blakely: The Loranthaceæ of Australia, Part 7. This part deals with *Korthalsella*, *Notothixos*, and *Viscum*. Three species of *Korthalsella* are segregated from *Viscum*, and in the latter genus, two species are offered as new.—W. D. Francis: The growth rings in the wood of Australian Araucarian conifers: The degree of distinction and regularity in the growth rings which characterises the wood of many European and North American trees is not shown by the wood of the subtropical Australian Araucarian conifers.

Spisy Vydávané Přírodovědeckou Fakultou Masarykovy University. (Publications de la Faculté des Sciences de l'Université Masaryk.) Čís. 90: Některé pokusy o geometrických pravděpodobnostech (Quelques expériences sur les probabilités géométriques). Napsal Jos. Bata. Pp. 22. Čís. 91: Propriétés projectives du contact, I. Par Edouard Čech. Pp. 36. Čís. 92: Výklad vzniku krátkých elektromagnetických vln v elektronových lampách, 2 část (An Explanation of the Origin of Short Electromagnetic Waves in Valves, Part 2). Napsal Dr Josef Sahánek. Pp. 24. Čís. 93: Sur les transformations itérées des variables aléatoires. Par B. Hostinský. Pp. 24. Čís. 94: Klimatická proměnlivost atmosférických srážek a její vztah k Brücknerově theorii (Les variations climatériques des précipitations atmosphériques et leurs rapports à la théorie de Brückner). Napsal Fr. Říkovský. Pp. 60. Čís. 95: Měření termomagnetického longitudinálního efektu potenciálového (De l'effet thermomagnétique longitudinal). Napsal Josef Zahradníček. Pp. 1[illegible]. (Brno: A. Píša.)

Diary of Societies.

SATURDAY, JUNE 30.

GENETICAL SOCIETY (at the John Innes Horticultural Institution, Merton, S.W.19), at 1.—Annual Meeting.

ROYAL SOCIETY OF MEDICINE (Disease in Children Section) (at Leicester).

At 2.—Dr. H. Stanley Banks: On the Treatment of Toxic Diphtheria by Large Intravenous Doses of Antitoxin.

At 2.30.—C. H. Bond: On the Effect of Certain Radiated Sterols on the Cellular Constituents of the Blood.

At 3.15.—Dr. G. Brittain Gill: On Calcium Deficiency and its Treatment.

At 5.—Discussion.

MONDAY, JULY 2.

ROYAL SOCIETY OF EDINBURGH, at 4.30.—Presentation of Prizes:—Keith Prize—Joint Award—to Prof. T. J. Jehu and R. M. Craig. Neill Prize to Prof. A. Robinson.—Prof. J. R. Wilton: The Lattice Points of a Circle. (*To be read by title.*)—Prof. H. W. Turnbull and J. Williamson: The Invariant Theory of the Quaternary Quadratic Complex. II. The Complete System. (*To be read by title.*)

ROYAL INSTITUTION OF GREAT BRITAIN, at 5.—General Meeting.

TUESDAY, JULY 3.

ROYAL SOCIETY OF MEDICINE, at 4.—Annual General Meeting.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Dr. E. H. Hunt: The Rock-hewn Temples of Ajanta and Ellora.

FRIDAY, JULY 6.

GEOLOGISTS' ASSOCIATION (in Architectural Theatre, University College), at 7.30.—F. Gosling: The Geology of the Country around Reigate.—H. A. Hayward: The Geology of the Lower Greensand around Dorking, Surrey.

PUBLIC LECTURE.

THURSDAY, JULY 12.

INSTITUTE OF PHYSICS (in Rooms of the Institution of Electrical Engineers), at 8.—Dr. C. E. Kenneth Mees: Physics in Photography.

CONGRESSES.

JULY 5, 6 AND 7.

OXFORD OPHTHALMOLOGICAL CONGRESS (at Keble College).

July 5.

Prof. Leonard Hill, W. S. Duke-Elder and others: Symposium on The Ultra-violet Ray.

July 6.

Prof. Arthur Thomson: Observations on the Eyes of Birds (Doyne Memorial Lecture).
